The history and physical examination findings determine the nature of any additional diagnostic tests to be performed.

BOX 56-3

# Historical Information for Female Infertility

1. What is the present stage of the estrous cycle?

2. Description of previous cycles

Age at puberty

Dates of onset of previous cycles

Lengths of previous cycles

Behavior during proestrus and estrus

Attractive to males?

Allow mounting?

Did intromission occur?

Did insemination occur?

Dates of insemination: How were these dates chosen?

Predetermined day of season

Behavioral changes

Vaginal cytologic findings

Ovulation timing

Method of insemination

Natural

Artificial with fresh, chilled, or frozen semen

3. Assess male fertility

Outcome of breeding to different males, if any

Has this male ever sired a litter? When?

Healthy litters from other females bred by him near the time of breeding the female in question?

Results of recent semen evaluation

4. Events after breeding or after unbred cycles

Early pregnancy diagnosis?

When?

What method?

Physical/behavioral changes?

Palpation?

Ultrasound?

Mammary development, overt false pregnancy?

Vulvar discharge?

Abortion?

**Parturition** 

Length of gestation

Dystocia?

Litter size

Health and survival of puppies or kittens

5. Previous diagnosis and treatment of reproductive problem

Tests performed and their results

Brucella canis

Thyroid profile

Feline leukemia virus

Medications administered

Correlate with stage of estrous cycle

Nonreproductive problems, diagnostic tests, and/or medication

In this individual animal (e.g., glucocorticoids)

In the kennel or cattery (e.g., feline viral rhinotracheitis infection)

Historic or physical abnormalities outside the reproductive tract should be investigated. All dogs should be tested for *Brucella canis* (see Chapter 58) before breeding and before infertility is evaluated further. A complete blood count (CBC), serum biochemistry panel, and urinalysis provide excellent information regarding the overall metabolic health of the animal and could reasonably be included as a routine part of the evaluation of infertility. Only normal, healthy animals in excellent body condition should be bred.

The reproductive history often dictates the nature of the diagnostic approach. Perhaps most important are characterizing proestrus-estrus and the interestrous interval of the female, identifying the criteria used to determine when the female is bred, and determining the female's behavior during mating (see Fig. 56-10). Typically, one of the following four descriptions applies: failure to cycle, abnormal interestrous interval, abnormal proestrus-estrus, or normal cycles.

# **FAILURE TO CYCLE**

There are two subcategories of animals with persistent anestrus. *Primary anestrus* refers to females 24 months of age or older that have never cycled. *Secondary anestrus* applies to females that have previously cycled but are no longer doing so. An animal that has never cycled may be a normal prepubertal animal younger than 24 months of age, may be experiencing "silent" heats, may have a congenital gonadal or chromosomal anomaly, or may have a concurrent disorder that is preventing estrous cycles. Exposure to light may be inadequate to initiate and maintain cyclicity in queens with persistent anestrus. Gonadal dysfunction, concurrent metabolic disorders or medications, and advancing age should be considered in females with secondary anestrus.

Diagnostic tests for persistent anestrus are usually delayed until a female is 2 years of age because of the probability that she is a normal prepubertal animal. Some veterinarians believe that an initial undetected or "silent" first heat cycle is common in bitches. If so, this could explain why some young bitches appear to have persistent anestrus. Unobserved or silent heats may be detected retrospectively by measuring the serum progesterone concentration. If the concentration is greater than basal anestrus levels (>2 ng/ml, or >6.4 nmol/L) in a bitch, a cycle has occurred within the previous 60 to 90 days. The finding of high serum concentrations of progesterone in a supposedly anestrous queen indicates that unobserved estrus has occurred and also that either unobserved mating or spontaneous ovulation occurred within the past 30 to 40 days. Clinical signs of false pregnancy (see Chapter 58) would also indicate that an undetected cycle occurred approximately 60 days earlier. Silent cycles could be detected prospectively by examining vaginal cytology every 1 to 2 weeks. Noncycling females should be housed with cycling females whenever possible because the pheromones from cycling females may induce noncycling females to cycle. Queens should be exposed to at least 12 hours of light for at least 2 months before further testing is done.

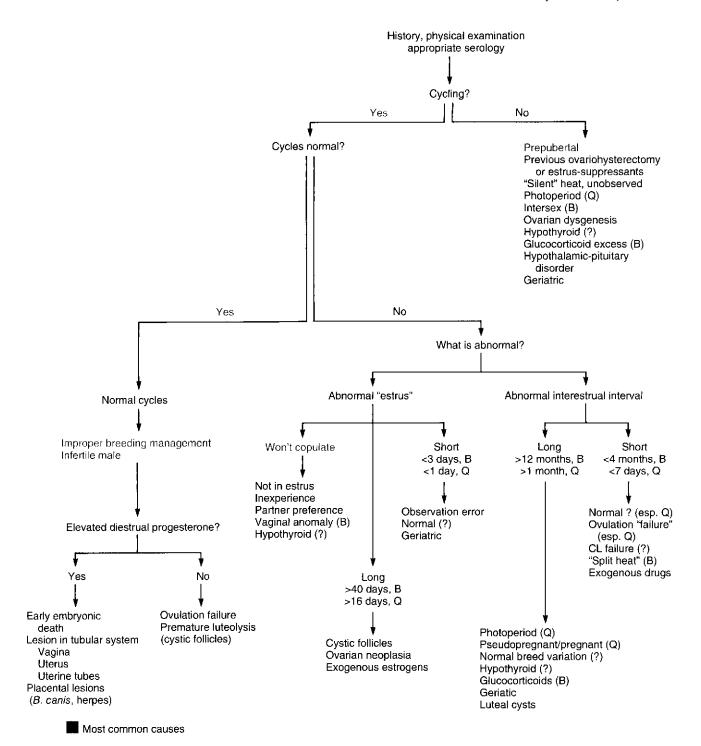

Persistent anestrus may result from suppression of function of the hypothalamic-pituitary-ovarian axis. Hypothyroidism, exogenous glucocorticoid therapy, and concurrent metabolic disease are commonly reported but rarely confirmed causes in bitches. Thyroid function is assessed by measuring serum concentrations of the thyroid hormones and canine thyroid-stimulating hormone (cTSH; see Chapter 51). The role of hypothyroidism in infertility in the bitch has not yet been thoroughly evaluated. Exogenous glucocorticoids are commonly administered to animals and cause many alterations in reproductive function, including prolonged anestrus and abortion. The history should be reviewed to determine if the animal could have received glucocorticoid treatment. In mature bitches increased serum alkaline phosphatase activity in conjunction with relatively normal alanine aminotransferase activity is suggestive of supraphysiologic amounts of glucocorticoids. If there is still doubt about excess endogenous or exogenous glucocorticoids, adrenocortical function can be assessed with an adrenocorticotropic hormone (ACTH) stimulation test. The presence of other concurrent metabolic disease is determined with a CBC, serum biochemistry panel, and urinalysis.

Persistent anestrus may also result from a primary abnormality anywhere within the hypothalamic-pituitary-gonadal axis, including intersex conditions, ovarian dysgenesis, progesterone-secreting luteal cysts, or ovarian tumor. It may also result from previous ovariohysterectomy. Females with ovarian dysgenesis or that have undergone oophorectomy are expected to have chronically increased serum concentrations of LH, which can be measured. Serum progesterone concentrations can be determined to assess functional luteal cysts. The functional status of the hypothalamic-pituitaryovarian axis can be evaluated by measuring serum LH and progesterone concentrations before and after GnRH administration. Ultrasonographic evaluation of the ovaries may identify ovarian abnormalities such as cysts or neoplasia. On close inspection, many apparently female intersex animals have detectable anatomic abnormalities of the clitoris, vestibule, and/or vagina that result from exposure to androgens. A GnRH stimulation or human chorionic gonadotropin (hCG) test, done to assess the serum concentrations of testosterone, could be used to demonstrate the presence of testicular tissue. Because protocols vary among laboratories, the laboratory should be consulted for dosages and sampling times. Karyotyping can also be performed, although intersex animals may have normal karyotypes. Abnormal karyotypes have been found in bitches and queens with ovarian dysgenesis.

Induction of estrus may be tried in otherwise normal, healthy females if other diagnostic tests have failed to identify the cause of persistent anestrus. Exploratory celiotomy or laparoscopy, done to assess the gross appearance of the reproductive tract and to obtain biopsy specimens of the internal genitalia, should be considered only after all noninvasive diagnostic methods have been tried.

#### PROLONGED INTERESTROUS INTERVAL

Interestrous intervals of greater than 12 months in bitches and greater than 1 month in cycling queens are usually

**FIG 56-10**Diagnostic approach to female infertility. *B,* Bitch; *Q,* queen.

considered abnormal, although long interestrous intervals may also be a normal breed variation, as seen in the Basenji, Tibetan Mastiff, and Dingo dogs, which often cycle only once a year. Many of the causes of persistent anestrus, such as glucocorticoid administration in bitches and inadequate photoperiods in queens, may also cause a prolonged interestrous interval. Pregnancy, pseudopregnancy, and early embryonic death are causes of prolonged interestrous inter-

vals in queens but not in bitches. This difference is because the CL life span in bitches is 60 to 70 days, irrespective of pregnancy status. Lack of hiding places and irregular feeding times have been shown to disrupt normal cycles in cats (Pelican, 2006). Prolonged interestrous intervals may also occur with increasing age or may signify an underlying disorder. Silent or unobserved heats should also be considered. The diagnostic workup in animals with prolonged

interestrous intervals should include a thorough review of the estrus identification techniques used by the owner, identification of medications being administered to the animal, assessment of the overall metabolic health of the animal (i.e., CBC, biochemistry panel, urinalysis), and an evaluation of thyroid gland and adrenocortical function in bitches.

#### SHORT INTERESTROUS INTERVAL

Abnormally short interestrous intervals of less than 4 months are occasionally seen in bitches and are usually associated with infertility. Infertility in these animals presumably results from implantation failure because the endometrium has not recovered from the previous cycle, a process that takes 120 to 150 days, although ovulation failure may be involved. In some breeds, most notably the German Shepherd Dog, and in some individual animals, an interestrous interval of 4 to 4.5 months may be normal and may not interfere with fertility. Cystic ovarian follicles might cause frequent cycling (i.e., short interestrous interval) but most commonly are associated with persistent estrus. The administration of gonadotropins, prostaglandin F<sub>200</sub> prolactin antagonists, or estrogen can artificially shorten the interestrous interval. In most bitches, however, the cause of short interestrous intervals is not discovered.

A short interestrous interval must be differentiated from a *split heat* cycle in bitches. Split heats are characterized by normal proestrus that stops abruptly before progressing to estrus. Two to 4 weeks later, proestrus begins again and progresses through normal, fertile estrus. Split heats are a normal phenomenon that can occur in any bitch during any estrus. Split heats are seen most often in pubertal bitches that have normal proestrus and estrus during subsequent cycles. Rarely do split heats occur repeatedly in an individual bitch. Split heats do not cause infertility, except in the sense that the initial proestrus frustrates breeding management.

Additional diagnostic tests are often not performed in bitches with confirmed short interestrous intervals, although ovarian ultrasound would be reasonable. Another diagnostic consideration would be to monitor the changes in serum progesterone concentrations during estrus and diestrus to assess whether the short cycles may be related to ovulation failure. Administration of an androgen such as mibolerone or methyltestosterone to prevent estrus for at least 6 months has been considered, but there is little published evidence of efficacy. Even though estrus can easily be delayed with androgen treatment, affected bitches usually remain subfertile. Interrupting the short cycle by administering a progestin during proestrus has enabled 10 previously infertile bitches to conceive on the next cycle (Wanke, 2006). Previous interestrous intervals for the bitches were 2 to 4 months (mean 3.2 months). Treatment with megestrol acetate (2 mg/kg, orally) or clormadinone acetate (0.5 mg/kg, orally) for 8 days, beginning within the first 3 days of proestrus, stopped the cycle before ovulation. Progesterone concentrations remained at basal levels. The next cycles occurred 1.5 to 3.5 months (mean 2.7 months) after treatment and were fertile. Although subsequent cycles were not discussed in this report, breeding on the first estrus occurring after the discontinuation of therapy has previously been recommended because short interestrous intervals frequently resume. The role of genetics in this problem is not known.

# **ABNORMAL PROESTRUS AND ESTRUS**

The most common abnormalities of procestrus and estrus are refusal to allow mating, prolonged estrus, and abnormally short estrus. Females that are not in estrus refuse mating. An occasional bitch or queen exhibits partner preference by refusing to mate with one male but readily mating with another. Inexperienced and timid females may also be reluctant to breed. In bitches physical abnormalities of the vulva or vagina are common causes of refusal to mate (see Chapter 57). Physical abnormalities include vaginal strictures; congenital defects in the vulva and vagina; vaginal hyperplasia/ prolapse; and, rarely, vaginal neoplasia.

Vaginal cytologic studies should be performed to identify the present stage of the cycle (see Fig. 56-6). As just mentioned, females that are not in estrus will not accept mating. Digital palpation of the vulva, vestibule, and vagina in animals of adequate size can identify vaginal prolapse and most vaginal strictures and congenital defects. Vaginoscopy should be performed if digital palpation fails to identify a cause for the refusal to allow mating.

Vaginal strictures that are identified during anestrus should always be palpated again during estrus to determine their actual significance. Annular vaginal strictures are usually located immediately cranial to the external urethral orifice, at the anatomic junction between the vestibule and the vagina. The vestibulovaginal junction is normally the narrowest part of the posterior tract (see Fig. 56-7). During anestrus this normal narrowing may be mistaken for an annular stricture. The diameter of the vestibulovaginal junction normally increases significantly during proestrus and estrus, making differentiation from a true stricture easy at this stage of the cycle. Strictures of the vulva or vestibule usually do not change as dramatically during estrus. Similarly, normal vaginal examination findings during anestrus do not exclude the possibility of vaginal hyperplasia/prolapse, which occurs only at times of estrogenic stimulation, as a potential cause for reluctance to mate. Artificial insemination can be used to breed otherwise normal estrual females that refuse to mate as well as those with vaginal hyperplasia/prolapse. With the exception of vaginal hyperplasia/prolapse, physical abnormalities should be surgically corrected if the female is to remain in the breeding program. Surgery is best performed during anestrus. The heritability of congenital vaginal and vulvar anomalies is unknown.

# Prolonged or Persistent Estrus

Although procestrus and estrus each last an average of 9 days, proestrus lasting as long as 17 days and estrus lasting 21 days have been observed in normal, fertile bitches. Understandably, many owners become concerned if a season (proestrus plus estrus) lasts longer than 3 weeks. Nevertheless, a season is not considered abnormally long in bitches until it reaches

FIG 56-11 Cystic ovaries and uterus with cystic endometrial hyperplasia from a 2-year-old Mastiff in heat for 12 weeks.

35 to 40 days. In queens estrus lasting longer than 16 days is considered abnormal. This must not be confused with the normal, multiple cycles that occur in queens.

Prolonged proestrus/estrus is usually caused by functional follicular cysts (Fig. 56-11), which occur in intact ovaries and also in ovarian remnants in spayed bitches and queens. Ovarian neoplasia and exogenous estrogen administration may also cause persistent signs of estrus. Vaginal cytology should be performed to confirm that estrogenic stimulation is present and thus could reasonably be considered the cause of the behavioral and physical signs. Usually, the diagnosis of ovarian follicular cysts is based on the historic, physical, vaginal cytologic, and ultrasound findings. Serum concentrations of estrogen could also be determined. Because spontaneous regression of follicular cysts may occur, watchful waiting for 2 to 4 weeks is often the initial therapeutic approach. If clinical signs do not promptly resolve, treatment is indicated. Induction of ovulation can be attempted using GnRH (Cystorelin®; 2.2 µg/kg, adminstered intramuscularly q24h for 3 days); however, the results have been variable. If mature follicles are present and induced to ovulate, signs of estrus should resolve in 5 to 7 days. The cysts can be manually ruptured via laparoscopy or celiotomy. In cases of unilateral ovarian cysts, unilateral oophorectomy can be performed. Ovariohysterectomy should be considered for those females that fail to respond promptly to medical management for cystic ovaries because the prognosis for fertility is guarded and continued estrogenic stimulation may be harmful to the uterus and bone marrow. Ovarian neoplasia is uncommon in bitches and queens. Surgical excision is the treatment of choice. If exposure to exogenous estrogenic drugs is the cause of persistent signs of estrus, it should be discontinued.

#### **Short Estrus**

Abnormally short estrus of less than 3 days in bitches or less than 1 day in queens is most often the result of an error in observation or recognition of estrus. Females older than 6 to 8 years of age may experience erratic cycles, including short estrus. A split heat cycle should also be considered in bitches with an apparently short estrus. Short estrus may be normal in some animals. Methods of proestrus and estrus detection should be changed in females with a truly short estrus so that they can be bred at the appropriate time. This usually entails beginning vaginal cytologic studies or teasing with a stud well before the expected transition from proestrus to estrus and continuing this until the first day of estrus is identified. Combining this with ovulation timing, as determined by serum progesterone or LH concentrations, may be helpful in identifying the optimal time for insemination.

#### **NORMAL CYCLES**

Infertility in a female otherwise normal in all aspects of the reproductive cycle may result from improper breeding management; infertility in the male; abnormalities in the ovary, uterine tubes, uterus, or vagina; early embryonic death; or advancing age. A history of false pregnancy occurring after previous cycles strongly suggests that the hypothalamicpituitary-gonadal axis was intact during those cycles. Therefore the investigation should initially focus elsewhere. Conception rates and litter size are greatest and neonatal mortality is lowest in bitches (Beagles) between 2 and 3.5 years of age. Reproductive performance in queens is best between 1 and 6 years of age. After 5 years of age in Beagles and 6 years of age in queens, conception rates and litter size decline and neonatal mortality begins to increase. Because of this age-related decrease in fertility, an extensive diagnostic evaluation of older females may not be warranted.

The most common causes of infertility in females with normal estrous cycles are improper timing of insemination and poor semen quality. Because male fertility can be so easily evaluated (see Chapter 60), the male should be evaluated before an extensive diagnostic evaluation of the female is undertaken. A solid history that the male sired litters that were born shortly before and shortly after mating with the bitch in question would provide good circumstantial evidence against male infertility. Semen evaluation would provide information about the male's current status. The process of freezing and thawing canine semen substantially decreases its quality. Because the post-thaw life span may be only 24 hours and because its ability to transverse cervical mucus is so diminished, pregnancy rates using frozen semen are very poor unless ovulation timing and intrauterine, not intravaginal, insemination are used. Although the effects of chilling semen are far less deleterious, freshly ejaculated semen retains the best quality.

In well-managed colonies of normal dogs, conception rates of better than 90% are expected. A thorough history concerning breeding management, particularly how the owner determines when to breed, is imperative. Canine breeding management is discussed on p. 887. Feline breeding management is discussed on p. 889. A common practice for dog breeders is to simply begin breeding on a predetermined day after the onset of proestrus (commonly day 10) and

continue breeding every other day for as long as the bitch is receptive. This method works well for normal bitches that have a very typical cycle. However, if a particular bitch has a short proestrus, for example, day 10 may actually be at the end of estrus rather than at the beginning. In queens the frequency of mating during estrus is a more important determinant of ovulation, and thus conception, than is the specific day of the cycle on which mating occurs.

Vaginal cytology can be used to identify estrus. Obtaining the specimen for cytologic evaluation may induce ovulation in some estrous queens, but this is apparently not a common occurrence. Monitoring serum concentrations of LH or progesterone can be used to determine ovulation and the fertile period in bitches. It has been shown in bitches in artificial insemination (AI) programs that two inseminations, done 48 hours apart during the fertile period, improve pregnancy rates and increases the number of pups per litter compared with only one insemination. If the first insemination happens to occur late in the fertile period, the second is done 24 hours later. Unlike the situation in queens, breeding a bitch several times during the same day appears to offer no advantage over breeding a single time on a given day. Intrauterine insemination with fresh, chilled, or frozen-thawed semen increases pregnancy rates over vaginal insemination. Also, the mean litter size was larger with intrauterine AI than with vaginal Al.

After the female has been bred using optimal protocols and semen of excellent quality, it should be examined 20 to 30 days later to determine whether pregnancy has occurred. Pregnancy can be diagnosed on the basis of abdominal palpation, ultrasonographic findings, or by finding high serum concentrations of relaxin. Ultrasonography should be performed in animals found not pregnant because the ovaries and uterus can be evaluated for a potential cause. If the female is not pregnant, the serum progesterone concentration should be measured to determine if ovulation occurred. Low serum progesterone concentrations (less than 2 to 5 ng/ ml or approximately 6.4 to 16 nmol/L) suggest ovulation failure or premature luteolysis. The cause of ovulation failure may be an ovarian abnormality or, in the case of queens, inadequate coital stimulation. Premature luteolysis, or failure of the corpora lutea to maintain progesterone production, results in fetal resorption with no outward clinical signs when it occurs before day 35 of gestation. Premature luteolysis is rarely documented in bitches or queens; however, to differentiate ovulation failure from premature luteolysis, serum progesterone concentrations are serially determined using quantitative methods (e.g., RIA) from the time of proestrus through diestrus. Progesterone concentrations that never exceed 8 ng/ml (approximately 25 nmol/L) suggest ovulation failure, whereas premature luteolysis is reflected by a more rapid or earlier decline than normal from high postovulatory concentrations of progesterone. Hypothalamic or pituitary dysfunction would be unlikely causes of ovulation failure in the female that is otherwise cycling normally. More likely, hypothalamic or pituitary malfunction would be manifest as abnormal cycles.

When a female with normal cycles is known to have been bred appropriately during estrus to a male that is known to be fertile and when ovulation has been confirmed by the finding of elevated serum progesterone concentrations during diestrus, the hypothalamic-pituitary-gonadal axis is considered intact (see Fig. 56-4). Abnormalities in the vagina, uterus, uterine tubes, placenta, or the conceptus itself are then likely to be the source of the infertility. The diagnostic approach should begin with a review of the history to identify potential causes of early embryonic death. Special attention should be paid to infectious disease and medications administered to the female. Early embryonic death is difficult to confirm in bitches and queens, but in queens a prolonged interestrous interval provides a clue. Attempts to confirm pregnancy by ultrasound or measuring serum concentrations of relaxin can be done as early as day 14 to 20, although false-negative results are understandably common at that stage.

Infectious agents are an important cause of early embryonic death. Although many agents are capable of causing placentitis or fetal death, B. canis in bitches and calici and herpes viruses in queens are the foremost such agents. In lieu of cultures of specimens from the uterine lumen, cultures of the cranial vagina should be performed. Some clinicians recommend that cultures be obtained during estrus because the cervix is open at that time and fluid in the cranial vagina may have originated from the uterus. Bacterial infections should be treated appropriately before breeding. The uterus may be incapable of supporting implantation or pregnancy because of disorders such as bacterial endometritis or cystic endometrial hyperplasia. Ultrasound of the reproductive tract is indicated. Vaginal lesions can easily be excluded as the cause of infertility by vaginoscopy and vaginal cytology. The potential teratogenic or abortifacient effects of medications should always be considered. Many commonly used medications, such as glucocorticoids and certain antibiotics, also cause embryonic death. In addition, some congenital fetal anomalies cause early embryonic death because they are incompatible with continued survival.

The presence of antisperm antibodies in the female has not yet been documented as a cause of infertility in dogs or cats. However, were they to occur, breeding with a different male could circumvent the problem. Finally, exploratory celiotomy can be performed during anestrus to visualize the reproductive tract, assess the patency of the uterus and uterine tubes, obtain uterine specimens for culture, and procure full-thickness uterine biopsy specimens for histologic assessment.

# ESTRUS SUPPRESSION, CONTRACEPTION, AND POPULATION CONTROL

# **SURGICAL METHODS**

In the United States and Canada ovariohysterectomy and castration are the most common methods of population

control for dogs and cats. They are permanent and relatively expensive, invasive procedures. Ovariohysterectomy can be accomplished by midline or flank approaches or via laparoscopy. Laparoscopy has also been used for castration of cryptorchid testicles. Some clinicians have recommended ovariectomy over ovariohysterectomy, although this has not been widely accepted among veterinarians in the United States. Ovariohysterectomy has traditionally been recommended at 5 to 8 months of age, just before the animal reaches puberty. Doing so dramatically reduces the risk that the animal will develop mammary cancer in the future, in addition to preventing estrus and unwanted pregnancy. To reduce the number of unwanted (i.e., relinquished by their owners) and stray animals euthanized at animal shelters, many shelters mandate surgical sterilization as part of the adoption agreement. Because postadoption compliance with sterilization agreements has universally been poor, preadoption "early spay-neuter" policies at 6 to 8 weeks of age have been advocated. Safe and effective anesthetic and surgical techniques have been developed. Several studies have shown that the physical and behavioral traits of animals neutered at 7 weeks of age are the same as those in animals neutered at the more conventional age of 7 months. However, there is an increased rate of urinary incontinence in female dogs spayed at 6 to 8 weeks of age compared with those spayed at 6 to 8 months. Whereas the risks associated with early spayneuter of male dogs and of both male and female cats are minimal, it may be prudent to delay spaying female dogs until they are older. Gonadectomy at any age results in decreased metabolic rate and decreased caloric requirements, irrespective of any change in physical activity. It has also been reported that food intake actually increases after neutering in male and female cats fed ad libitum. Neutering has been shown to cause hyperleptinemia in male cats, but not female cats, after neutering. Unless caloric intake is diminished to match the changed metabolic rate, animals will gain weight after gonadectomy. Gonadectomized animals have delayed physeal closure, and less developed genitalia and secondary sex characteristics than do age-matched, sexually intact controls. Tubal ligation and vasectomy can be used to prevent pregnancy in dogs and cats without circumventing the physical and behavioral changes associated with sexual maturation. Owners may or may not consider this desirable.

# NON-SURGICAL METHODS FOR CONTRACEPTION OR STERILIZATION

Less expensive, permanent, nonsurgical methods of sterilization would be ideal for preadoption programs at humane societies and animal shelters and for large-scale application in trap-neuter-release programs to control feral populations. The injection of sclerosing agents into the testis, epididymis, or ductus deferens has been investigated in dogs and cats. These agents have included various concentrations of zinc, formalin, chlorhexidine in DMSO, ethanol, silver nitrate, potassium permagnate, Freund's Complete Adjuvant, BCG, methallibure, dexamethasone, metopiron, niridazol, α-chlorohydrine, and danazol. Treated animals may remain

fertile for 6 to 8 weeks after treatment. Some animals never become sterile, whereas in others the effects are transient. There appears to be some species variation as well because intratesticular 70% glycerol was ineffective in dogs, whereas it has consistently resulted in azoospermia in monkeys, rabbits, rats, and hamsters. Some studies have reported minimal signs of discomfort. Others have reported swelling, scrotal ulceration and mutilation, local granulomatous reactions, vomiting, diarrhea, leukocytosis, and lethargy. A zinc gluconate solution (Neutersol®; Addison Biological Laboratory) for intratesticular injection is marketed for chemical castration of puppies between 3 and 10 months of age. At this time there is no published evidence that the use of sclerosing agents has resulted in lifelong sterility in pet dogs or cats or that there has been an impact on control of feral populations.

The concept of immunizing animals against GnRH, LH, LH receptors, sperm antigens, and the zona pellucida of oocytes has appeal for both permanent sterilization and temporary contraception. Because GnRH and LH control gonadal function, blocking their effects would theoretically suppress estrus cycles and ovulation in females, spermatogenesis in males, and sexual behavior in males and females. These effects might be maintained permanently or temporarily, depending on the duration of adequate antibody titers. GnRH is highly conserved across species and therefore is poorly immunogenic unless conjugated with other molecules. A GnRH vaccine (Improvac®; CSL Animal Health) is available in Australia for use in mares. An antigonadotropin releasing factor (GnRF) product (Canine Gonadotropin Releasing Factor Immunotherapeutic®; Pfizer) is marketed in the United States for treatment of benign prostatic hyperplasia in dogs. Although not marketed for these effects, it does cause the testes to shrink and serum testosterone concentrations to decline, both of which would be deleterious to spermatogenesis. GnRH has also been conjugated with cytotoxic agents designed to destroy the GnRH receptors. Although this markedly suppressed reproductive activity in peripubertal male dogs, the response was variable. Induction of antibodies against LH and LH receptors results in impaired reproduction; however, the responses have been so variable that a consistent vaccination protocol has not been established for dogs or cats. Bitches and queens have resumed normal cycling after antibody titers declined. Attempts to immunize animals against sperm antigen have not had satisfactory results for sterilization or contraception. The zona pellucida (ZP) is the acellular coating around ova, and vaccination with porcine ZP has been found to consistently produce high antiZP titers and prevent conception in bitches. Significant ovarian abnormalities also develop, including ovarian cysts of various types and prolonged proestrus/ estrus. Vaccination of queens against ZP has not resulted in contraception. An antiporcine ZP vaccine (SpayVac®; Immuno Vaccine Technologies, Nova Scotia) is commercially available for immunocontraception in some captive wild species.

Intravaginal spermacides have not yet been developed for use in bitches or queens. An intravaginal mechanical barrier was marketed for use in bitches, but the failure rate was high. An intrauterine contraceptive device is available for bitches (Biotumer, Argentina). Although it was quite effective in a small clinical trial (Volpe, 2001), it is somewhat impractical because of the difficulty in transcervical placement. High intensity ultrasound suppresses spermatogenesis when applied to the testes and causes luminal occlusion when applied to the epididymides and ductus deferentia in dogs and cats. However, skin burns occur in approximately 20% of treated animals. Bisdiamines are amebicidal drugs that have been found to cause spermatogenic arrest in all species studied thus far, including dogs and cats. They have generated great interest for contraception in zoo animals because, when administered daily in food, they cause spermatogenic arrest before the spermatid stage but spermatogonia are preserved. Therefore the effects are reversible. Side effects in dogs and men have been only slight weight loss and slight decrease in red blood cell count. In cats there was no change in red blood cell counts, but testosterone concentrations declined during treatment. The drug must be administered daily to be effective. Females must not be exposed to bisdiamines because they are highly teratogenic.

#### CONTRACEPTION

Contraception may be defined as a reversible method of blocking fertility. Contraception is particularly desirable for animals that eventually will be bred but for which estrus will interfere with their work (e.g., racing, hunting) or show career. Progestins and androgens can inhibit the release or synthesis of gonadotropins in dogs and cats and thereby prevent estrus. GnRH analogues reversibly inhibit reproductive function in males and females by downregulating LH and FSH receptors, thereby suppressing the pituitary-gonadal axis.

# **Progestins**

Megestrol acetate (Ovaban®; Pfizer) is the only progestin approved for estrus control in bitches in the United States. It is not labeled for use in cats. It is intended for short-term (2 years), temporary use. In some European countries oral and injectable progestins such as medroxyprogesterone acetate (MPA; 3 mg/kg, administered intramuscularly every 5 to 6 months) and proligestone are commonly used to prevent estrus. Progestins are most reliable in preventing estrus when treatment is initiated during anestrus and are less reliable if initiated during early proestrus. The synthetic progestin levonorgestrel (Norplant®; Wyeth-Ayerst) is a slow-release, subdermal implant. It is effective in suppressing estrus for 12 months in cats, with no adverse effects except the development of cystic endometrial hyperplasia. The return to normal cycling after discontinuing progestin therapy is variable but typically is within 2 and 9 months. Progestins have many dose-dependent undesirable effects that commonly occur at therapeutic doses. Progestins routinely cause cystic endometrial hyperplasia, which may predispose the animal to the development of pyometra. Twelve weeks after initiating MPA treatment at 10 mg/kg subcutaneously, every 3 weeks, there was atrophy of the endometrium and dramatic reduction in estrogen and progesterone receptors. However, by 24 weeks, most uterine cell types had escaped progestin downregulation, estrogen and progesterone receptors had returned to normal, and cysts of endometrial glands had developed (De Bosschere, 2002). Progestins are also associated with mammary hyperplasia and an increased incidence of mammary tumors. When progestin therapy is discontinued, signs of false pregnancy may develop (see Chapter 58). Other adverse effects in bitches and queens include diabetes mellitus, acromegaly, and adrenocortical suppression. Conversely, some progestins (MPA and proligestone) act as glucocorticoid agonists in the bitch, and longterm treatment with high doses may result in iatrogenic hyperadrenocorticism, including steroid hepatopathy. Alopecia, thinning of the skin, and discoloration of the hair at the site of progestin injection have also been observed. For these reasons, the benefit of progestins for estrus suppression should be carefully weighed against the risks. Medroxyprogesterone is used for the treatment of benign prostatic hyperplasia in dogs (see Chapter 62) with no apparent adverse effects on semen quality. At higher doses (20 mg/kg), MPA decreases sperm output and motility and increases morphologic abnormalities.

# **Androgens**

Mibolerone (Cheque Drops®; Pfizer) was the only androgen approved for estrus suppression in bitches in the United States. The dose varied according to body weight and breed. Daily doses of 50 µg were required to suppress estrus in queens, but doses of 60 µg caused heptotoxicity. Although not labeled for this use, various forms of testosterone (testosterone propionate, 110 mg, administered intramuscularly or subcutaneously, once weekly; methyltestosterone, 25 to 50 mg, administered orally, twice weekly) are routinely administered to Greyhound bitches during training and racing. Prolonged anestrus occurs in some of these bitches after androgen therapy is discontinued. Adverse effects of androgens are clitoral hypertrophy (sometimes with permanent ossification), mucopurulent vulvar discharge, and vaginitis. Liver enzyme activity may also be increased. These effects are usually reversible after androgens are discontinued, but they may persist for months to years. Irreversible masculinization of the female fetuses occurs when androgens are administered to pregnant females. Additional androgenic effects include thickening of the skin on the neck of queens and an apparent increase in muscle mass and aggressiveness in bitches. Subcutaneous administration of 0.6 mg/kg testosterone propionate to dogs caused marked decline in sperm motility that persisted for 3 months. Oral administration of 50 mg of methyltestosterone for 1 month decreased sperm output. Chronic administration of the synthetic testosterone danazol causes azoospermia in dogs.

#### **GnRH Agonists**

The GnRH agonist deslorelin has been shown to safely and effectively suppress reproductive function for up to 2 years

in adult male and female dogs and cats when administered as a slow-release subcutaneous implant. (Ovuplant®, Fort Dodge; Suprelorin®; Peptech Animal Health). Depending on the age of the bitch and the stage of the cycle at which a GnRH agonist is implanted, it can initially induce an estrus cycle. This unwanted effect can be overcome by the simultaneous short-term administration of a progestin such as megestrol acetate. After an initial stimulatory effect on the pituitary gonadotropins, GnRH agonists suppress further LH and FSH release by downregulation of receptors. Other GnRH agonists, nafarelin, leuprolide, and buserelin, are also effective contraceptives in bitches and dogs. A formulation of nafarelin safely and effectively delayed puberty when administered to prepubertal bitches (mean age 5 months) as a slow-release subcutaneous implant for the duration of the 1-year study. Spontaneous cycling occurred 1 to 13 months after the implants were removed. The implants were difficult to find and remove from two obese bitches.

# OVARIAN REMNANT SYNDROME

Occasionally, queens and bitches resume cycling or continue to exhibit behavioral and physical signs of estrus after oophorectomy. This may happen weeks or as long as 5 years after oophorectomy. The signs may be cyclic in nature, or there may be persistent signs of hyperestrogenism, including alopecia, hyperpigmentation, and lichenification. The cause is remnant ovarian tissue that has regained folliculogenesis and estrogen production. The presence of high concentrations of estrogen can be detected using vaginal cytology to identify cornification of epithelial cells (see Fig. 56-6). The history should be reviewed to ensure that the patient is not being exposed to exogenous estrogens (e.g., agents prescribed to treat urinary incontinence in the patient) or estrogen-containing creams, contraceptives, or hormone replacement therapy used by owner. In the absence of exogenous estrogens, the findings of clinical signs typical of estrus, along with vaginal cytology consistent with estrus, confirm the presence of ovarian remnants and justify a recommendation for exploratory celiotomy to find and remove the ovarian remnants. If additional confirmation of the ovarian remnant syndrome is desired before exploratory surgery, the remnant ovary's ability to ovulate and produce progesterone can be evaluated. Measuring serum concentrations of progesterone 5 to 7 days after expected ovulation achieves this goal. In bitches progesterone increases during heat, coincident with the LH surge, and remains elevated for about 60 days thereafter. Therefore progesterone could be measured while the bitch is showing the clinical signs of heat or for several weeks thereafter. Queens generally are considered to be induced to ovulate by coital stimulation. However, many also ovulate spontaneously. Progesterone remains elevated for only 30 to 40 days after ovulation in nonpregnant queens. Therefore progesterone is measured a week or two after the signs of heat in queens. Progesterone concentrations greater than 2 ng/ml (6.4 nmol/L) are indicative of spontaneous ovulation and the presence of CL in the ovarian remnants. The clinician should keep in mind that ovarian remnants may not be "cycling" in a normal manner and ovulation may not occur. Some ovarian remnants develop cystic follicles that produce estrogen but do not ovulate. The finding of high progesterone confirms the presence of ovarian remnant, but low progesterone does not exclude it. Another approach is to attempt to induce ovulation while the female is in heat by administering hCG (10 IU/kg, intramuscularly, in bitches; 250 IU/queen, intramuscularly) or GnRH (0.5 µg/kg, intramuscularly, in bitches; 25 µg/cat, intramuscularly). Approximately 5 to 7 days later the serum progesterone concentration should exceed 2 ng/ml if responsive ovarian tissue is present. The finding of low serum concentrations of LH indicates the presence of ovarian tissue. However, it is possible that exogenous estrogens could also suppress LH.

Ovarian remnants are often bilateral. They are typically found in the usual anatomic location for ovaries, not in aberrant or ectopic places. The cause of ovarian remnant syndrome is evidently the surgical technique. Treatment consists in the surgical removal of the ovarian remnants. Ovarian remnants are often small, despite the magnitude of the clinical signs they cause. They may be obscured by periovarian fat, especially in bitches. Some veterinarians have suggested that ovarian remnants may be easier to identify if follicles (i.e., when the female is in heat) or CL (i.e., shortly after ovulation) are present rather than during the interestrous period (i.e., anestrus). However, in our experience, the most important determinant of success is adequate surgical exposure and dissection.

# OVARIAN NEOPLASIA

Ovarian neoplasia is rare in bitches and queens. Granulosa cell tumors are reported to occur in ovarian remnants as well as in intact females (Fig. 56-12). Bitches with estrogen-producing ovarian tumors may have clinical signs of estrus, bone marrow toxicity, dermatologic changes, or a combination of these. Estrogen-producing ovarian tumors would not be expected to respond to exogenous hCG or GnRH administration. Bitches with progesterone-producing granulosa cell tumors may show mammary gland development and may have cystic endometrial hyperplasia.

# INDUCTION OF ESTRUS AND OVULATION

Estrus induction has been attempted in bitches in clinical settings to shorten the normal interestrous interval, to treat primary and secondary anestrus, and to time pregnancy and parturition for the owners' convenience. In research settings estrus induction has been used for in vitro fertilization (IVF) and to synchronize estrus for embryo transfer (ET). Although some estrus-induction protocols are associated with superovulation, as revealed by examination of ovarian follicles, the

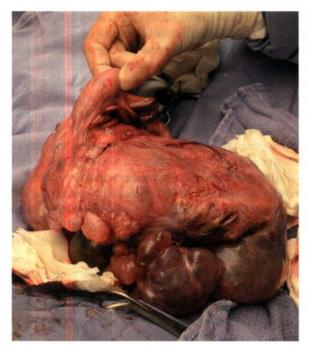

FIG 56-12
Ovarian papillary cystadenocarcinoma in an 8-year-old mixed-breed dog weighing 35 lb, in heat 6 weeks ago. (Courtesy Dr. Jennifer Ellis, Elkhart, Ind.)

superovulation is apparently not reflected in increased litter size. Induction of ovulation may be indicated for females with ovulation failure as shown by low diestrous serum concentrations of progesterone or for those with persistent estrus caused by ovarian follicular cysts.

#### THE QUEEN

The photoperiod can be manipulated to induce estrus in queens. Continuous exposure to 12 to 14 hours of light of at least 50 foot-candles and exposure to 10 to 12 hours of dark per day causes normal, mature queens to begin cycling within 4 to 8 weeks. Housing anestrous queens with cycling queens also helps to induce estrus. If the hormonal induction of estrus is to be attempted, the queen should first be exposed for several months to a minimum of 12 hours of light per 24 hours. Induction of ovulation may be indicated for cycling queens in AI or IVF/ET programs or to induce pseudopregnancy, which would temporarily prolong the interestrous interval when frequent cycles are troubling the owners. The intramuscular administration of 250 IU of hCG or 25 | g of GnRH (Cystorelin; Ceva) on the first 2 days of estrus is recommended, although a single 25-µg dose of GnRH is known to cause an LH surge in normal cats. Probing the vagina with a smooth rod such as a thermometer or with a cotton swab four to eight times, at 5- to 20-minute intervals, may also stimulate an LH surge in normal cycling queens. The probing need last only 2 to 5 seconds.

Estrus induction has primarily involved using domestic cats as models for AI and IVF/ET in endangered wild felids.

The most common hormones used to induce estrus (i.e., folliculogenesis) in cats are porcine FSH and equine chorionic gonadotropin (eCG). A disadvantage of pFSH is the need for daily administration until the onset of estrus. Because of its longer half-life, a single injection of eCG (100 IU, intramuscularly) is often sufficient. Ovulation is then induced with LH (hCG; 75, 100, or 250 IU, administered intramuscularly or intravenously, depending on the formulation), or mating with a tomcat. A commonly used protocol for artificial insemination regimens is eCG followed by hCG 80 to 84 hours later. Protocols using GnRH for estrus induction have also been successful, but to date, pregnancy rates have been lower. Although there is much variation in response to estrus induction protocols among feline species, a common problem is hyperstimulation of the ovaries. This has resulted in excessive or prolonged estrogen production, premature or prolonged progesterone production, or premature luteolysis, all of which disrupt rather than enhance reproduction. It has been shown in cattle that follicular cysts develop following luteal phases with inadequate progesterone levels. Therefore the use of progestins before gonadotropins to help prevent ovarian hyperstimulation is being investigated (Pelican, 2006).

# THE BITCH

Many drugs have been used to induce estrus—in other words, to shorten the interestrual interval—in bitches. Prostaglandin  $F_{2\alpha}$ , which is used to treat pyometra, causes luteolysis and decreased progesterone production by the CL. This shortens the normally long diestrous period and thereby shortens the interestrual interval by 1 to 2 months.

The mechanisms by which the dopamine agonists cabergoline and bromocriptine induce estrus are multifactorial. One mechanism is by suppression of prolactin, which is luteotropic. Suppressing luteal function decreases progesterone, shortens diestrus, and increases LH pulsatility in bitches. However, this is not the sole explanation because metergoline, a seratonin antagonist that also decreases prolactin, does not induce estrus in bitches. Furthermore, even at low doses that do not suppress prolactin nor shorten diestrus, bromocriptine significantly shortens the interestrous interval. Bromocriptine (Lactafal®, Eurovet), given orally q12h at doses of 5, 20 and 50 µg, beginning in mid-diestrus until the onset of the next cycle, resulted in mean interestrual intervals of  $136 \pm 16$  days,  $96 \pm 6$  days, and  $92 \pm 11$  days, respectively, compared with untreated controls' mean interval of 216  $\pm$  9 days (Beijerink et al., 2003). The higher doses suppressed prolactin and progesterone, whereas the low dose did not. Other researchers have reported that some bromocriptineinduced cycles are not fertile, despite hormonal variations similar to those in normal cycles. Cabergoline (Galastop®, Ceva Vetem; Dostinex®, Pfizer) at a dosage of 5 µg/kg orally, q24h, through the first 2 days of proestrus has induced fertile estrus in bitches with primary and secondary anestrus. The duration of treatment ranged from 4 to 34 days, with a mean of 16 days. Other researchers have suggested that continuing

treatment through the first 4 to 5 days of proestrus is important for success.

GnRH agonists, administered as slow-release implants, induce estrus in bitches. The effectiveness of estrus induction and the fertility of the induced cycle are dose dependent and age dependent and vary according to the stage of the cycle during which the drug is administered and perhaps the anatomic location of the implant. These variations are apparently the result of competing upregulation and downregulation of LH release. The GnRH agonist deslorelin has been studied for both estrus induction and estrus suppression in bitches. High doses induced fertile estrus, but abortions occurred during the ensuing diestrus. Lower doses of 1.05 mg or 2.1 mg deslorelin (Ovuplant®, Fort Dodge) implanted in Beagle bitches beneath the vestibular submucosa in the ventral commissure of the vulva reliably induced proestrus within 3 to 5 days of administration, and the LH surge occurred 9 to 17 days later (Volkmann et al., 2006). All the bitches implanted during anestrus ovulated, and 69% became pregnant when bred to the same dogs as were the untreated controls. All the untreated controls also ovulated, and 67% became pregnant. However, although bitches implanted during diestrus also came into estrus and experienced an LH surge, only 69% ovulated and the pregnancy rate was only 15%. Furthermore, 15% of those treated in diestrus developed pyometra during the diestrus after the induced estrus.

Induction of ovulation might be indicated for cycling bitches in which ovulation is failing to occur or bitches with follicular ovarian cysts. Potential agents include hCG (22 IU/kg, intramuscularly) and GnRH (50 to 100 µg, intramuscularly; or 2.2 µg/kg, intramuscularly GnRH; Cystorelin®, Ceva). It has been recommended that hCG and GnRH be given on the first day of estrus, as determined by the behavior of the bitch and vaginal cytology. Success is confirmed by the finding of a serum progesterone concentration of greater than 8 ng/ml in early diestrus. For the treatment of follicular cystic ovarian disease in the bitch, 2.2 µg/kg of GnRH is administered intramuscularly for 3 days. However, the results of this treatment have been disappointing.

# DIAGNOSTIC APPROACH TO VULVAR DISCHARGE

Vulvar discharge is commonly found in bitches with disorders of the reproductive tract and, less commonly, disorders of the urinary tract. Vulvar discharge is also normal during proestrus, estrus, and the postpartum period. Vulvar discharge is uncommonly observed in queens. Determining the significance of the discharge depends on the stage of the reproductive cycle, the cellular composition of the discharge, and the source of the discharge. The diagnostic approach includes a thorough history-taking, physical examination, vaginal cytology, and vaginoscopy. When taking the history, the clinician should establish the stage of the reproductive cycle and the overall health of the bitch. The complete physi-

cal examination includes inspection of the discharge and vulva and palpation of the reproductive tract. Disorders of the vulva, vestibule, or vagina rarely cause signs other than vulvar discharge, licking of the vulva, and/or pollakiuria. Physical abnormalities are usually confined to these areas. In contrast, disorders of the uterus frequently result in systemic signs of illness in addition to a vulvar discharge. Historical findings such as malaise, weight loss, vomiting, or polydipsia-polyuria are suggestive of systemic illness, as are physical findings such as fever and dehydration. They deserve prompt attention.

The character of the vulvar discharge is determined by visual inspection and vaginal cytology (Box 57-1). Some characteristics, such as meconium, urine, and uteroverdin, can be confirmed by visual inspection. Uteroverdin is the dark green heme pigment normally found in the canine placenta. In the cat placental blood is red-brown in color. Its presence in a vulvar discharge indicates that placental separation has occurred. This is normal during stage II of parturition and during the first few hours postpartum, but it is abnormal at any other time. Sometimes, inflammation of the lower urinary tract or vestibule will cause dribbling of urine, which may be described by owners as a discharge. Meconium is the bright yellow fetal fecal material. Its presence indicates extreme fetal distress.

There are two important aspects of evaluating vaginal cytology. The first is examination of the vaginal epithelial cells for the maturation and cornification induced by estrogen (see Chapter 56 and Fig. 56-6). The second is identification of other cell types and mucus. The source of the vulvar discharge is confirmed by physical examination of the vulva and endoscopic examination of the vestibule and vagina. If a uterine source of the discharge is suspected, abdominal radiography and/or ultrasonography of the uterus should also be performed. Further diagnostic tests may be indicated once the origin and probable cause of the discharge have been established.

# HEMORRHAGIC VULVAR DISCHARGE

Red blood cells (RBCs) are commonly found in normal and abnormal vulvar discharges. The other types of cells that are

Differential Diagnoses for Vulvar Discharge Based on Predominant Cytologic Characteristics

#### Cornified (Mature or Superficial) Epithelial Cells

- Vaginitis
- Metritis or pyometra (possible but unlikely)

Septic (organisms seen)

- Vaginitis
- Metritis
- Pyometra
- Abortion

also present, particularly vaginal epithelial cells and white blood cells, determine their significance. In addition to the plentiful RBCs, the predominant cytologic finding during normal proestrus and estrus is numerous mature (cornified) superficial vaginal epithelial cells, indicating an estrogenic influence. White blood cells (WBCs) and extracellular bacteria may also be present. Ovarian remnant syndrome, exogenous estrogen, and the pathologic production of estrogens by ovarian follicular cysts or ovarian neoplasia can cause similar cytologic findings.

When RBCs are the predominant cytologic finding in the absence of cornified vaginal epithelial cells (i.e., no estrogenic influence), a cause for hemorrhage, such as vaginal laceration, uterine and vaginal neoplasia, subinvoluted placental sites, uterine torsion, and coagulopathies, should be sought. Vaginal laceration or other trauma to the reproductive tract is uncommon but may occur during breeding or as a result of vaginoscopy or obstetric procedures. Although bleeding from the vulva is certainly not common in animals with coagulation defects, it has been observed as the sole site of bleeding in some bitches with coagulopathies. When RBCs are accompanied by WBCs as the predominant cytologic abnormality, especially when the number of WBCs exceeds that expected in peripheral blood, a cause of inflammation (WBCs) rather than of hemorrhage (RBCs) should be sought.

#### MUCOID VULVAR DISCHARGE

Mucus is the predominant component of the normal postpartum discharge, lochia (see Chapter 59). It may also be present during normal late pregnancy and possibly in small amounts during the nonpregnant luteal phase. Cervicitis and mucometra can cause a mucoid vulvar discharge. In rare instances no apparent cause can be found in some bitches with small amounts of mucous discharge.

#### **EXUDATE**

Cellular debris is often the predominant component of the discharge that accompanies abortion and also of the discharge that accompanies the metritis associated with retained fetal or placental tissue. Some debris is also present in lochia.

# **Purulent Vulvar Discharge**

Purulent and mucopurulent vulvar discharges are characterized by a predominance of polymorphonuclear cells (PMNs), with or without mucus. When bacteria are also present, the exudate is referred to as *septic*. Large numbers of PMNs without signs of degeneration or sepsis are often found during the first day or two of diestrus (see Chapter 56). This normal diestrual return of WBCs to the vaginal smear can be differentiated from inflammation of the reproductive tract by the absence of clinical signs, the temporal correlation with recent estrus, and the prompt disappearance of WBCs within 48 hours of the onset of diestrus.

A nonseptic exudate is often found in prepubertal bitches with vaginitis. Androgenic stimulation (exogenous testosterone or an intersex condition) can also cause a nonseptic inflammation. Other causes of nonseptic and septic vulvar discharges include vulvitis, vaginitis, pyometra, metritis (see Chapter 59), abortion (see Chapter 58), and a uterine stump granuloma or abscess.

### **ABNORMAL CELLS**

The characteristic appearance of endometrial cells easily distinguishes them from other cells seen on vaginal cytologic preparations. They are columnar and have a basal nucleus

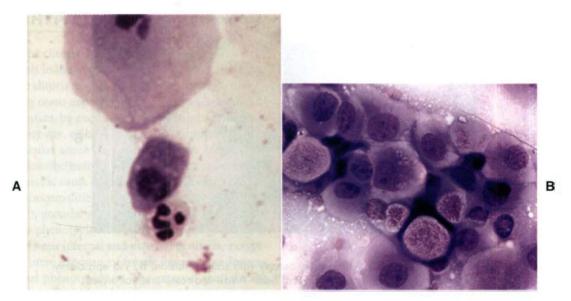

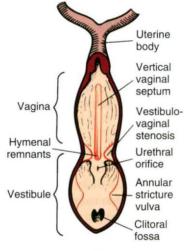

FIG 57-1
Abnormal findings on vaginal cytology. A, Canine endometrial cell with superficial vaginal epithelial cell and neutrophil. B, Transitional cell carcinoma from a bitch with hemorrhagic vaginal discharge.

and foamy cytoplasm (Fig. 57-1). The presence of endometrial cells indicates uterine involvement. They may be found in animals with cystic endometrial hyperplasia, even in the absence of an overt vulvar discharge, or, less commonly, in lochia and in animals with metritis. Transmissible venereal tumors and transitional cell carcinomas readily exfoliate, and neoplastic cells may be found on vaginal cytologic preparations (see Fig 57-1). Leiomyomas do not readily exfoliate.

# ANOMALIES OF THE VULVA, VESTIBULE, AND VAGINA

The müllerian ducts are the embryologic origin of the uterine tubes, uterus, and vagina. The vestibule, urethra, and urinary bladder develop from the urogenital sinus. Thus the vestibulovaginal junction is immediately cranial to the urethral orifice. The genital folds also form part of the vestibule (Fig. 57-2). The fusion of the Müllerian ducts with the urogenital sinus forms the hymen, which is composed of two epithelial surfaces separated by a thin layer of mesoderm. In bitches the hymen reportedly disappears before birth. The genital tubercle gives rise to the clitoris, and the genital swellings become the labia (vulva).

The abnormal formation or disappearance of the hymen can result in a vertical band of tissue or in an annular stricture at the vestibulovaginal junction. The latter condition has also been referred to as *vestibulovaginal stenosis*. Abnormal or incomplete fusion of the paired müllerian ducts can result in the formation of an elongated vertical septum that bisects the vagina (Fig. 57-3) or in the formation of a vaginal diverticulum (pouch). Vaginal diverticula are uncommon.

**ANOMALOUS STRUCTURES** 

FIG 57-2
Anatomic location of normal structures and common congenital anomalies of the canine vagina and vulva. (Redrawn from Miller ME et al, editors: Anatomy of the

dog, Philadelphia, 1964, WB Saunders.)

Complete duplication of parts of the urogenital tract, including a true double vagina, has been reported, but this is extremely rare. Abnormal fusion of the genital folds with the genital swellings can result in the formation of strictures within the vestibule and vagina. With the exception of abnormalities of the vulva and vestibule, the common congenital anomalies are located immediately cranial to the external urethral orifice. Hypoplasia or agenesis of parts of the reproductive tract also occurs. All these congenital anomalies of

FIG 57-3
Vaginal septa in two bitches. **A,** Via vaginoscopy with saline infusion. **B,** Via episiotomy. Spay hook used to bring septum into surgical field. *Arrow* indicates urethral orifice.

the vagina and vulva have been found in bitches, but they are apparently extremely rare in queens.

Growth and maturation of the vulva and vagina depend on the ovarian hormones. When ovariectomy is performed before puberty, the reproductive tract remains in its infantile or juvenile stage of development. When the ovaries are removed after puberty, some atrophy occurs, but the reproductive tract does not return to its prepubertal size. Depending on the smallness of the vulva and the overall perineal conformation, the vulva may be recessed in the perineal skin. A recessed vulva could be congenital or acquired. In some obese individuals rolls of perineal fat cover the vulva.

#### **Clinical Features**

Anomalies of the vulva and vagina often cause no clinical signs, or they may be associated with perivulvar dermatitis, recurrent urinary tract infections, chronic vaginitis, or refusal to mate. Vulvar-vaginal anomalies are often recognized only because the female refuses to mate or because the male dismounts without being able to achieve intromission. Occasionally, vulvar-vaginal anomalies are associated with urinary incontinence. This may be due to urine pooling anterior to the lesion, or there may be other, concurrent congenital anomalies in the urogenital tract, such as ectopic ureters.

#### Diagnosis

Anomalies of the vulva and vagina are easily identified by physical examination and digital palpation. Most anomalies involve the caudal aspect of the tract, from the vestibulovaginal junction outward, and are easily reachable. Vaginoscopy (see Chapter 56) is very useful for evaluating the vestibule and vagina and may be combined with urethrocystoscopy in cases with urinary incontinence. Vaginography (see Chapter 56) can also be performed, but care must be taken with the plane of anesthesia, positioning of the patient, and interpretation of the findings. The vestibulovaginal junction is normally so narrow during anestrus, especially in pubescent bitches, that it may be mistaken for a stricture or

stenosis. Furthermore, contraction of the constrictor vestibuli muscle, which may occur during manipulation of the genitalia, resembles a stricture. Before surgical treatment of vestibulovaginal stenosis (annular strictures) is considered for an intact animal, it should be evaluated during proestrus and estrus, at which time the normal vestibulovaginal junction relaxes considerably and is easily differentiated from a true stricture. Some strictures in the vestibule-vulva also "relax" during estrus. Abdominal radiography or ultrasonography can be performed to identify vaginal diverticula.

## **Treatment**

Anomalies of the vulva and vagina often are incidental findings. Treatment is unnecessary if they are causing no clinical signs. Anomalies of the vulva and vagina that are causing clinical signs should be corrected surgically, during anestrus. Vulvar anomalies are corrected by episioplasty. The prognosis after episioplasty for recovery from perivulvar dermatitis, recurrent urinary tract infection, and vaginitis is excellent. Episioplasty should be delayed until puppies have reached physical maturity and, whenever possible, obese animals have returned to normal body condition. Thin bands of persistent hymenal tissue can sometimes be broken using digital pressure alone. Some annular strictures are amenable to bougienage. Surgical repair is necessary for the treatment of vaginal septa, and this can be achieved with minimally invasive endoscopy or an episiotomy (see Fig. 57-3). The prognosis for normal mating ability after surgical correction of vaginal septa and hymenal remnants is excellent. Animals with annular strictures may be prone to fibrosis and restricture. Celiotomy may be necessary to correct a vaginal diverticulum. Because hypoplasia or agenesis cannot be rectified, affected animals should be neutered to prevent additional complications, such as cystic endometrial hyperplasia. The role that heredity plays in the development of congenital vaginal and vulvar anomalies in bitches is unknown, but it is known that certain vaginal anomalies are inherited in mice.

# CLITORAL HYPERTROPHY

In the female the clitoris develops from the genital tubercle, as does the penis in the male. Under the influence of androgens the canine clitoris may enlarge and even ossify. This can be caused by in utero exposure of female fetuses to androgens and progestins, by exogenous androgen administration to females of any age, or by endogenous androgen production from testicular tissue in intersex animals. Intersex is a term used to describe individuals with ambiguous genitalia in which the specific cause has not yet been determined. The cause may be abnormalities in chromosomal sex (e.g., XXY, XO, or XX/XY), gonadal sex (e.g., testis, ovotestis, and XX sex reversal), or phenotypic sex (e.g., ambiguous genitalia or discrepancy between internal and external genitalia, ±cryptorchidism). In utero exposure of female fetuses to androgens causes abnormal phenotypic sex. The external genitalia are ambiguous or cryptorchid male, whereas chromosomal sex is normal XX, the gonadal sex is normal ovary, and the internal genitalia are normal uterus, ±epididymis.

Clitoral hypertrophy may go unnoticed. More commonly, however, the enlarged clitoris protrudes from the vulva. This is often first apparent when the animal nears puberty or following the administration of exogenous androgens. A mucoid discharge is common, as is licking of the area. There may be a history of recurrent urinary tract infection. Physical examination will demonstrate the abnormal clitoris, which occasionally will have a distinctly phallic shape. When present, ossification is usually palpable. The vulva may have a normal appearance and position, or in intersex animals it may be ventrally displaced anywhere along the line from the normal vulvar position to the normal position of the preputial orifice (Fig. 57-4). This is because of the embryologic influence of androgens on the genital swellings, which normally develop into either the vulva (no androgen) or the prepuce and scrotum (androgen). The vestibule-vagina may be imperforate in females exposed in utero and in intersex animals.

Treatment is to remove the source of androgen if it still exists. The hypertrophic soft tissue of the clitoris will usually regress, but ossified tissue is usually permanent. Unless it is clear that a previously normal female has been treated with androgens, such as might be the case with racing Greyhound bitches, affected animals should be evaluated for the presence of an intersex condition. Exploratory laparotomy with the intent of removing the gonads and internal genitalia may be the most cost-effective approach, although hormonal testing to confirm the presence of testicular tissue and karyotyping easily can be done (see Chapter 56). Clitorectomy may be needed to eliminate the clinical signs associated with chronic exposure.

#### **VAGINITIS**

Vaginitis (i.e., inflammation of the vagina) occurs in sexually intact or neutered bitches of any age or breed during any

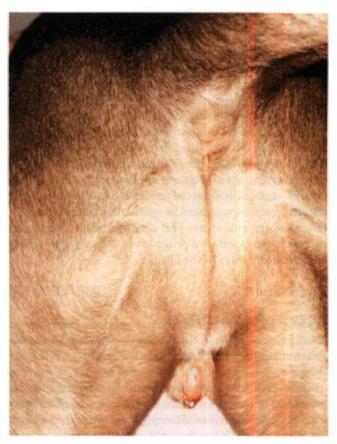

FIG 57-4
Clitoral hyperplasia in a 1-year-old Weimaraner examined because of recurrent urinary tract infection and vulvar discharge. Note the ventral displacement of the vulva. Testes and uterus were found at surgery. Gonadectomy, hysterectomy, and clitorectomy were curative.

stage of the reproductive cycle. It is rare in queens. Vaginitis may result from immaturity of the reproductive tract; anatomic abnormalities of the vagina or vestibule; chemical irritation, such as that caused by urine; bacterial, viral, or yeast infections; androgenic stimulation; or mechanical irritation, such as that caused by foreign material or neoplasia.

#### Diagnosis

The diagnosis is based primarily on the historical and physical finding of a mucoid, mucopurulent, or purulent vulvar discharge, which is present in most bitches (90%) with vaginitis. The vulvar discharge of vaginitis rarely contains blood, except in cases caused by foreign material or neoplasia. Licking of the vulva and pollakiuria are less common additional clinical signs that are present in about 10% of affected animals. Animals with vaginitis are otherwise normal and healthy. If they are not, a diagnosis in addition to, or other than, vaginitis should be pursued. For example, the vulvar discharge may be originating from the uterus, not the vagina, in the case of pyometra. The diagnosis of vaginitis can be substantiated by vaginal cytology and vaginoscopy, but this is not always necessary for a first occurrence. The cytologic

finding with vaginitis is nonseptic or septic inflammation without hemorrhage. Vaginoscopy is especially useful for identifying the underlying cause of vaginitis, such as anatomic abnormalities, foreign material, or neoplasia. The extent of the vaginal inflammation can also be assessed by vaginoscopy, and biopsies can be obtained if indicated. Urinalysis and urine culture should be performed in animals with a history of pollakiuria. Because the bacterial organisms isolated from bitches with vaginitis are quantitatively and qualitatively similar to the normal bacterial florae of the canine vagina, vaginal cultures are not helpful in the diagnosis of vaginitis. Rather, the results of bacterial culture and sensitivity testing are used to guide the formulation of a rational therapeutic plan. The clinical findings, diagnostic approach, treatment, and prognosis of canine vaginitis vary according to the age of the bitch.

#### **Treatment**

#### PREPUBERTAL BITCH

In bitches younger than 1 year of age, physical and historical abnormalities almost always consist only of the vulvar discharge and inflammation of the vulva and vagina. The animals are otherwise healthy. Vaginal cytologic findings are most often nonseptic in nature. Systemic or topical antibiotics, douches, and perineal cleansing are common treatments, but the evidence shows that 90% of young bitches recover from vaginitis with or without treatment. Therefore healthy young bitches in which clinical findings are limited to a nonhemorrhagic vulvar discharge usually need no further diagnostic tests and require no treatment. Most such animals recover spontaneously as they reach physical maturity. Whenever any additional historical or physical abnormali-

ties are found, young bitches should be evaluated using the approach described for the mature bitch.

The role of estrus, if any, in the resolution of vaginitis in young bitches is unclear. Because attaining physical and sexual maturity is so closely related, it is difficult to evaluate the relative contributions of each. In some bitches there is a temporal relationship between the onset of estrous activity and the resolution of vaginitis. However, vaginitis resolves spontaneously in most young bitches as they reach physical maturity, irrespective of estrus. Because ovariohysterectomy is traditionally performed before the first heat, the evidence is clear that ovariohysterectomy does not hasten the resolution of vaginitis. However, the effect of ovariohysterectomy on the persistence of vaginitis in the prepubertal bitch has not been reported. Because maturation of the reproductive tract during estrus may cause vaginitis to resolve (or, conversely, the absence of estrus may enable chronic vaginitis to persist), consideration may be given to delaying ovariohysterectomy in young bitches with chronic vaginitis until after the first heat.

# MATURE BITCH

A predisposing factor for vaginitis can be identified in most (70%) affected bitches older than 1 year. The key to the successful therapy of vaginitis in mature bitches is the identification and elimination of underlying disorders. Of the identifiable factors in mature bitches, abnormalities of the genital tract are the most common (35%). They are found during physical and endoscopic examinations and include vulvar anomalies, vaginal strictures, vertical vaginal septa, foreign material, clitoral hypertrophy, and vaginal neoplasia (Fig. 57-5). Disorders of the urinary tract, including urinary tract infection and urinary incontinence, are the next most

Vaginal abnormalities. A, Vaginal dermoid causing discharge in a 3-month-old Boxer.

B, Fibroma in an 11-year-old spayed Golden Retriever with swollen vulva, chronic mucopurulent discharge, and ovarian remnants with follicular cysts and luteoma.

commonly (26%) identified abnormalities in mature bitches with vaginitis. Therefore thorough physical examination and vaginoscopy to identify abnormalities in the genital tract, vaginal cytology to characterize the discharge, and analysis and culture of urine obtained by cystocentesis should always be included in the evaluation of mature animals with vaginitis. Canine herpes virus infection has been cited as a rare cause of vesicular lesions on the mucosal surfaces of the genitalia in bitches and dogs. The lesions are discovered on the vulvar mucosa or during vaginoscopy. They rarely cause discharge or other signs of vaginitis, and isolation of the virus is rarely reported. Much more commonly, canine herpes virus infection causes fulminant multiorgan system failure and death in neonates, mild respiratory infection in adults, and abortion.

The resolution of vaginitis in mature bitches is directly related to the elimination of the underlying disorder. The prognosis is excellent for resolution of vaginitis after vulvar and vaginal anomalies are surgically corrected, after foreign material is removed, and after urinary incontinence is controlled. Urinary tract infection and vaginitis have some mutual predisposing causes as well as being predisposing factors for each other. Fortunately, correction of mutual causes and appropriate antibiotic therapy usually resolve both, irrespective of which came first. The choice of antibiotics should be based on the results of urine culture. Some mature bitches with vaginitis recover spontaneously.

The role of estrus, if any, in resolving vaginitis in mature bitches is unknown. The signs of vaginitis continue to improve in some mature bitches with each succeeding cycle. In others there is no apparent change in response to estrus. The effects of ovariohysterectomy on vaginitis in mature bitches are even less clear. In most bitches ovariohysterectomy has no apparent therapeutic effect on the outcome. Signs of vaginitis occur after ovariohysterectomy in some previously healthy bitches.

# CHRONIC, NONRESPONSIVE VAGINITIS

Animals with chronic vaginitis in which an underlying cause has not been found and that do not recover in response to appropriate therapy remain a source of frustration. The initial minimum database of history, physical examination, urinalysis and urine culture, vaginal cytology, and vaginoscopy should be repeated. The database should be expanded to evaluate overall health with a complete blood count (CBC) and biochemical panel and to assess the rest of the urogenital tract with abdominal radiographs and ultrasound. The purpose is to assess progression of disease with the minimum database and find clues to less common predisposing factors or underlying disease with the additional diagnostic tests. For example, uterine stump abscess or pyometra or abnormal hormone production from ovarian remnant should be considered in the spayed bitch with chronic vaginitis. Yeast vaginitis, which is very uncommon in bitches, can occur after long-term antibiotic therapy. Body condition may have changed such that recessed vulva is now a factor. As a final diagnostic step, biopsy should be considered.

Some veterinarians recommend the use of over-the-counter douches containing dilute vinegar or povidone-iodine for the treatment of canine vaginitis. There is no published evidence that vaginal douching is efficacious in the treatment of canine vaginitis. In women douching is one of the risk factors for the development of bacterial vaginosis (Eckert, 2006). Povidone-iodine is cited as a contact irritant cause of noninfectious vaginitis and vulvitis in women (Sobel, 1997). Given the anatomy of the canine vagina, the discomfort of vaginitis, and the need for adequate animal restraint, many pet owners are unable to instill douches into the vagina instead of the vestibule. Until there is evidence that douching is helpful and that it is not harmful in management of canine vaginitis, the practice should probably be discontinued.

# **NEOPLASIA**

Leiomyoma is the most common neoplasm of the vagina and uterus in geriatric bitches and queens. It often causes hemorrhage. However, because leiomyomas do not exfoliate readily, neoplastic cells are usually not seen on cytologic preparations. The histologic diagnosis is made from biopsy specimens of the mass that is identified by palpation, diagnostic imaging, and/or vaginoscopy. Treatment of leiomyomas is surgical excision. The prognosis is good if the location of the tumor is amenable to complete surgical excision. Transitional cell carcinoma (TCC) occasionally invades the vestibule-vagina from the urethra. When it does, it can often be detected by vaginal palpation and can be seen during vaginoscopy. TCCs readily exfoliate, and the diagnosis is easily made on the basis of cytology obtained directly from the lesions during vaginoscopy (see Fig 57-1). Treatment of TCC is chemotherapy. The prognosis for cure is guarded, but quality of life may be good while urine flow is maintained and urinary tract infection and inflammation are controlled.

Bitches with transmissible venereal tumors (TVTs) are more likely to be examined because of a mass protruding from the vulva than because of a vulvar discharge. TVT is a contagious round-cell tumor. Venereal transmission is most common. It occurs primarily on the mucosal surfaces of the external genitalia of male and female dogs, but it can be transplanted to other sites and transmitted to other dogs by licking and by direct contact with the tumor. Primary TVTs have been found on the skin and in the oral and anal mucous membranes. The prevalence of TVT varies greatly with the geographic area. For example, the prevalence of TVT among 300 pound-source bitches in Yucatan, Mexico, was 15% (Ortega-Pacheco et al., 2007). Some TVTs regress spontaneously, but most do not. Some TVTs are quite locally invasive, and some metastasize to the regional lymph nodes (Fig. 57-6). Rarely, metastasis to distant sites such as the lungs, abdominal viscera, or central nervous system (CNS) occurs.

TVTs have a fleshy, hyperemic appearance. Initially, they appear as a raised area. As they grow, they acquire a

FIG 57-6 Invasive transmissible venereal tumor of the vulva.

cauliflower-like shape and may reach a diameter of 5 cm or larger. They are often quite friable and bleed easily. TVTs in males are most often found on the bulbus glandis area of the penis, but they may appear anywhere on the penile or preputial mucosa. Affected animals are usually examined because of a mass on the external genitalia, but they may also be seen because of a preputial or vulvar discharge. The diagnosis of TVT is strongly suspected on the basis of the physical appearance of the tumor on the external genitalia. Differential diagnoses, especially in animals with nongenital lesions, include other round-cell tumors such as mast cell tumor, histiocytoma, and lymphoma. Pyogranulomatous lesions and warts of the genitalia may also have a similar gross appearance. The diagnosis of genital TVT is easily confirmed by exfoliative cytologic studies, fine-needle aspiration, or histopathologic findings.

TVTs respond to several chemotherapeutic agents. Vincristine, administered once weekly as a single agent (see Chapter 77), is quite effective for solitary, localized lesions. It has a low toxicity and is financially acceptable to most owners. It is administered for two treatments beyond the time when the tumor disappears. The total duration of treatment is usually 4 to 6 weeks. Complete remission is achieved in more than 90% of dogs treated with vincristine alone, and they usually remain disease free. TVTs are also extremely sensitive to radiation therapy. Although surgical excision results in long-term control, relapses occur in as many as 50% of animals.

# VAGINAL HYPERPLASIA/PROLAPSE

During proestrus and estrus the vagina becomes edematous and hyperplastic. Sometimes, the change is so severe in bitches that vaginal tissue protrudes out of the vulva. This condition has been referred to as *vaginal hyperplasia* or *vaginal prolapse* because these are the most prominent microscopic and physical findings, respectively. Vaginal hyperplasia/prolapse occurs in bitches exclusively during

times of estrogenic stimulation—in other words, during proestrus and estrus. On rare occasions, prolapse recurs later in the same cycle at the end of diestrus or at parturition, a time when additional estrogen may be secreted. It is common for vaginal hyperplasia/prolapse to recur during each estrus in affected individuals, although each episode is not always of the same severity.

The amount of edema and hyperplasia is extremely variable. Digital palpation of the vagina shows that the mass originates from the ventral vagina, immediately cranial to the urethral orifice. All other areas of the vagina are normal. If the edematous tissue is small enough to be contained within the vagina and vestibule, it is usually very smooth, glistening, and pale pink to opalescent because of the edema (type I vaginal prolapse; Fig. 57-7, A). If the hyperplastic tissue protrudes from the vulva, it is dry, dull, and wrinkled. With continued exposure, fissures and ulcers develop (type II vaginal prolapse; Fig. 57-7, B). Although the tissue protruding from the vulva may be quite massive, it originates from a stalk involving only a few centimeters of the vaginal floor. Much less commonly, the hyperplastic tissue involves the circumference of the vagina (type III; Fig. 57-7, C). In all three types of vaginal hyperplasia/prolapse, the tissue is located at the level of the urethral orifice; the rest of the vagina is normal. Despite the fact that the edematous hyperplastic tissue lies over the external urethral orifice, urine flow is rarely impeded.

The diagnosis of vaginal prolapse is made on the basis of the history and physical examination findings. Bitches may be seen because they refuse to allow intromission or because of the mass protruding from the vulva. The history indicates that they are in proestrus or estrus. If it does not, the stage of the cycle can be confirmed by vaginal cytology. The protrusion of this edematous, hyperplastic tissue must not be confused with a true prolapse of the vagina or uterus that occurs rarely during parturition (Fig. 57-8). The history alone (estrus versus parturition) should be sufficient to do so. If the clinician is concerned that the hyperplastic tissue could be neoplastic, the two can be differentiated on the basis of findings yielded by the cytologic examination of material obtained by fine-needle aspiration.

#### **Treatment**

The treatment of vaginal hyperplasia/prolapse is primarily supportive. The edema and hyperplasia will resolve spontaneously when the follicular phase of the cycle and the ovarian production of estrogen are over. This can be hastened by ovariohysterectomy. Ovariohysterectomy also prevents the recurrence of vaginal hyperplasia/prolapse because there will be no more estrous cycles. After oophorectomy the edema and hyperplasia usually resolve within 5 to 7 days. There is no published evidence that the pharmacologic induction of ovulation hastens recovery.

Exposed tissue must be protected from trauma and, if the mucosa is damaged, from infection. This is usually accomplished by applying topical antibiotic (e.g., bacitracinneomycin-polymyxin) or antibiotic-steroid creams and

Vaginal hyperplasia and prolapse. A, Type I, edema.

B, Type II. C, Type III.

cleaning the tissue (with warm saline solution or warm water and pHisoHex) as needed. Attention should also be paid to the underlying perineal and vulvar skin, which may be subject to maceration (see Fig. 57-7C). Potentially irritating bedding such as straw or wood chips should be removed. An

FIG 57-8
Periparturient vaginal prolapse in a cat.

Elizabethan collar may be used to prevent self-mutilation, but this is rarely necessary. Artificial insemination can be performed if vaginal hyperplasia/prolapse prevents copulation. The condition will resolve spontaneously as soon as the female goes out of heat. It is unlikely to recur (although this is possible) and cause dystocia at the time of parturition.

Surgical resection of the edematous tissue has been considered for brood bitches, but this should probably be reserved for extremely valuable animals. The hemorrhage that results is often significant, despite excellent surgical technique. The resection of hyperplastic tissue also does not prevent recurrence during subsequent estrous cycles, although the severity of the prolapse may be markedly reduced. We have seen one bitch with recurrent hyperplasia/ prolapse in which the prolapse did not resolve despite ovariohysterectomy after the fourth recurrence. Resection was the only recourse. Because of its recurrent nature and the care required to manage severe cases, affected animals are not the best brood bitches. The role that heredity plays, if any, in the development of vaginal hyperplasia/prolapse is not known, but it appears to be at least familial in nature.

# **DISORDERS OF THE UTERUS**

The clinical signs of disorders of the uterus are variable and nonspecific. For example, there may be no clinical signs associated with congenital anomalies such as segmental aplasia. Rather, it may be an incidental finding at the time of elective ovariohysterectomy. Conversely, in cycling animals segmental aplasia may be the cause of infertility. Many uterine disorders are manifested by the presence of an abnormal vulvar discharge. Uterine enlargement may cause abdominal discomfort and abdominal distention. In addition to those signs, uterine infections typically cause signs of systemic illness, such as anorexia, lethargy, polydipsia-polyuria, or fever. Uterine disease should be considered among the ruleouts for infertility, vulvar discharge, and postpartum illness. Uterine disease is much more likely in sexually intact animals,

but the history of having been spayed does not exclude the possibility of a uterine stump abscess or granuloma, or pyometra in an animal with ovarian and uterine remnants.

Determining the stage of the estrus cycle is important for several reasons. First, some disorders are seen during certain stages; for example, pyometra is almost always seen during diestrus. Second, interpretation of diagnostic tests, such as cytology of vulvar discharge, depends on knowledge of the cycle. Physical examination will assess the overall health, and identify abnormalities in the reproductive tract. Uterine enlargement is usually detectable by abdominal palpation, especially in cats. Vulvar discharge may be more evident after palpation of the uterus. The absence of these findings, however, does not exclude uterine disease. Diagnostic imaging, particularly abdominal ultrasound, is extremely helpful. A uterine source of a vulvar discharge can be confirmed by vaginoscopy. Whenever there are signs of systemic illness, a CBC, biochemical panel, and urinalysis are indicated. The most common uterine disorders causing systemic illness in dogs and cats are pyometra (discussed later) and postpartum metritis (see Chapter 59).

Uterine neoplasia is rare in dogs and cats. Leiomyoma is the most common. Rarely, adenocarcinoma has been reported. Uterine neoplasia may be an incidental finding, or it may be associated with sangineous vulvar discharge, anorexia, weight loss, and abdominal discomfort and enlargement. The diagnosis is made by the finding of uterine enlargement on abdominal palpation and diagnostic imaging. Treatment is ovariohysterectomy. The prognosis for uterine leiomyoma is good if the location of the tumor is amenable to complete surgical excision. The prognosis for uterine carcinoma is poor because metastasis is often present. Focal, benign uterine masses, such as adenomomas, have also rarely been reported in geriatric bitches.

Uterine torsion is a life-threatening condition that usually occurs in the near-term gravid uterus in bitches and queens. It has also been reported in conjunction with other uterine pathology, such as hematometra and pyometra. One or both horns may be involved (Fig. 57-9). Affected animals are usually very ill and present as an acute abdomen with abdominal splinting and pain. Clinical signs also include sanguineous vulvar discharge and straining. The diagnosis is suspected on the basis of physical examination and ultrasonographic findings. It is confirmed at surgery. There are often significant metabolic derangements that should be evaluated with a biochemical panel and/or venous blood gas analysis. Treatment is ovariohysterectomy and intensive supportive therapy.

# CYSTIC ENDOMETRIAL HYPERPLASIA, MUCOMETRA, AND PYOMETRA

# CYSTIC ENDOMETRIAL HYPERPLASIA

Cystic endometrial hyperplasia (CEH) is characterized by an increase in the number, size, and secretory activity of the endometrial glands and by endometrial hyperplasia. Proges-

FIG 57-9
Torsion of both uterine horns.

terone plays the most prominent role in the development of CEH, although it is not the only mechanism by which CEH can be experimentally induced. In bitches and queens CEH develops during the luteal phase (diestrus) of the cycle, a time when endogenous progesterone concentrations are high. It also develops in response to exogenous progestins under therapeutic as well as experimental conditions. The most common therapeutic use of progestins in bitches and queens is to suppress estrus. The endometrial response to endogenous and exogenous progesterone seems to be dose dependent because most affected animals are middle-aged, having experienced multiple cycles or having been treated for a length of time. In experimental conditions, as well as clinical application, the addition of estrogen when serum progesterone concentrations are high, such as is the case when estrogens are used for "mismating" in bitches, enhances the development of CEH, whereas estrogen alone does not cause CEH. Under experimental conditions ovariectomized 2- to 4-year-old bitches given a progestin (megestrol acetate) for 30 days developed CEH that was reversible when the progestin was withdrawn but that persisted when the progestin was continued. The same experiment confirmed previous findings that mechanical irritation of the endometrium (in this case by implanting silk suture material) also can cause CEH, but the silk-induced CEH was not maintained in the absence of the progestin (Chen et al., 2006). In and of itself, CEH does not cause clinical illness. Cystic endometrial hyperplasia does cause increased thickness in the uterine wall, which may be detectable on abdominal palpation and ultrasound. It may also cause decreased fertility.

## **MUCOMETRA**

The general consensus is that CEH is the precursor of mucometra or hydrometra. In addition to the fluid accumulation within the cystic endometrial glands, sterile fluid accumulates in the uterine lumen. There may also be a mucoid or seromucoid vulvar discharge if the cervix is open. The dis-

**FIG 57-10 A,** Cat mucometra. **B,** Canine pyometra with severe cystic hyperplasia.

charge is not purulent on cytologic evaluation. Uterine enlargement is detected by abdominal palpation and with diagnostic imaging. The uterus can be large enough to cause abdominal distention and associated signs of discomfort. Because bitches normally experience diestrus lasting more than 60 days after every estrous cycle and because queens usually experience diestrus only after having been induced to ovulate, mucometra is much more common in bitches than in queens.

Some bitches with mucometra also have a history of polydipsia-polyuria and vomiting or anorexia, but vital signs usually are normal and attitude usually is good. Ultrasonography will demonstrate the luminal fluid as well as the character of the uterine wall. Usually, the wall will be thicker than normal and the cystic nature of the endometrium is evident (Fig. 57-10). However, in some cases the histopathologic finding is endometrial atrophy. This may be related to the duration and degree of uterine distention. The historical and physical findings of animals with mucometra can be very similar to those of pregnancy or pyometra. Pregnancy can easily be excluded on the basis of ultrasound, but before days 42 through 45 of gestation when fetal skeletons become visible, the radiographic appearance of mucometra and the pregnant uterus is the same. Differentiating animals with mucometra from those with pyometra may be more difficult. Ultrasound alone would not be sufficient to differentiate among hydrometra, mucometra, and pyometra, but hydrometra and mucometra typically have a relatively anechoic ultrasonographic appearance, whereas the fluid associated with pyometra is usually echogenic. Animals with mucometra are not seriously ill, whereas those with pyometra often are. Both groups of animals are likely to be mildly anemic. The mean total WBC count of bitches with mucometra is normal, although an individual animal may have counts as high as 20,000/µl; whereas the mean total WBC of bitches with pyometra is reported to about 23,000/µl, with great variation among individuals. The most striking difference on the hemogram is the percentage of band neutrophils, which are much higher in bitches with pyometra. Fransson et al. (2004) reported that the percentage of band neutrophils had

a sensitivity of 94% in differentiating pyometra from mucometra. Animals with mucometra typically have normal biochemical results. Ovariohysterectomy is curative. Medical management, as for pyometra, could also be considered for valuable breeding animals with mucometra.

#### **PYOMETRA**

Pyometra is characterized by purulent uterine contents and histologic evidence of variable degrees of inflammatory cell infiltrates (neutrophils, lymphocytes, plasma cells, macrophages) in the endometrium and, in severe cases, in the myometrium. There is also cystic endometrial hyperplasia, which is sometimes severe. Mild to severe fibroblast proliferation in the endometrial stroma, variable degrees of edema, necrosis, and sometimes ulceration of the endometrium and abscess formation in the glands are found. Occasionally, there is severe inflammation in the endometrium and myometrium, with endometrial atrophy rather than hyperplasia (De Bosschere et al., 2002). What initiates pyometra is still not completely understood. Although progesterone clearly plays a role, it is apparently not the sole explanation because serum progesterone concentrations are similar among normal healthy bitches and bitches with CEH, mucometra, and pyometra. It is also evident that neither CEH nor mucometra invariably progresses to pyometra. Differences in uterine estrogen and progesterone receptors have been demonstrated among normal, CEH, and pyometra specimens, but the differences have not always reached statistical significance and have not clearly demonstrated a different pathogenesis.

Bacterial invasion, presumably from the vaginal florae, is an important trigger. *Escherichia coli* is the most common organism isolated from bitches and queens with pyometra. Gram-negative bacteria such as *E. coli* produce endotoxins that are capable of initiating the cytokine cascade and the release of many inflammatory mediators. These are thought to be the cause of the local and systemic inflammatory reactions associated with pyometra. Inflammatory mediators such as C-reactive protein, tumor necrosis factor—1, lactoferrin, and PGF<sub>2 $\alpha$ </sub> are present in significantly greater serum or

uterine concentrations in bitches with pyometra than in normal animals. Serum concentrations of C-reactive protein and PGF<sub>2 $\alpha$ </sub> are significantly greater in bitches with pyometra than in bitches with CEH alone. In addition to the local and systemic inflammatory response, bitches with pyometra are immunosuppressed as assessed by lymphocyte blastogenesis.

As with mucometra, pyometra is more common in bitches than in queens. Age, previous hormonal therapy, and nulliparous status are risk factors for the development of pyometra. The risk of developing pyometra increases with age, presumably because of repeated hormonal stimulation of the uterus. Reported mean ages of bitches with pyometra range from 6.5 to 8.5 years. There is a sixfold increased risk of pyometra in nulliparous bitches compared with primiparous or multiparous animals. Previous hormonal therapy with progestins and estrogen is also a risk factor. Estrogens given during diestrus, a time when endogenous serum concentrations of progesterone are high, increase the risk of pyometra. Younger bitches (mean age 5.5 years) that develop pyometra were more likely than older bitches (mean age 8.5 years) to have been treated with estrogens (Niskanen et al., 1998). Analysis of survival rates in Swedish dogs indicates that, on average, about 24% of bitches will develop pyometra by age 10 years. In Sweden progestins, rather than ovariohysterectomy, are the most common method used to control estrus.

#### **Clinical Features**

Pyometra is a serious, potentially life-threatening disorder because septicemia and endotoxemia can develop very quickly (over a matter of hours) and at any time. For this reason it is usually treated as an emergency situation. The clinical signs become evident during diestrus or early anestrus. The history typically shows that the female was in heat 4 to 8 weeks earlier or that progesterone was recently given, either as a treatment or as contraception. Owners often report a vulvar discharge. The other historical findings are not specific for pyometra. They include lethargy, anorexia, and vomiting. Polydipsia-polyuria is a common finding in bitches but not in queens. On physical examination a purulent, often bloody vulvar discharge is found in most (85%) bitches and queens with pyometra. Pyometra is classified as open or closed depending on whether there is a vulvar discharge. The degree of uterine enlargement is variable. Dehydration is a common finding, as is abdominal discomfort. Other physical examination findings vary according to the severity of sepsis or endotoxemia. Most affected animals are lethargic. Rectal temperature is often normal. Fever is reported in only 20% to 30% of bitches and queens with pyometra. Subnormal temperature may be found in those in septic or endotoxic shock. Capillary refill time may be prolonged.

#### Diagnosis

The diagnosis of pyometra is strongly suspected on the basis of the occurrence of clinical signs in a sexually mature female

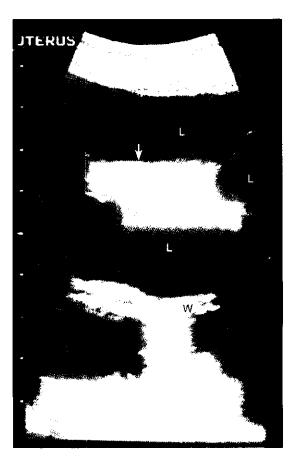

FIG 57-11 Sonogram of pyometra. L, Fluid-filled uterine lumen; W, uterine wall; arrow, endometrial cysts.

during or shortly after diestrus or after exogenous progestin administration, the presence of a septic vulvar discharge, and uterine enlargement. Abdominal ultrasound (or radiographs taken more than 45 days after having been in heat) confirms a fluid-filled uterus and rules out pregnancy (Fig. 57-11; see also Fig. 56-9). Neutrophilia with a shift toward immaturity (band neutrophils), monocytosis, and evidence of WBC toxicity are the most common findings on the CBC. The left shift (band neutrophils) is the single most sensitive test to differentiate pyometra from mucometra. Animals with pyometra may have a total WBC count as high as 100,000 to 200,000/µl, or there may be a leukopenia with a degenerative left shift. A mild normocytic, normochromic, nonregenerative anemia is usually also evident. Biochemical abnormalities are common, but nonspecific for pyometra. They include hyperproteinemia, hyperglobulinemia, and azotemia. Occasionally, alanine aminotransferase and alkaline phosphatase activities are mildly to moderately increased. Urinalysis findings include isosthenuria and/or proteinuria in one third of the bitches with pyometra. Bacteriuria is common.

There is often a prerenal component to the azotemia. Most bitches and queens with pyometra are middle-aged or older and may have preexisting renal disease. Additionally, azotemia, proteinuria, and isosthenuria are often a direct result of the pyometra and are potentially reversible once the

uterine infection is resolved. Immune complex glomerulonephritis is thought to be the cause of pyometra-induced azotemia and proteinuria. Even without overt azotemia, it has been shown that most (75%) bitches have decreased glomerular filtration rates as determined by ioxhexol clearance. The decreased glomerular filtration rate is demonstrable irrespective of age, indicating that pyometra, not solely preexisting renal disease, is a factor. The complete pathophysiology of the isosthenuria and polyuria has not been elucidated. It has been demonstrated that the ability to secrete vasopressin is not diminished in these animals but that the renal tubules of bitches with pyometra do not respond adequately to vasopressin. It is thought that bacterial endotoxin interferes with renal tubular response. Vaginal cytology reveals a septic exudate, sometimes containing endometrial cells (see Fig. 57-1). Results of bacterial culture and sensitivity testing of the uterine exudate identify the offending organism and the appropriate antibiotic therapy.

The most important alternate diagnosis for pyometra is pregnancy. Both conditions occur during the diestrous stage of the cycle. A modest mature neutrophilia, mild anemia, and hyperglobulinemia normally occur during pregnancy. Pregnant animals are not always healthy, and the presence of a septic vulvar discharge does not preclude the possibility of co-existent pregnancy. Uterine infection during pregnancy does not invariably result in the death of all fetuses. Even in the event of overt abortion, the entire litter is not always lost. The owner's goals of treating an ill pregnant animal may be quite different from the goals of treating one with pyometra.

#### **Treatment**

Treatment of pyometra must be prompt and aggressive if the animal's life is to be saved. Septicemia, endotoxemia, or both can develop at any time if they do not already exist. Uterine rupture also sometimes occurs. Intravenous fluid therapy is indicated to correct existing deficits, maintain adequate tissue perfusion, and improve renal function. Very aggressive fluid therapy will be needed for animals in septic shock. Even if they survive ovariohysterectomy, postoperative mortality is higher in bitches when blood pressure and urine output remain low than among those in which fluid therapy corrected hypotension and increased urine output. Whether or not they are septic, the prognosis for survival is worse when azotemia cannot be resolved before ovariohysterectomy. Appropriate antibiotic therapy should be instituted as soon as possible. Pending the culture results, an antibiotic that is typically effective against E. coli, the organism most commonly isolated from pyometra, could be considered. These include enrofloxacin, trimethoprim-sulfa, and amoxicillinclavulanate. Ovariohysterectomy is the treatment of choice for pyometra in bitches and queens. Despite appropriate supportive and surgical treatment, morbidity of 3% to 20% and mortality of 5% to 28% are reported. This is not unexpected, given the serious metabolic derangements caused by pyometra. Barring complications resulting from the disease itself, surgery, or anesthesia, ovariohysterectomy is curative.

# **Nonsurgical Treatment of Pyometra**

Whether surgical or nonsurgical treatment is chosen, the needs for fluid and antibiotic support must be addressed. The justifications for the medical, rather than surgical, treatment of pyometra are the owner's desire for offspring from the affected female and the health of the animal. Although medical management may effectively resolve the clinical illness and preserve the potential for future litters, unlike ovariohysterectomy, medical management of pyometra is not curative. Pyometra can be expected to recur. Recurrence is more common in bitches than in queens because bitches will have progesterone stimulation, the factor initiating pyometra, for at least 60 days after every cycle. Queens, on the other hand, are under the influence of progesterone only after copulation-induced ovulation or, less commonly, after spontaneous ovulation. Recurrence rates of 20% to 25% after the next estrus, 19% to 40% by 24 months, and 77% by 27 months after nonsurgical treatment of pyometra are reported for bitches. Recurrence rates of 7% to 15% are reported for queens. Some of the animals in these reports successfully became pregnant before pyometra recurred, whereas others did not. Because reproductive performance is limited by recurrence, the desired number of offspring should be obtained as soon as possible. Breeding to a fertile male during the first posttreatment estrus is recommended. Although there are reports of successful medical treatment of recurrent pyometra in bitches and queens, ovariohysterectomy, rather than repeated attempts at medical management, is usually recommended.

The other important consideration for medical, as opposed to surgical, treatment of pyometra is the animal's health. Medical treatments take days to weeks to rid the animal of the infected uterine contents, whereas ovariohysterectomy accomplishes this in a matter of hours. Surgery is the better choice for critically ill animals. Response to medical treatment is much better in animals with open-cervix pyometra than in those with a closed cervix. Unless the cervix dilates during treatment of closed-cervix pyometra, treatment will fail. There is a greater risk of uterine rupture. For these reasons ovariohysterectomy should be considered for animals with closed-cervix pyometra even if they are not critically ill.

A variety of luteolytic and uterotonic drugs are used to treat pyometra. Luteolysis is important to stop continued progesterone production. Myometrial contractions are necessary to expel the uterine contents. Dopamine agonists such as bromocriptine and cabergoline suppress luteal activity by suppressing prolactin, which is luteotropic in bitches. Prostaglandins, such as prostaglandin  $F_{2\alpha}$  and cloprostenol, cause luteolysis via apoptosis, and they also cause myometrial contractions. Competitive antagonists of the progesterone receptor, such as aglepristone, block the effects of progesterone, and this results in cervical dilation and uterine contractions. Women who might be pregnant should handle all these drugs with great care. These drugs have been used alone and in combination with each other according to a variety of protocols that have been designed to minimize side

# Nonsurgical Treatment of Pyometra

All treatments are "to effect," as described in the text:

- Resolution of clinical signs
- 2. Empty uterine lumen
- 3. Return toward normal uterine wall

Note: Several drug dosages are given in micrograms, µg

#### Prostaglandin $F_{2\alpha}$ as a Single Agent

Prostaglandin  $F_{2\alpha}$ , 0.1-0.25 mg/kg, SC, q24h or q12h (Lutalyse<sup>®</sup>, Pfizer, New York City)

#### Cabergoline and Cloprostenol

Cabergoline, 5 µg/kg, PO, q24h for 7 days (Dostinex®, Pfizer, New York City, can be compounded to the appropriate concentration) (Galastop®, Ceva Vetem, Milan, Italy)

Cloprostenol, 1 µg/kg, SC, q24h for 7 days; if no response, continue cloprostenol alone, without cabergoline, for 7 more days [Estrumate®, Schering-Plough, Union, NJ)

#### Aglepristone and Cloprostenol

Aglepristone, 10 mg/kg, SC, once daily on days 1, 2, and 8 (Alizine®, Virbac, Carros, France)

Cloprostenol, 1 µg/kg, SC, once daily on days 3-7 (Estrumate®, Schering-Plough, Union, NJ)

Reevaluate on day 14; if not resolved, administer one dose of aglepristone, 10 mg/kg, SC, on day 14

SC, Subcutaneous; PO, oral.

effects and take advantage of their different modes of action. Treatment is continued until the uterus is empty, which is typically 7 to 14 days. During treatment the vaginal discharge is expected to increase as the uterus empties, and the animal's clinical condition and laboratory abnormalities are expected to improve. If the clinical status worsens during medical treatment, ovariohysterectomy should be performed instead. Ovariohysterectomy can be considered at any time during medical treatment of pyometra if the condition is not improving as expected. Some of the treatment protocols are summarized in Box 57-2. These drugs are not labeled for use in dogs or cats in the United States at this time, although veterinary preparations are available in many other countries.

Adverse reactions are common in animals receiving  $PGF_{2\alpha}$  (Lutalyse®, Pfizer) therapy and include panting, salivation, emesis, defecation, urination, mydriasis, and nesting behavior. Intense grooming behavior and vocalization may also be seen in the queen. Adverse reactions usually develop within 5 minutes of  $PGF_{2\alpha}$  administration and last for 30 to 60 minutes. The severity of reactions is directly related to the dose administered and inversely related to the number of days of therapy. Adverse reactions tend to become milder with subsequent injections. Fewer side effects are reported for cloprostenol (Estrumate®, Schering-Plough), but gastro-

intestinal signs still occur in 30% to 54% of bitches given the drug. Gastrointestinal signs are the most common side effect of cabergoline (Galastop®, Ceva Vetem; Dostinex®, Pfizer). The only side effect reported for Aglepristone (Alizine®, Virbac) is transient pain or swelling at the injection site. Massaging the injection site to help disperse the drug can minimize this reaction. The posttreatment interestrous interval is shortened by 1 to 3 months by all of these drugs.

Pregnancy rates of 80% to 90% are reported for bitches that have received PGF<sub>2 $\alpha$ </sub> therapy for open-cervix pyometra, whereas pregnancy rates are only 25% to 34% in bitches with closed-cervix pyometra. Pregnancy rates of 70% to 90% are reported for queens after PGF<sub>2α</sub> treatment for open-cervix pyometra. The successful treatment with PGF<sub>2α</sub> of closedcervix pyometra in queens has apparently not yet been reported in the English-language literature. Other studies have focused more on survival of the animals than on subsequent fertility. In these studies success was defined as the resolution of clinical illness, absence of intraluminal uterine fluid, and return of uterine horn diameter to normal as assessed by ultrasound. Treatment with a combination of cloprostenol and cabergoline for 7 to 14 days was considered successful in 24 of 29 bitches (83%) with open-cervix pyometra when the bitches were evaluated at 14 days (Corrada et al., 2006). The other five bitches were spayed at 14 days. Only two of the successfully treated bitches were subsequently bred, and one conceived. Six of the bitches (25%) had a recurrence of pyometra after the first posttreatment estrus. Treatment with combinations of cloprostenol and aglepristone for 8 to 15 days was successful in 60% to 75% of bitches (n = 15) with open-cervix pyometra when the bitches were evaluated at 15 days, and all 15 bitches had returned to normal by 29 days (Gobello et al., 2003). Three of the 15 remaining bitches (20%) had a recurrence of pyometra after the first posttreatment estrous cycle. Only one bitch was mated, and she did conceive.

Fieni (2006)studied the efficacy of aglepristone given alone on days 1, 2, and 8 or in combination with cloprostenol on days 3 through 7 in 52 bitches with pyometra. Aglepristone caused the cervix to open within 4 to 48 hours (mean = 26 hours) in all 17 of the bitches with closed-cervix pyometra. The animals' clinical condition improved immediately thereafter. Treatment of pyometra with the combination of aglepristone and cloprostenol was more successful (84%) than was treatment with aglepristone alone (60%). Five bitches were mated during the first posttreatment estrus, and 4 (80%) became pregnant. Two bitches that did not respond to treatment died 5 and 15 days later. Of the successfully treated bitches, 13% had recurrence of pyometra by 12 months after treatment and 19% had recurrence by 24 months after treatment. Treatment was successful even when serum concentrations of progesterone were already below 1 ng/ml at the onset of treatment. This would support the concept that the pathogenesis of pyometra is related to the interactions of progesterone with progesterone receptor and not solely to high serum concentrations of progesterone. The absence of side effects and the rapidity with which aglepristone caused cervical dilation in bitches with close-cervix pyometra suggest that aglepristone may be beneficial in presurgical stabilization of bitches undergoing ovariohysterectomy for pyometra. This possibility deserves further study.

# **FALSE PREGNANCY**

# Etiology

False pregnancy is a clinical phenomenon in which a female that was not pregnant displays maternal behavior such as nesting, the adoption of inanimate objects or other animals, mammary gland development, and lactation. False pregnancy occurs commonly in intact, cycling bitches and is considered to be normal. It occurs after diestrus (i.e., luteal phase), when serum concentrations of progesterone decline. The terms *false pregnancy*, *pseudopregnancy*, and *psuedocyesis* are often used interchangeably, but none accurately reflects the situation in bitches in which the clinical signs occur during what would have been the postpartum period, not during what would have been the pregnant period (i.e., luteal

phase) of the cycle. Progesterone causes mammary gland development and weight gain, irrespective of pregnancy status. The drop in serum concentrations of progesterone at the end of diestrus causes an abrupt increase in prolactin secretion, which causes lactation and the behavioral changes of false pregnancy. Because the bitch ovulates spontaneously and always enters a long luteal phase, false pregnancy is a common phenomenon in cycling bitches. It is uncommon in queens. In bitches false pregnancy also occurs after the withdrawal of exogenous progestins and after oophorectomy performed during diestrus.

False pregnancy is considered a normal phenomenon in bitches. It is not associated with any reproductive abnormalities, including cycle irregularities, pyometra, or infertility. To the contrary, the occurrence of false pregnancy provides evidence that ovulation took place during the preceding cycle and that the hypothalamic-pituitary-gonadal axis is intact. Why some bitches are prone to developing clinical signs and why the severity of the clinical signs vary from cycle to cycle are not known. Although serum concentrations of prolactin do increase when progesterone is withdrawn, they are not always elevated to the same degree, nor are they always found to remain elevated by the time bitches are evaluated for false pregnancy. This may be due in part to the 6-hour pulsatile secretion pattern of prolactin, which makes interpretation of the results of a single blood sample less reliable. Nevertheless, at similar prolactin concentrations some bitches show clinical signs of false pregnancy and others do not. Some individual predisposition toward the development of false pregnancy evidently exists. In addition, factors relating to nutrition influence the occurrence of false pregnancy. Thin bitches are less likely to experience false pregnancy than bitches of the same breed in ideal body condition.

# **Clinical Features**

The most common clinical signs of false pregnancy are mammary gland enlargement and lactation. The mammary secretion varies from a small amount of clear or brownish fluid to large amounts of milk that may drip spontaneously from the glands. Nesting behavior is the next most common clinical sign of false pregnancy. Many bitches will "adopt" things. Some animals also experience restlessness, irritability, abdominal enlargement, anorexia, and vomiting. The diagnosis is based on the historical and physical findings in a nonpregnant bitch or, less commonly in a queen, at the end of diestrus. It may also occur after oophorectomy during diestrus or when exogenous progestins are discontinued. Before treatment of false pregnancy is undertaken, it is essential that the evaluation, such as diagnostic imaging, be sufficient to rule out pregnancy because all treatments for false pregnancy will be deleterious to pregnancy, should it exist.

#### **Treatment**

False pregnancy is a normal, self-limiting phenomenon in bitches that usually does not require treatment. The clinical signs usually resolve after 2 or 3 weeks. Stimulation to the mammary glands, such as licking, can promote lactation. Withholding food for 24 hours, followed by a gradual (i.e., 3 to 5 days) increase back to usual quantities, helps to reduce lactation. When treatment is needed, drugs that inhibit prolactin release, such as dopamine agonists and serotonin antagonists, are effective in ameliorating the behavioral and physical signs of false pregnancy in bitches. These drugs are not labeled for veterinary use in the United States at this time. The dopamine antagonist cabergoline (Galastop®; Ceva Vetem; Dostinex®, Pfizer), 5 µg/kg orally, once daily, causes improvement in 3 to 4 days, with the signs resolving by 7 days. Dostinex® can be compounded to the appropriate concentration. Cabergoline may cause vomiting and, rarely, increased aggression. The serotonin antagonist metergoline (Contralac®; Virbac Laboratories) also inhibits prolactin secretion. The suggested dose is 0.1 to 0.2 mg/kg twice daily for 8 days. It does not cause vomiting but can cause hyperexcitability, aggression, and whining. Mild tranquilization can be considered for bitches showing aggressive behavior, keeping in mind that phenothiazines can increase prolactin secretion.

Progestins, such as megestrol acetate (Ovaban®, Shering-Plough), and androgens also suppress prolactin secretion and can diminish the clinical manifestations of false pregnancy. As would be expected, however, clinical signs often recur after progestins are withdrawn. Therefore although labeled for this use, Ovaban® is not recommended. Ovariohysterectomy should not be performed during mid- to late diestrus because false pregnancy can occur as a result of removing the ovarian source of progesterone, particularly in those animals with a prior history. When false pregnancy does occur after ovariohysterectomy, it may be more persistent than in intact bitches. Furthermore, in bitches spayed during an episode of false pregnancy, the condition may be greatly prolonged. Spaying during false pregnancy is therefore not recommended. Cabergoline treatment has been beneficial in the majority of these cases of prolonged false pregnancy.

If any signs of false pregnancy become recurrent in a spayed animal, the likely possibility of an ovarian remnant

should be considered. If signs of false pregnancy persist for longer than the expected 2 to 3 weeks, bitches should be evaluated for hypothyroidism (see Chapter 51). Primary hypothyroidism is associated with increased hypothalamic thyrotopin-releasing hormone (TRH), which can stimulate prolactin release. In some hypothyroid bitches an increased secretion of prolactin, presumably in response to increased TRH secretion, may result in excessive lactation if false pregnancy occurs. Thyroid hormone replacement therapy causes the lactation to resolve in these hypothyroid bitches.

# NORMAL EVENTS IN PREGNANCY AND PARTURITION

In the bitch and queen fertilization occurs in the uterine tubes (oviduct), where the fertilized ova then develop into morulae before entering the uterus. Early canine blastocysts enter the uterus about 8 to 10 days after ovulation. From 12 to 17 days after ovulation, embryos migrate within the uterus, ultimately becoming equally spaced within both uterine horns. Implantation is completed within 18 to 21 days after ovulation. In the queen morulae enter the uterine horns 5 or 6 days after ovulation and migrate within the uterus from days 6 to 8. Implantation is complete 12 to 14 days after ovulation.

Functional corpora lutea (CLs) are essential throughout pregnancy in the bitch and queen. The serum progesterone concentration can be used to assess corpora luteal function. After ovulation it should be greater than 5 to 8 ng/ml (approximately 16 to 25 nmol/L) and should continue to increase for the next 15 to 25 days (see Fig. 56-1). The serum progesterone concentration remains at peak levels for 7 to 14 days and then gradually declines throughout the remainder of pregnancy. In pregnant bitches a rapid, prepartum drop in the concentration to less than 2 ng/ml (approximately 6.4 nmol/L) is consistently found within 48 hours of whelping. This abrupt decline in progesterone is the result of an acute rise in prostaglandin  $F_{2\alpha}$  concentrations, which does not occur during the nonpregnant cycle. The luteal secretion of progesterone depends on both pituitary luteinizing hormone (LH) and prolactin. During the second half of the canine pregnancy, prolactin is the main luteotropic factor. A similar trend in the corpora luteal secretion of progesterone is observed in queens. As in the bitch, prolactin is luteotropic. Serum concentrations of prolactin and relaxin increase during the second half of pregnancy in bitches and queens.

Body weight and caloric needs steadily increase throughout pregnancy, especially during the last trimester, in both bitches and queens. Body weight steadily increases through weeks 4 to 7, with as much as a 40% increase in caloric intake. Appetite often declines during the last 2 weeks of pregnancy, but body weight continues to increase because of fetal and mammary growth. Weight loss does not occur during normal pregnancy. Animals that are underweight may have difficulty maintaining body condition and milk production after parturition. Conversely, obesity is known to contribute to the development of dystocia and increased neonatal mortality. In bitches the packed cell volume (PCV) declines to 40% by day 35 and to less than 35% at term. Mild, mature neutrophilia is common in pregnant bitches. Red blood cell (RBC) numbers, the hemoglobin concentration, and PCV decline throughout pregnancy in queens as well, but the absolute numbers are often still within the normal range.

# **FECUNDITY**

Overall health, body condition, nutrition, and age greatly influence fecundity. Conception rates and litter size are greatest and neonatal mortality is lowest in Beagles between 2 and 3.5 years of age. After 5 years of age, conception rate and litter size decline and neonatal mortality begins to increase. Litter size also varies with parity, with the largest litters at third and fourth parity. In the bitch litter size varies according to breed, with smaller breeds tending to have smaller litters than larger breeds. Analysis of litters registered by the American Kennel Club showed that litter size for Labrador Retrievers and Golden Retrievers ranged from five to ten pups, with 70% of the litters containing seven or more pups. Conversely, litter size for Chihuahuas and Yorkshire terriers ranged from two to five pups, with 80% of the litters having four pups or less (Kelley, 2002). In the queen litters typically consist of two to five kittens, with an average of four, irrespective of breed. Litter size and neonatal survival are best in queens 1 to 5 years of age, provided that first parity occurs before 3 years of age. Litter size and neonatal survival usually improve after first parity. If first parity occurs after 3 years of age, however, litter size and neonatal survival usually remain poor. Reproductive performance of queens declines after 6 years of age. Superfecundation, in which litter mates have different sires, commonly occurs in queens and bitches. When it does, DNA tests for paternity can be performed by various laboratories (examples: VetGen.com; VGL.ucdavis.edu).

#### **PREGNANCY DIAGNOSIS**

Pregnancy can be confirmed by palpating the abdomen, performing diagnostic imaging, and detecting the hormone relaxin in blood. Abdominal palpation is easily and quickly performed, especially in cats. Although this is the most subjective method of pregnancy diagnosis, it is a reliable method for those skilled in palpation. Palpably distinct uterine swellings that represent uterine edema, embryonic membranes, and early placental development are about 1 cm in diameter at 20 days after breeding and about 2.5 cm by day 25. By 30 to 35 days the gestational sacs are becoming elongated and the uterus is more diffusely enlarged, making it more difficult to detect pregnancy by palpation at that time. Uterine enlargement caused by pregnancy cannot be accurately differentiated from uterine enlargement caused by some other process, such as pyometra, on the basis of abdominal palpation findings alone.

Ultrasonography is an excellent method of pregnancy detection in bitches and queens. It has the advantage of also assessing fetal viability because cardiac activity and fetal movements are evident. Pregnancy can be diagnosed when the gestational sac or fetal structures are identified (see Fig. 56-9, A; Fig. 58-1). The gestational sac appears as a spherical, anechoic structure surrounded by a hyperechoic wall composed of the uterine wall and placenta. Hyperechoic fetal structures are seen within the gestational sac. Although it is possible to identify the gestational sac as early as 10 days after breeding in the bitch and queen, pregnancy is more reliably detected 24 to 28 days after breeding in bitches and 20 to 24 days after breeding in queens. At that time fetal structures and cardiac activity are detected within the gestational sacs. Fetal heart rates range from about 200 to 250 beats per minute. Fetal movement characterized by dorsiflexion of the head and extension of the limbs is common in both species after day 33 to 39. By days 40 to 50 fetal anatomy is obvious (Fig. 58-2). Nonviable fetuses show no motion and lose identifiable morphology within 1 day of death. After death the

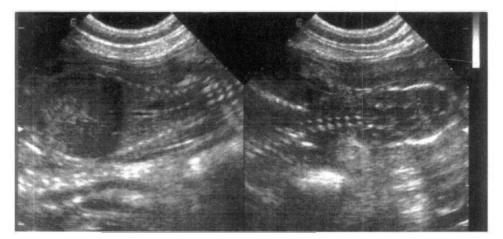

FIG 58-1
Sonograms of canine pregnancy, 40 days after first breeding (dorsal view). Fetal spine and ribs appear on left image. On right image cervical spine and outline of fetal skull are shown.

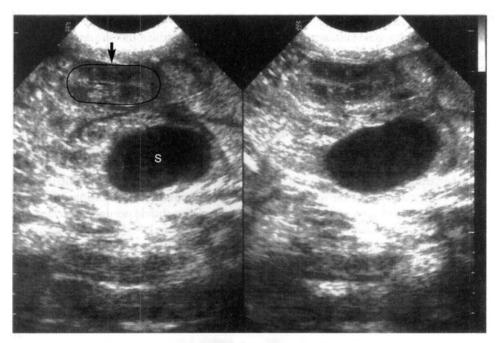

FIG 58-2 Sonogram of 59-day canine fetus. Fetal kidney (arrow) and stomach (S).

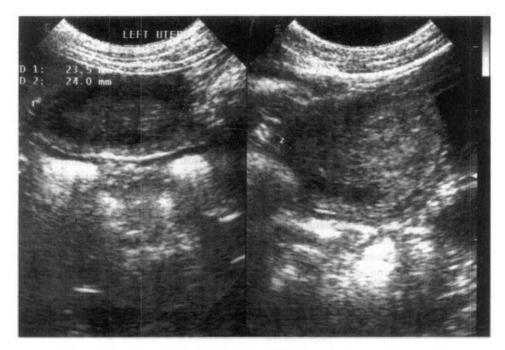

FIG 58-3 Sonogram of resorbing fetus, 30 days after first breeding.

fetal size decreases, and the fetus assumes the appearance of an ovoid mass of heterogeneous echogenicity (Fig. 58-3).

Because the hormone relaxin is produced primarily by the placenta, it is pregnancy specific in bitches and queens. In pregnant females, relaxin reaches detectable levels in serum or plasma as early as 20 days after the LH surge and peaks 30 to 35 days after the LH surge. It remains high throughout pregnancy, until parturition or abortion, when

it declines precipitously. Although relaxin can be detected 21 days after breeding, it is a more sensitive indicator of pregnancy when performed 30 or more days after breeding. Finding high concentrations of relaxin in serum or plasma confirms pregnancy. Declining or undetectable concentrations are found in cases of spontaneous or induced abortion and after parturition. Relaxin is undetectable in pseudopregnant and nonpregnant bitches and queens.

Abdominal radiography can be used to confirm pregnancy after the fetal skeleton has calcified sufficiently to be detected on radiographs. This usually happens approximately 40 to 45 days after breeding in the bitch and 35 to 40 days after breeding in the queen. Before that time the enlarging uterus appears as a tubular fluid density. Because abdominal radiographs are taken later, they are usually not used for pregnancy diagnosis per se. They are used to estimate fetal numbers, identify problems that might lead to dystocia, and confirm the remaining presence of fetuses in the bitch or queen examined because of dystocia.

#### **GESTATION LENGTH**

Gestation length, defined as the interval from a fertile mating to parturition, averages 66 days (range 64 to 71 days) in queens. Because the bitch ovulates spontaneously at any time during estrus, determining gestation length on the basis of breeding date is more variable (see Chapter 56). The average gestation length is  $63 \pm 7$  days if calculated from the date of first breeding to parturition. It is  $65 \pm 1$  days if calculated from the LH peak and  $57 \pm 3$  days if calculated from the first day of cytologically confirmed diestrus. Gestation length appears to vary somewhat according to breed of dog and the size of the litter as well. In a group of 308 large dogs (Hounds, Retrievers, German Shepard Dogs), litters of four or fewer pups averaged 1 day longer gestation than litters with five or more pups (Eilts et al., 2005). Conversely, in 36 Beagles litter size, which ranged from two to eleven pups, had no significant effect on gestation length (Tsutsui et al., 2006b).

# **PARTURITION**

Physiologically, parturition may be thought of as a release from inhibitory effects on the uterus and the recruitment of factors promoting uterine activity. Factors that maintain uterine quiescence during pregnancy include progesterone and relaxin. Factors that stimulate uterine activity include prostaglandin and oxytocin. In the bitch maternal cortisol (and probably also fetal cortisol) concentration and maternal prostaglandin PGF<sub>2α</sub> concentration increase before parturition. PGF<sub>2α</sub> causes luteolysis and a subsequent decrease in the serum progesterone concentration to less than 1 ng/ml (approximately 3 nmol/L) 24 hours before parturition. Although a similar prepartum decline in the serum progesterone concentration is seen in queens, basal concentrations are apparently not necessary for parturition to be initiated. Prostaglandin also stimulates uterine contractions, as does oxytocin. Among other mechanisms, oxytocin is released in response to pressure against the cervix. The decrease in progesterone and increase in prostaglandin cause the placenta to separate. Relaxin, which is produced by the placenta, abruptly declines at parturition. In both bitches and queens a prepartum increase in the prolactin concentration is seen, which is probably also a result of the decreased serum progesterone concentration. Postpartum, prolactin secretion is stimulated by suckling. In queens the serum estradiol concentration increases before parturition, but in the bitch  $PGF_{2\alpha}$  increases without an increase in estradiol.

#### PREDICTING LABOR

Accurate prediction of the due date is helpful in planning for normal deliveries, scheduling cesarean sections, and evaluating females with suspected prolonged gestation. Because queens are induced to ovulate by coitus, breeding date can be used to predict parturition within ±1 day of the average 66-day gestation. Using breeding dates alone, the clinician can predict parturition within ±7 days of the average 63-day gestation in bitches. A range of 14 days is too imprecise to be helpful in managing problem pregnancies. In bitches identifying the first day of diestrus on the basis of vaginal cytologic findings (see Chapter 56) can be used to predict when labor should occur because most bitches whelp  $57 \pm 3$ days after day 1 of diestrus. Parturition occurs  $65 \pm 1$  days after the LH surge in the bitch. The LH surge can be measured directly, or estimated by the concomitant initial rise above basal serum progesterone concentrations that occurs during estrus (Chapter 56). Because the serum concentrations of progesterone decrease from more than 3 ng/ml (approximately 9 nmol/L) to less than 1 ng/ml (approximately 3 nmol/L) during the 24 hours before labor in bitches, determining the prepartum progesterone concentration is very useful to determine that a bitch has reached full term.

Alternatively, because the decrease in the scrum progesterone concentration just before whelping causes a transient drop in the rectal temperature in most bitches, measuring the rectal temperature is a useful way to predict impending labor. The usual recommendation is for owners to monitor rectal temperature two to three times daily during the last 2 weeks of gestation to establish a baseline. Temperature decreases below baseline by 2° to 3° F (1.1° to 1.7° C) 6 to 18 hours before parturition. In small breeds it may drop as low as 95° F (35° C), in medium-size breeds as low as 96.8° F (36° C), and in large breeds to 98.6° F (37° C). When the drop in temperature is identified, it is usually a reliable indication that parturition will soon occur. In some bitches the temperature fluctuates. In a study of 100 canine pregnancies in which rectal temperature was taken approximately every 12 hours, the prepartum drop in rectal temperature was not detected in 19 animals before the delivery of the first pup. A prepartum drop in the rectal temperature of queens is an inconsistent finding. Many, but not all, queens refuse to eat during the last 24 to 48 hours of gestation. Loss of appetite usually is a good indicator of impending parturition.

If obvious signs of labor are not present within 24 hours of the rectal temperature drop in near-term bitches or of the loss of appetite in near-term queens, the gravid female should be examined. Unfortunately, diagnostic imaging does not add precision when estimating impending parturition. However, it is very useful for assessing fetal development and viability. Using the extent of fetal skeletal mineralization on radiographs, including the recognition of teeth and phalanges, to predict parturition was only accurate to within 3 days in 75% of cats. Using the diameter of the inner chorionic cavity and the biparietal (skull) diameter on ultrasound to predict parturition was only accurate to within 2 days in 86% of bitches.

# STAGES OF LABOR

Three stages of labor exist in bitches and queens. Stage I is characterized by nesting behavior, restlessness, shivering, and anorexia. Bitches usually pant. The cervix dilates during stage I. No external signs of uterine or abdominal contractions exist. However, uterine contractions can be documented using ultrasound or external pressure transducers (tocodynamometers) that are strapped around the belly. During pregnancy, uterine contractions are slow and tonic in nature. During stage I of parturition, uterine contractions increase in frequency, duration, and strength. These changes are coincident with the decline in progesterone concentrations, the decline in rectal temperature, and the change in behavior of the bitch. As determined by changes in rectal temperature and change in the dam's behavior, stage I normally lasts for 6 to 12 hours. As determined by the change in uterine contractions until the delivery of the first pup, the duration of stage I was reported to be 13 to 24 hours in one study (n = 5 bitches) and to average 12 hours in another (n = 100 bitches) (Copley, 2002).

Stage II is characterized by obvious abdominal contractions, passage of amnionic fluid, and delivery of the puppy or kitten. Rectal temperature is normal or slightly above normal. Stage II is usually accomplished in 3 to 6 hours. It may last as long as 12 hours in some normal bitches. In some normal queens it may rarely last 24 hours. There may be intermittent, active abdominal straining for several hours before the birth of the first neonate. Constant, unrelenting straining is not normal. Usually less than 1 hour passes between the delivery of subsequent puppies or kittens. The dam may rest for as long as 1 hour or so between births, with no active straining during that time. Occasionally, 12 to 24 hours pass between the births of apparently healthy kittens, but this is not normal for puppies and may be associated with neonatal mortality in both species.

The placenta is normally passed within 5 to 15 minutes of the birth of each neonate. This is stage III. The dam removes the amniotic membranes and cleans the neonate, severing the umbilical cord and eating the placenta. If the dam fails to remove the fetal membranes from the neonate's face, the owner should do so. Cleaning the neonate is important maternal behavior necessary for bonding between the dam and her offspring; thus the dam should be encouraged to do it. All placentas should be passed within 4 to 6 hours. If the owner is attending, the umbilical cord should be clamped and cut about 1 cm from the body wall. If bleeding occurs, the cord can be ligated.

#### DYSTOCIA

Dystocia, or difficult birth, has an estimated overall prevalence of approximately 5% to 6% of pregnancies in bitches and queens. In certain breeds, however, the prevalence is much higher, approaching 18% in Devon Rex cats in the United Kingdom and 100% in English Bulldogs in the United States. With the exception of those breeds at high risk, dys-

tocia might be considered a relatively uncommon cause of morbidity or mortality in bitches and queens, accounting for fewer than 1% of emergency admissions. However, it is the most common periparturient problem requiring emergency care and a major cause of neonatal mortality in puppies and kittens. Overall mortality rates from birth to weaning average 12% (range 10% to 30%) in puppies and 13 % in kittens, but 65% of those losses occur at parturition and during the first week of life as a result of stillbirth, fetal stress, and hypoxia related to parturition.

There appears to be an increased risk of dystocia in aged bitches, but no relationship between age and dystocia has been found in queens. In both dogs and cats purebred animals are more likely to have dystocia than are mixed breeds. Dolicocephalic (e.g., Siamese type) and brachycephalic (e.g., Persian type) are at greater risk for dystocia than mesocephalic (e.g., domestic shorthair type) cats. In dogs chondrodysplastic breeds and those selected for large heads are at greater risk. When normal parturition is used as a criterion in selection of breeding bitches or queens, the occurrence of dystocia within the colony can be decreased, demonstrating that breed alone is not the determinant. The majority (71%) of privately owned queens presented for dystocia have experienced dystocia during more than one pregnancy, whereas in a large commercial colony of domestic shorthair cats, the incidence of dystocia was only 0.4%. This could reflect different husbandry practices or genetics of brood stock selected on the basis of reproductive performance.

The two most common causes of dystocia in small animals are (1) uterine inertia and (2) fetal malpresentation. Of these, uterine inertia is by far the most common, accounting for about 60% of all cases. Uterine inertia is the failure to develop and maintain uterine contractions sufficient for normal progression of labor. Uterine inertia has a variety of potential causes (e.g., genetic factors, age, nutrition, metabolic factors), but the specific cause for a particular case usually is not identified. The exception is mechanical obstruction that results in myometrial exhaustion and secondary uterine inertia. Fetal malpresentation accounts for approximately 15% of dystocia cases in bitches and queens.

Maternal causes of obstructive dystocia relate primarily to abnormalities in size or shape of the pelvic canal. These abnormalities may be congenital or acquired, involving the bony or soft tissue structures. Within breeds, certain individuals are at greater risk than others. For example, in both the Boston Terrier and Scottish Terrier, breeds with distinctly different head conformation, bitches with a dorsoventral flattening (i.e., vertical diameter ≤ horizontal diameter) of the pelvic canal are more likely to have obstructive dystocia than bitches with normal pelvic conformation (i.e., vertical diameter > horizontal diameter). Cephalopelvic disproportion, in which the fetal head is too large for the small maternal pelvic canal, also can occur. Uterine torsion is also a cause of obstruction (Fig. 57-9). Malpresentation is the most common fetal cause of obstruction. Fetal oversize or congenital deformities causing large abnormal shape (Fig. 58-4) may also cause obstruction.

**FIG 58-4 A,** Cause of dystocia: newborn Cardigan Welsh Corgi puppy with anasarca (ventral view). **B,** Dorsal view of same puppy with normal litter mate.

Small litter size predisposes to dystocia in bitches for a variety of reasons. The fetal signals that initiate parturition may be insufficient in very small litters, which may lead to prolonged gestation. A negative correlation between litter size and puppy size exists: the smaller the litter, the larger the individual pup. This may increase the likelihood of obstruction. Conversely, a very large litter may overstretch the uterus and lead to inertia. Litter size has no apparent bearing on the occurrence of dystocia in queens. Fetal death accounts for 1% to 4.5% of dystocia in bitches and queens, respectively. Extreme anxiety reportedly inhibits normal progression of labor. How often this contributes to dystocia in dogs and cats is not known.

## History

Early recognition and correction of dystocia is crucial to the successful management and optimal neonatal health. The first things that should be determined are the presence of placental membranes or fetal parts at the vulva, and the presence and character of any vulvar discharge. A partially delivered puppy or kitten needs immediate attention. The history should continue with an investigation of the length of gestation, known predisposition to or previous occurrence of dystocia, the progression through the stages of labor, and any indication of illness in the dam. This would include information on rectal temperature monitoring, behavior of the dam, presence and characterization of contractions, number of puppies or kittens already born, and the duration of each of these events. Breeders should be asked if they have already administered any drugs or performed any obstetric procedures. Any sign of illness in the pregnant female is reason to recommend that she be examined. On the other hand, a common error made by owners and veterinarians is to delay intervention because the dam does not appear to be in trouble. The decision to delay is usually made without regard to the well-being of the fetuses, which are often severely stressed long before the dam shows clinical signs relating to the demise of her fetuses. The dam should be examined if the expected due date has arrived and no signs of labor exist, irrespective of a lack of maternal discomfort or illness. This is to ensure that all is well with the fetuses and to determine if continued watchful waiting is a reasonable approach.

If stage I has not progressed to stage II within 12 hours, the dam should be examined, even if other signs of labor or maternal illness are lacking. Exercise often stimulates abdominal contractions. For that reason, some veterinarians have recommended that the owners walk the bitch up and down the stairs or around the house before loading her in the car for the drive to the veterinary hospital. The onset of stage II of labor is recognized by the return of rectal temperature to normal, the presence of strong abdominal contractions, and the passage of amnionic fluid. The passage of amnionic fluid is an indication of stage II labor, irrespective of contractions. The first pup should be born within 2 to 3 hours of amnionic fluid. Other findings of concern are the presence of a vulvar discharge, fetal membranes, or a partially delivered fetus (Box 58-1). Partially delivered puppies or kittens need prompt attention if they are to survive. A dark-green discharge in bitches or red-brown discharge in queens originates from the placenta. Its presence indicates that at least one placenta has begun to separate. If a pup or kitten has not been delivered within 2 to 4 hours, the dam should be examined. A bright yellow vulvar discharge is meconium. Passage of meconium is indicative of severe fetal stress. It is often associated with fetal aspiration of amnionic fluid and a grave prognosis for neonatal survival. A purulent discharge may be found if uterine infection or fetal maceration exists. Viable fetuses may also still be present.

It has been shown in dogs that neonatal mortality is directly correlated to duration of labor (Linde-Forsberg, 2005). For example, one study found that if delivery was complete within 1 to 4.5 hours of the onset of stage II labor, puppy mortality was 5.8%, whereas neonatal mortality was 13.7% after 5 to 24 hours of stage II labor. The outcome for the bitch and the puppies is favorable when the dam is healthy, the fetal heart rates are normal (>200 bpm), stage I

Indicators of Dystocia

Any sign of illness in full-term female
History of previous dystocia
Known predisposition to dystocia
More than 24 hours since rectal temperature drop in full-term bitch

More than 24 hours of anorexia in full-term queen Abnormal vulvar discharae

Failure to progress from stage I to stage II after 12 hours Partially delivered fetus for more than 10 or 15 minutes More than 3 hours of stage II labor before birth of first neonate

More than 1 hour of active labor between births Constant, unrelenting, unproductive straining of 20 to 30 minutes

Labor appears to have stopped before entire litter delivered

is less than 6 hours in duration, and the duration of stage II is less than 12 hours. When stage II lasts longer than 12 hours but less than 24 hours, the prognosis for puppy survival is poor, although the prognosis for the bitch is still fine. If stage II lasts longer than 24 hours, the puppies are likely to die and morbidity for the bitch is increased. Fetal heart rates less than 150 to 160 bpm or illness in the bitch is also associated with worsening prognosis. In a different study puppy mortality from birth to 7 days of age decreased from 33% to 6% as a result of fetal monitoring and early intervention during parturition (Davidson, 2001). Among the multiparous bitches in that study, neonatal mortality decreased from 42% to 12%.

Weak, intermittent straining lasting more than 2 to 4 hours before the first puppy or kitten is born or lasting longer than 1 hour between births is cause for concern. Strong, persistent straining lasting longer than 20 to 30 minutes without delivery of a pup or kitten is not normal. If more than 12 hours of stage II have elapsed or, conversely, if labor appears to have stopped before the entire litter is delivered, the dam should be examined. Cats have been observed to deliver live kittens over 24 to 40 hours, with no obvious straining or discomfort between kitten births. Even though live kittens are often born, such prolonged delivery is associated with increased neonatal morbidity and mortality and therefore should probably not be considered normal. The average duration of labor was reported to be 16 hours in one colony, but kitten mortality was 29%.

# **Diagnosis**

The historical and physical findings are diagnostic of dystocia. The first step is to examine the perineum for evidence of a partially delivered fetus, which requires immediate attention. There may be a bulge in the perineum dorsal to the vulva, or there may be fetal limbs or tail protruding from the vulva. When it is determined that no partially delivered

fetus is present, the complete physical examination of the dam proceeds as usual. Systemic illness in the dam should be pursued as usual for any ill animal. For example, hyperthermia may be caused by the exertion of labor, but infection, especially of the mammae or uterus, should be considered. A complete blood count (CBC) and biochemical panel would be reasonable. Regardless of cause, dehydration must be corrected.

The abdomen is palpated to evaluate uterine size, tone, and the presence of fetuses. Fetal movement and uterine contractions may be felt, but their adequacy cannot be assessed by palpation alone. The inability to detect movement or contractions via abdominal palpation is not necessarily cause for concern. The perincum is examined for the presence and character of any discharge. In bitches of adequate size a digital vaginal exam should be performed to assess for the presence of a fetus in the birth canal. If one is found, it should be delivered immediately. If none is found, the dorsal wall of the vagina should be stroked because doing so often stimulates abdominal contractions. This procedure has been referred to as feathering. The cervix is not palpable per vaginum. Puppies or kittens stuck in the vagina may be delivered by obstetric manipulation or with the aid of episiotomy. The mammary glands are palpated to assess the presence and character of secretions. Some primiparous bitches may not have obvious milk. Lactation begins within 24 hours of parturition. Multiparous bitches and queens may lactate during the last week of gestation.

After assessing maternal health by physical examination, the clinician assesses the fetuses using radiology and ultrasonography. The number, size, shape, location, posture, and presentation of any remaining fetuses are often best determined by radiographs. A cause for obstruction, such as large fetus, an abnormal pelvic canal, or fetal malposition may be identified. Fetal viability is difficult to assess on radiographs because postmortem changes are not detectable for hours or days after death (Box 58-2). Intrafetal gas may be detectable as early as 6 hours after death. The bones of the fetal skeleton and head may collapse as early as 48 hours after death. However, the absence of those radiographic signs is not diagnostic of life or death. The number of fetuses remaining cannot be accurately determined with ultrasonography; however, ultrasonography is ideal for assessment of fetal viability on the basis of heart rate and fetal movement.

As determined by ultrasound, normal canine fetal heart rates during labor are 170 to 230 bpm. Fetal kittens' heart rates are 190 to 250 bpm. Fetal movement is observed from about day 40 of gestation onward. Normal fetuses are quite active near term. Subjectively, this activity seems to increase during ultrasonographic examination. Fetal movement and heart rates are decreased as a result of stress and hypoxemia. In fetal pups heart rates below normal are associated with poor neonatal survival unless pups are delivered promptly. It has been shown that heart rates < 150 to 160 bpm indicate fetal stress. When heart rates are less than 130 bpm, there is poor survival unless pups are delivered within 1 to 2 hours. There is high neonatal mortality among pups with fetal

BOX 58-2

#### Radiographic Signs of Fetal Death

Absence of continued uterine enlargement before fetal skeletons are detected

Absence of continued fetal growth after initial detection of fetal skeletons

Demineralization or inadequate mineralization of fetal skeleton for gestational age

Overlap of skull bones, collapse of axial skeleton, or misalignment of fetal bones

Intrauterine or intrafetal gas

heart rates less than 100 bpm unless they are immediately delivered. We have also observed that lack of fetal movement, irrespective of heart rate, is also a poor prognostic indicator. Presumably, the situation is similar in cats, taking the normally faster feline heart rate into account. The precise gestational age cannot be determined on the basis of ultrasonographic findings, but fetal maturity and impending fetal death can be assessed by the development, or lack thereof, of fetal organs (see Fig. 58-2). Previously recognizable fetal anatomy begins to be lost within 24 hours of fetal death. The overall size of the fetal mass decreases and condenses into a heterogeneous echotexture (see Fig. 58-3).

# **Treatment**

A partially delivered fetus should be delivered within 10 minutes. Care must be taken to avoid disarticulating the extremities. Liberal amounts of lubrication should be used. Rotating the fetus 45 degrees to take advantage of the widest diagonal part of the pelvic canal may be helpful. Gently alternating traction from left to right (i.e., rocking) may help relieve shoulder or hip lock. Traction should be applied in a ventral direction that follows the natural conformation of the vestibule. It may be helpful to lift the vulvar lips upward while pressing the pup downward. A vaginal exam should be performed in all dams of adequate size to determine whether a fetus is lodged in the vagina and to stimulate the vagina (i.e., feathering) in hopes of initiating abdominal contractions. If the dam is extremely nervous, mild sedation should be considered.

When the clinician has determined that an "overdue" bitch is healthy and the fetuses are healthy (as determined by the presence of fetal movement and normal heart rates), serum concentrations of progesterone may be determined. This would be especially helpful when information by which the actual length of gestation might be calculated is lacking. The finding of progesterone that is greater than 3 ng/ml (9 nmol/L) in a bitch would indicate that the pregnancy has not yet reached full term. Intervention should be delayed, and watchful waiting should continue for several hours. If 24 hours pass with no progression of labor, all parameters should be reassessed. Aglepristone, 15 mg/kg, given subcutaneously twice on 1 day, safely and effectively induced parturition in Beagle bitches (Baan et al., 2005). Progesterone

concentrations were still elevated when treatment began. Parturition occurred 32 to 56 hours (mean 41 hours) after the first injection. Puppy survival rates were no different from those of control bitches that whelped naturally. The only side effect was irritation at the injection site.

Animals in stage I of labor are expected to progress to stage II in less than 12 to 24 hours. When that does not happen, watchful waiting no longer applies, nor does it apply to dams already in stage II of labor. Sometimes, all other parameters are found to be normal except one of the fetuses is not moving or has a heart rate of 150 to 160 bpm or less. The dam and the other fetuses are healthy. In that situation the benefits of immediate intervention in an attempt to save all the fetuses should be weighed against the cost and risks. For example, the decisions made in a situation in which all but one of 10 puppies are apparently normal might be different from the decisions made under identical circumstances but a litter size of only two. The owner's attitude about the relative value of each puppy or kitten in the litter and about stillbirth or neonatal death must be considered. It is common for bitches and queens to carry healthy fetuses to term despite the death of some litter mates.

The type of treatment is dictated by the presence or absence of obstruction and by the health of the dam and fetuses. If obstruction or serious fetal compromise exists, cesarean section is indicated without delay. If no obstruction exists, medical management may be attempted in healthy dams with no signs of fetal stress. Several studies have found that 65% to 80% of bitches and queens presented for dystocia were eventually treated with cesarean section. Medical management was successful in resolving the dystocia in only 20% to 30% of canine and feline cases. The maternal mortality rate is reported to be about 1% among bitches undergoing cesarean section. In addition to maternal survival, the goal of managing dystocia is to achieve puppy and kitten survival beyond the most critical first week of life.

When the dam and the fetuses are healthy and no obstruction exists, medical management of dystocia can be considered. The goal of medical management is to reestablish a normal labor pattern of uterine contractions. This is done with oxytocin and calcium. Typically, oxytocin increases the frequency of uterine contractions and calcium increases the strength. High doses and/or frequent administration of oxytocin are contraindicated because they cause sustained uterine contractions that delay the expulsion of fetuses and compromise placental blood flow. This causes placental separation, fetal hypoxia, and fetal acidosis. These actions contribute to fetal and neonatal mortality. The goal of oxytocin therapy is to increase the frequency of uterine contractions to a normal labor pattern. This is best accomplished while the uterine contractions are being monitored. Unfortunately, this is often not done in veterinary medicine. Studies in which uterine monitoring was done have demonstrated that the large doses of oxytocin that have traditionally been recommended are not necessary. Current recommendations are to administer small doses, 0.25 to 4.0 U per dog, intramuscularly. In our colony of mixed-breed dogs weighing 35 to 45 lb, we administer 0.25 U. We do not monitor uterine pressure. Labor should progress (i.e., straining begins) within 30 minutes, and a pup should soon be delivered. If so, the clinician may repeat administration of oxytocin as needed to perpetuate normal parturition. Repeated doses should not be administered if a normal labor pattern is not established. In studies that monitored uterine contractions of whelping bitches, the mean total cumulative doses of oxytocin needed were 4 to 7.7 U per bitch. When the animal does not respond to oxytocin administration within 30 to 45 minutes, it is unlikely that further treatment with single agent oxytocin will be beneficial.

Myometrial contraction depends on the influx of calcium ions. Generally speaking, calcium administration increases the strength of uterine contractions even in the absence of documented hypocalcemia. For this reason some clinicians have recommended the routine administration of calcium gluconate in the management of nonobstructive dystocia. It has been recommended by some that 10% calcium gluconate be administered before the administration of oxytocin. If normal labor does not resume, oxytocin is added. Calcium gluconate 10%, 0.2 ml/kg or less, or 1 to 5 ml/dog, is administered subcutaneously or intravenously depending on the preparation and the label directions. Some preparations are too irritating to be administered by routes other than intravenous (IV). If the IV route is chosen, calcium is administered slowly (1 ml/min) while monitoring the heart. Administration should be immediately discontinued if bradycardia or dysrhythmia occurs. If labor progresses (i.e., straining begins), calcium may be repeated as needed or continued with oxytocin. In a study using uterine monitoring as a guide, the mean total cumulative dose of 10% Ca gluconate administered to bitches was 3 ml. Conversely, before uterine monitoring was available, doses of 1.5 to 20 ml were reported. Higher doses or bolus IV administration of Ca gluconate should be reserved for animals with documented clinical signs or laboratory evidence of hypocalcemia. When medical management fails to initiate a normal labor pattern, cesarean section should be performed without delay.

Cesarean section is indicated, without delay, in the following circumstances: obstruction, such as fetal oversize, fetal malposition, or uterine torsion; existence of fetal compromise; failure of medical management with calcium and oxytocin administration; the possibility that continued pregnancy or labor might be harmful to the bitch or queen; or preexisting maternal illness. At the time of this writing, at least one company provides fetal and uterine monitoring services for veterinarians: Veterinary Perinatal Specialties (www.whelpwise.com).

# PREGNANCY LOSS

# Etiology

Infectious disease is an important cause of pregnancy loss in dogs and cats. Infectious diseases can cause early embryonic

death, resorption, or abortion through their effects on the dam, the fetus, or the placenta. Other than interrupting pregnancy, many of these pathogens cause minimal clinical signs of maternal illness. Bacteria reported to cause fetal death and abortion in bitches include *Brucella canis, Escherichia coli*, β-hemolytic *Streptococcus, Leptospira, Campylobacter, Salmonella, Mycoplasma* spp., and *Brucella abortus*. Bacterial causes of pregnancy loss are uncommonly reported in cats. Experimental infection with *Toxoplasma gondii* has also been found to cause abortion in bitches and queens.

# **Clinical Features**

Embryonic and fetal death can result from maternal disorders, fetal disorders, or placental disorders. Queens and bitches often lose one or more fetuses and yet carry the rest of the litter to term and deliver normal healthy puppies or kittens. Anything that adversely affects the health of the dam and medications used for treatment have the potential to adversely affect the pregnancy. Other than a disorder that causes overt clinical illness in the dam, the signs associated with fetal death depend primarily on the stage of gestation at which the loss occurs.

When early embryonic death occurs, there are no clinical signs of the bitch having been pregnant. Therefore the bitch is likely to be presented for (apparent) failure to conceive rather than for pregnancy loss. In pregnant queens, early embryonic death will be reflected by a prolonged interestrual interval of 30 to 50 days rather than the usual nonovulatory cycles every 14 to 21 days. Pregnancy loss has no effect on the canine interestrual interval because the canine CLs persist for more than 60 days regardless of whether the bitch is pregnant. Progesterone, produced by the CLs, causes mammary development and weight gain regardless of whether pregnancy exists. Therefore bitches may continue to appear pregnant for 60 or more days. If early pregnancy is lost in queens, the CLs regress in 30 to 50 days; thus any appearance of pregnancy diminishes after that time. Other than the loss of mammary development in queens, usually there are no physical signs, such as vulvar discharge, when embryonic death occurs during the first 30 days of gestation in bitches and queens. Resorption occurs. When fetal death occurs after about day 30 of pregnancy, uterine contents are passed (abortion). The first clinical sign of abortion is usually a blood-tinged vulvar discharge. The character of the discharge is variable, according to the underlying cause of the abortion. The quantity is variable from scant to substantial. The later in gestation fetal death occurs, the more obvious it becomes that fetal parts are being expelled.

#### MYCOPLASMA

Mycoplasma and Ureaplasma are members of the normal florae in the canine vagina, prepuce, and distal urethra. Mycoplasma has been isolated from 59% of vaginal cultures, 80% of preputial samples, and 27% of semen samples from normal dogs in kennels with excellent pregnancy rates of 88% to 90%. Mycoplasma infection has been reported to cause conjunctivitis, polyarthritis, abscesses, and urinary

tract infection in cats. In dogs pneumonia, urinary tract infection, colitis, and reproductive disorders have been associated with *Mycoplasma* and *Ureaplasma* infection. Although experimental inoculation of the reproductive tract with *Mycoplasma canis* causes endometritis in bitches and orchitis and epididymitis in dogs, the significance of *Mycoplasma* in spontaneously occurring canine reproductive disease is unclear because there is no difference between the prevalence of *Mycoplasma* isolated from normal animals and the prevalence of *Mycoplasma* isolated from animals with reproductive disorders.

Because Mycoplasma and Ureaplasma are members of the normal canine genital florae and because they are isolated with equal frequency from normal dogs and dogs with reproductive disorders, Mycoplasma or Ureaplasma infection should not be diagnosed on the basis of culture results alone. The clinical signs and cytologic findings should also be consistent with an infectious process. Mycoplasma and Ureaplasma are fragile organisms. A special medium such as Amies should be used for culture studies, and samples should be placed on ice and arrive at the laboratory within 24 hours. Susceptibility testing is rarely available. Usually, the organisms are susceptible to tetracycline, chloramphenicol, and fluoroquinolones. Unfortunately, many of these antibiotics are contraindicated during pregnancy and lactation. Isolation and even culling of infected animals have been recommended for the control of Mycoplasma infection in a kennel, but such extreme measures are not usually necessary.

# **BRUCELLA CANIS**

Brucella canis is a small, gram-negative coccobacillus. Dogs are the definitive host for *B. canis* infection. They are much less susceptible to *Brucella abortus* and *Brucella suis*. Cats are resistant to *B. canis* but can be infected under experimental conditions. Compared to *B. abortus* and *Brucella mellitensus* infection, people are relatively resistant to *B. canis*. The source of infection is usually the person's own pet. Laboratory personnel have also acquired the disease from infected specimens. Biohazard precautions should be taken when handling specimens from suspect animals. The prevalence of human *B. canis* infection in the United States is not known because although human brucellosis is a notifiable disease, the Centers for Disease Control (CDC) does not require speciation. In one study *B. canis* infection accounted for 4 of the 331 people with brucellosis in a 10-year period.

B. canis readily crosses all mucous membranes. Although venereal transmission occurs, the most common routes of infection are oronasal and conjunctival. Neutered and "virgin" animals can become infected as well as sexually intact animals. The greatest numbers of organisms are shed in aborted material and postabortion vaginal discharge, which readily contaminate the environment. Large numbers are shed in semen, particularly during the first 6 to 8 weeks of infection, but shedding persists for 60 weeks to 2 years. Organisms are also shed in urine, especially from males. Urinary shedding persists for at least 3 months. Urine is

especially important in transmission when animals are housed in groups. *B. canis* is shed in milk, and transplacental transmission occurs. It can also be transmitted on contaminated fomites.

Tissue macrophages and other phagocytic cells carry the organism to lymphoid tissue, bone marrow, and the reproductive tract, where they multiply. Organisms persist in mononuclear phagocytes, bone marrow, lymph node, spleen, and prostate. Persistence of the organism in the prostate is thought to explain the greater number of organisms recovered from the urine of infected males than from females. Bacteremia is present 1 to 4 weeks after infection and persists for 6 months to 5.5 years. Nonprotective antibodies develop within weeks of infection but may not be detectable until 8 to 12 weeks after inoculation. Titers persist for as long as the bacteremia is present. Titers decline after the bacteremia subsides, even though the organism is still present in tissues.

#### **Clinical Features**

B. canis infection primarily affects reproduction. Transient lymphadnopathy may be observed. Animals are afebrile. Placentitis caused by B. canis results in fetal death. Abortion after about day 45 is the most commonly reported clinical sign of B. canis infection in females. However, fetal death may occur at any time during gestation, and early embryonic death would go unnoticed or could be misinterpreted as conception failure. Occasionally, a litter is carried to term, but the pups usually die within a few days of birth.

The most common clinical sign of B. canis infection in males is infertility. Scrotal and epididymal enlargement are usually transient early in infection. Testicular enlargement is uncommon. Abnormalities in seminal quality occur within 5 weeks of infection and become pronounced by 8 weeks. White blood cells, macrophages, sperm agglutination, and abnormal sperm morphology are found. By 20 weeks of infection, more than 90% of the sperm may be abnormal. Eventually, testicular atrophy and azoospermia develop, and inflammatory cells are no longer found in semen. Other than reproductive signs, dogs are healthy. B. canis may infect nonreproductive organs, most notably the eye and intervertebral disk. In such cases there are clinical signs associated with uveitis and discospondylitis. Osteomyelitis, dermatitis, meningoencephalitis, and glomerulonephropathy are less common.

# Diagnosis

The diagnosis of *B. canis* infection is suggested by the history of abortion in females, infertility and seminal abnormalities in the male, and the relative absence of physical abnormalities. The diagnosis of *B. canis* is confirmed by identification of the organism by culture or polymerase chain reaction (PCR). Positive serologic results must be confirmed by these methods. Blood, postabortion vaginal discharge, and semen are the best specimens for culture. Blood culture or PCR is the best method for identifying early (2 to 8 weeks) infection. The number of bacteria in blood usually remains very high for at least 6 months after infection. Bacteremia subsides as

the infection becomes chronic; thus blood cultures are not always positive. Semen cultures are most helpful during the first 3 months of infection, when the number of organisms in semen is high. Urine cultures may be positive, especially in males. The organism can also be recovered from lymph nodes, spleen, liver, bone marrow, prostate, epididymis, placenta, and the lumen of the gravid or postabortion uterus. *B. canis* is rarely recovered from the nonpregnant uterus or the vagina except after abortion.

Although isolation of the organism is the definitive diagnosis, it is impractical for the routine screening of asymptomatic animals. For this reason serologic testing is the most frequently used screening diagnostic procedure for *B. canis* infection. Antibodies to cell wall (somatic) lipopolysaccharide (LPS) antigens of *B. canis* cross-react with many other organisms including *Pseudomonas aeruginosa*, *Staphylococcus*, *Actinobacillus equuli*, and *Brucella ovis*. Therefore any of the serologic tests using cell wall LPS antigens have high false-positive rates, some as high as 60%. The addition of 2-mercaptoethanol (2-ME) eliminates the less specific reactions of IgM antibodies, but false-positive results are still common. Internal cytoplasmic protein antigens (CPAg), on the other hand, are highly specific for *Brucella* infection.

Serologic tests using cell wall antigens include the following: 2-ME rapid slide agglutination test (RSAT), 2-ME tube agglutination test (TAT), indirect fluorescent antibody (IFA), agar gel immunodiffusion (AGID), and enzymelinked immunosorbent assay (ELISA). The serologic tests that include the more specific cytoplasmic protein antigen are the AGID (CPAg) at NYS Diagnostic Laboratory, Cornell University, Ithaca, New York, and an ELISA (CPAg) that has limited availability. Unfortunately, laboratory reagents and/or methods have not been standardized for any of these tests except 2-ME RSAT and 2-ME TAT. Availability of the standardized reagents for 2-ME TAT is sporadic. Therefore the reliability of test results and the accuracy of interpretation are extremely variable among laboratories.

Despite its lack of specificity the RSAT (D-Tec CB®; Synbiotics) has the tremendous advantage of being easy, quick to perform, and highly sensitive. Negative RSAT results are rare (1%) in animals that have been infected long enough to develop detectable antibodies (8 to 12 weeks). Treatment with antibiotics causes negative culture and serology results, despite persistence of the organism in tissues. Titers decline in chronic infection, but they may persist for months after the bacteremia has ceased.

#### **Treatment**

Antibiotic therapy rarely, if ever, results in a cure for *B. canis* infection. The results of cultures and serologic testing become negative in animals with chronic infection and also in those receiving antibiotic therapy, despite the persistence of *B. canis* in tissues; thus it is difficult to ascribe declining titers or negative culture findings to treatment rather than to the natural progression of the disease. Bacteremia and positive serologic results often recur days to months after treatment. Minocycline, tetracycline, dihydrostreptomycin,

trimethoprim sulfadiazine, gentamicin, doxycycline, enrofloxacin, and various combinations thereof have been used to treat *B. canis*. The vast majority of treated dogs remained infected. Evidence shows that, despite therapy, the organism is not cleared from the prostate. Testicular damage is usually irreversible. Treated dogs are readily susceptible to reinfection. Because the chance of successful treatment is so unlikely and because infected animals remain a source of infection for other dogs and people, treatment is ill advised. If treatment is attempted, infected animals should be neutered to minimize the shed of organisms. No vaccine exists.

## **Prevention and Control**

B. canis is insidious. No readily recognizable signs appear until animals have been infected for weeks or months, during which time they have exposed other members of the colony to the infection. Eventually, B. canis infection will devastate the reproductive performance of the individual animal and the kennel. In kennels with infected animals, conception rates can decline to as low as 30%; the proportion of pregnancies ending in abortion can reach 80%; litter size (Beagles) can decline from a previous average of six pups to one pup per litter; and the number of pups surviving to weaning age can reach zero. Obviously, the risk of inadvertent exposure to asymptomatic, infected animals that are brought into the colony, even briefly, is too great to leave to chance. All animals should be tested before breeding. New members to be added to the colony should be quarantined for 8 to 12 weeks until the results of at least two tests performed at 4-week intervals are negative. Animals with any of the symptoms of B. canis infection should never be admitted to the colony for any reason until B. canis infection is positively excluded as the cause. As with asymptomatic animals, it may take as long as 3 months to ensure that the animal is not infected.

The RSAT is recommended for the routine screening of asymptomatic animals because it is so sensitive. If the animal has been infected for 8 to 12 weeks so that antibodies have reached detectable levels, if the animal is not so chronically infected that the titers have declined, and if no antibiotics have been administered, animals that do not have the infection should be correctly identified by a negative test result. Positive test results must be confirmed with other methods because the RSAT lacks specificity and false-positive results are common.

When an animal is found to be positive on the basis of the RSAT or other screening test, especially if clinical signs compatible with *B. canis* infection are seen, the animal should be isolated from the rest of the colony and the entire kennel should be quarantined until the results can be verified. The definitive diagnosis can be made only on the basis of the isolation and identification of the organism from culture or PCR of appropriate specimens. An AGID test that uses CPAg, but not those using LPS antigen, may also be helpful to confirm the diagnosis.

When the infection is confirmed, the positive animal should be eliminated from the colony and all other colony members tested monthly. All positive animals are eliminated.

Monthly colony-wide testing of all remaining animals, including those with negative results to the previous month's test, continues until all results are negative in all the remaining animals for 3 consecutive months. Because of the biologic behavior of the infection, it is expected that additional positive animals will be found for several months. Therefore the prevalence of infected animals in the colony is usually not significantly lowered until testing and culling have continued for 4 to 5 months.

Testing and culling are time-consuming and expensive, even in small colonies. Many are tempted to try treating the disease rather than to accept the immediate losses incurred by culling. Treatment is made all the more attractive by reports of apparent success. Bacteremia and serologic titers diminish in response to antibiotic therapy, and many treated bitches successfully conceive and carry a healthy litter to term during that time. However, evidence from studies in which animals were evaluated by culturing internal organs or blood 6 or more months after treatment shows that many still harbor the organism despite negative serologic test results. Thus far, the evidence of all the studies of spontaneously occurring infection have shown that B. canis is not eliminated from the colony, even when infected animals are strictly isolated and regardless of treatment, until infected animals are actually culled.

A different approach might be considered for a household pet than for a breeding animal. Antibiotic therapy plus neutering should essentially eliminate genital secretions and the shedding of organisms by this route, but not necessarily others. Treatment and neutering would not absolutely exclude the possibility that the animal might remain a source of infection for other dogs or human members of the household. Owners of pets or kennels should be informed of the zoonotic potential. All people exposed to infected or suspect animals should practice good hygiene.

## **HERPES VIRUS**

Herpes virus has been implicated as a cause of abortion, stillbirths, and infertility in dogs and cats. Canine herpes virus (CHV) has been suggested as the causative organism of vesicular lesions of the vagina and prepuce, but isolation of the virus from spontaneously occurring genital cases is rarely reported. Mild respiratory tract disease is by far the most common clinical sign of herpes virus infection in dogs and cats older than 12 weeks of age. The lesions are usually limited to the mucosal surfaces of the oropharynx. Occasionally, the manifestations of feline herpes virus (FHV) type I (i.e., rhinotracheitis) may be severe and include conjunctivitis, corneal ulceration, and fatal pneumonia. In neonates herpes virus infection causes fulminant multiple-organ failure and death. Neonates become infected in utero, through exposure to infected secretions of the dam, or through postnatal exposure to infected older members of the colony. Neonatal herpes virus infection is one of the most common manifestations of CHV infection in a breeding colony. Neonates nursing from seropositive bitches are resistant to infection.

Because herpes viruses are spread primarily by aerosolization and direct contact with oronasal secretions, the population density, segregation of life stages, and sanitation of the facility influence the severity of disease within the colony. The prevalence of CHV is estimated to be 10% to 15% in single-pet households and as high as 85% in kennels. Once infected, animals are considered infected for life. The infection may remain latent or be expressed at any time. Nasal secretions, even from asymptomatic carriers, are considered epizootiologically the most important routes of transmission. Venereal transmission of CHVs and FHVs is rare.

# Diagnosis

The most common clinical signs of herpes virus infection in dogs and cats are respiratory. From the standpoint of reproductive disease, herpes virus infection should be considered in cases of acute neonatal death, as a potential cause of abortion in dogs and cats, as a potential cause of infertility in cats, and as a potential cause of vesicular lesions of the mucosal surfaces of the genitalia in adult dogs. The diagnosis can be confirmed by the finding of the characteristic intranuclear inclusion bodies in tissue sections, by serologic studies, and by virus isolation and PCR.

Swabs from the affected area (genital lesion, conjunctiva, nasal) should be submitted on ice for virus isolation. Some laboratories have found that herpes viruses are more easily recovered from rayon-Dacron swabs (Dacron-tipped applicators; Baxter) than from wooden cotton-tipped swabs. This is especially important if the virus concentration is low. Herpes virus has usually not been isolated beyond 2 to 3 weeks after the primary infection. Therefore virus isolation is not a very useful diagnostic test for chronic infection, unless viral recrudescence has occurred. Herpes viruses induce a weak systemic humoral response in the host, with antibody titers rising and falling quickly (4 to 8 weeks) after infection. If seropositive animals also show typical clinical signs, this is considered diagnostic for herpes virus infection. Suspected herpes-induced genital lesions can be biopsied. Histopathologic findings typical of herpes virus infection include the vesicles, degeneration of epithelial cells, and marked acantholysis. Intranuclear inclusions may be found but are less common in the material from genital lesions than in nasal epithelium or kidney tissue

The diagnosis of CHV infection is most easily established in cases of neonatal death because the clinical signs and postmortem lesions are very characteristic. Grossly, the lesions consist of multifocal, diffuse hemorrhages and gray discoloration of parenchymal organs, especially the kidney, liver, and lungs. Microscopically, multifocal, necrotizing lesions are found. The virus can be isolated from many organs, especially the adrenals, lung, liver, kidneys, and spleen. In cases of neonatal death, chilled (not frozen) samples from the liver, kidney, and spleen should be submitted for virus isolation and formalin fixed for histopathologic examination. The whole abortus or placenta can be submitted chilled for virus isolation. Although FHV infection causes

abortion in pregnant cats, the virus is usually not recoverable from aborted material. Intranuclear inclusions are found in histologic specimens from the uterus, placenta, and aborted fetus of infected queens.

Herpes virus infection is prevented and controlled by changing management practices. Crowded conditions should be eliminated. Herpes viruses are very labile, and commonly available disinfectants are effective in destroying them. Sanitation and hygiene should be improved. Animals should be segregated according to life stages. Pregnant females and neonates should be isolated from all other colony members to prevent exposure to asymptomatic carriers. Although a bitch infected late in pregnancy is likely to suffer neonatal losses, she is also likely to acquire some immunity, which will protect her subsequent litters. For that reason, neonatal CHV usually is not a recurrent problem in an individual bitch. Neonatal CHV may remain a colony problem, however, unless management practices are changed. Vaccines are available.

# OTHER CAUSES OF PREGNANCY LOSS

Viral agents are the most commonly reported infectious cause of abortion in queens. Calici virus is one of the most important. In addition to calici and herpes viruses, parvo virus (panleukopenia), feline leukemia virus, feline immunodeficiency virus, and feline infectious peritonitis have been implicated as causes of abortion in cats. Canine distemper is reported to cause bitches to abort.

Apparent luteal insufficiency is discussed as a cause of resorption and abortion, but it is rarely documented in bitches or queens. Determination of serial serum progesterone concentrations would be the first step in documenting this problem. Certain drugs that may be used to treat or prevent maternal illness are also known to be toxic to pregnant females, to be teratogenic, to cause fetal death, or to cause abortion (Box 58-3). Nutritional imbalances can cause pregnancy loss. This can be prevented by feeding highquality commercial pet foods that are labeled for reproduction and lactation or labeled for use in all life stages.

Fetal anomalies and chromosomal aberrations are reported to be a major cause of spontaneous abortion in women. Anatomic abnormalities are found in 20% of kittens that are stillborn or that die during the first 3 days of life. Most congenital fetal anomalies have no identifiable cause. Some are known to be heritable. Some are caused by environmental factors, such as exposure to teratogens. Chromosomal anomalies have been poorly investigated as a cause of spontaneous abortion in domestic animals, but they have been identified in some stillborn kittens and puppies. When normal-appearing, full-term puppies or kittens are stillborn, the most likely cause is fetal distress during parturition. Subsequent pregnancies and labor should be monitored more closely for signs of fetal stress.

remaining viable fetuses can be treated properly, (2) the problem can be avoided during the subsequent pregnancies of this particular female, and (3) the rest of the colony can be protected from similar occurrences. The diagnostic approach should begin with a thorough history taking that includes such factors as changes in the bitch's or queen's environment, the recent addition of new animals to the house or kennel, the vaccination status of the animal, current drug therapy being given, and dietary supplements being administered. This should provide clues to possible exposure to infectious agents and teratogens. Many of the potential causes of fetal resorption-abortion can be excluded or identified during a careful history taking.

The dam should be thoroughly examined for signs of illness and the presence of remaining fetuses. Bitches and queens may abort part of a litter and carry the rest to term. Diagnostic imaging should be performed to determine the status of the uterine contents. Radiographs are most useful for identifying and counting fetal skeletons. Ultrasound is most helpful in assessing the viability of any remaining fetuses and assessing the character of other uterine contents, such as fluid or retained placentas. The metabolic status of the dam or queen should be determined with appropriate laboratory tests, such as a CBC, a serum biochemistry panel, and urinalysis. A sample of the uterine discharge obtained from the anterior vagina should be submitted for bacterial culture and antibiotic sensitivity testing. Appropriate serologic tests (e.g., Brucella titer, feline calicivirus) should also be performed on the dam. The abortus and placenta should be submitted for gross, microscopic, and microbiologic examinations. This complete postmortem examination of the abortus is the single most helpful procedure when attempting to identify the causes of abortion.

Hereditary causes of fetal anomalies may be difficult to prove. Knowledge of the hereditary defects common to the breed is an important aspect of such investigations. The breeding records of related animals should be scrutinized to determine whether there have been similar occurrences. If any are found, hereditary causes become more likely. If birth defects occur in subsequent litters from the same dam and sire, both should be eliminated from the breeding program. If hereditary causes and environmental causes (i.e., exposure to teratogens) can be ruled out, the dam and sire can reasonably be bred again because most birth defects have no identifiable cause, occur sporadically as isolated events, and do not recur in subsequent pregnancies.

#### **Treatment**

Therapy for the aborting female is supportive and symptomatic unless a cause can be found. If viable fetuses remain, the pregnancy can be allowed to continue. If not, any remaining contents of the uterus should be removed by ovariohysterectomy or through the administration of ecbolic agents as described for the treatment of pyometra in Chapter 57. Antibiotics should be administered as soon as appropriate specimens for microbiologic and serologic studies have been obtained. In many bitches and queens fetal resorption-

abortion is an isolated event with no identifiable cause or treatment. Subsequent breedings are often uneventful.

The next pregnancy should be monitored closely with ultrasonography, beginning about day 10 for queens and about day 15 for bitches, to differentiate failure to conceive from early embryonic death and to recognize impending resorption by the delay in development of specific structures or a slow fetal growth rate. Fetal death will be recognized by lack of cardiac activity and fetal movement. The status of the CL (possible luteal insufficiency) and the placenta can be monitored with serial serum concentrations of progesterone and relaxin, respectively. To evaluate the possibility of premature labor, uterine activity can also be monitored (WhelpWise.com).

# OTHER PREGNANCY DISORDERS

With the availability of uterine monitoring, premature labor has now been identified in bitches. Its prevalence and causes are unknown. At this time, treatment recommendations follow those for women but experience is limited so far. Uterine rupture is uncommon in the dog and cat. It occurs during or after labor. Typically, the animal presents with an acutely painful abdomen. Other causes of acute abdominal pain are excluded by diagnostic imaging and biochemical evaluation. The diagnosis is confirmed by exploratory surgery. Treatment is ovariohysterectomy. Ectopic pregnancy rarely occurs in bitches and queens. The clinical signs are usually nonspecific abdominal discomfort or the finding of an abdominal mass. Diagnostic imaging usually reveals a mummified fetus (Fig. 56-9). Treatment is surgical excision. The gravid uterus occasionally is incarcerated in an abdominal wall hernia. Presumably, this is the result of blunt abdominal trauma. Severe electrolyte and glucose abnormalities have been reported in the occasional pregnant bitch and queen and in association with retained fetuses. Treatment is aggressive fluid therapy appropriate to the specific metabolic derangement. Some pregnant animals responded well enough to carry their litters to term. Others were spayed as a part of the treatment plan.

# **MISMATING (ABORTIFACIENTS)**

Queens and bitches may occasionally mate at an undesirable time or with an undesirable male. The dilemma is then whether and how to prevent the birth of unwanted puppies or kittens without offending the moral sensibilities of the owner and veterinarian or threatening the health of the dam and her future reproductive capabilities. If continued reproductive function is not important, ovariohysterectomy can be performed when the female goes out of heat. Ovariohysterectomy should be performed during the first 3 to 4 weeks of diestrus because doing so is less likely to cause galactorrhea than when performed after 30 days in diestrus.

If continued reproduction is important, a question is whether to intervene immediately or wait until pregnancy is confirmed, at about 25 days. A single mating does not always result in pregnancy. As many as 26% to 62% of bitches examined 25 to 40 days after a misalliance are found to be not pregnant. Therefore an option is to do nothing until pregnancy has been confirmed. The risk that this misalliance might result in conception could be assessed by vaginal cytology and serum progesterone concentration, although this is not commonly done. Spermatozoa may sometimes be found on vaginal cytology during the first 24 hours after breeding. Their absence, however, does not preclude the possibility that insemination has occurred. Finding basal serum concentrations of progesterone (<1 ng/ml) indicates that ovulation has not yet occurred, whereas finding progesterone concentrations around 10 ng/ml to 20 ng/ml indicates optimal fertility. Some owners may elect to intervene early, especially if the risk of conception seems high, rather than to wait until pregnancy is confirmed. At this time, our recommendation is to wait until pregnancy is confirmed rather than to treat unnecessarily because the abortifacients currently available in the United States have side effects.

As with the treatment of pyometra, a variety of luteolytic and uterotonic drugs can be used to induce abortion (Box 58-4). Luteolysis is important to stop continued progesterone production, which is necessary to maintain the endometrium for implantation, maintain the health of the placenta, and suppress myometrial activity. Myometrial contractions are necessary to expel the uterine contents. Dopamine agonists such as bromocriptine and cabergoline suppress luteal activity by suppressing prolactin, which is luteotropic in bitches. Prostaglandins, such as prostaglandin  $F_{2\alpha}$  and clo-

# Therapeutic Options for Canine Misalliance

Ovariohysterectomy (may cause galactorrhea)

Estrogen not recommended

Natural PGF<sub>2\alpha</sub> (Lutalyse):

0.1-0.25 mg/kg SC q8-12h 30 to 35 days after breeding or

0.15-0.25 mg/kg SC q12h for 4 days; begin day 5-11 of cytologic diestrus

Cats: after day 45, 0.25 mg/kg SC q24h or q12h for 5 days (may produce side effects)

Cabergoline: 5 µg/kg PO q24h for 5 days, week 7 or

Cloprostenol (Estrumate): from day 25 after LH surge
1 μg/kg SC q48h, plus cabergoline 5 μg/kg PO q24h,
to effect or

 $2.5 \, \mu g/kg$  SC once, plus cabergoline  $5 \, \mu g/kg$  PO q24h for 10 days

Aglepristone: two SC doses (10 mg/kg) 24 hours apart, day 0-45 after breeding

prostenol, cause luteolysis via apoptosis, and they also cause myometrial contractions. Competitive antagonists of the progesterone receptor, such as aglepristone, block the effects of progesterone on the uterus and cervix. All these drugs will cause the next interestrous interval to be shortened by 1 to 3 months. None of these drugs is labeled for use in dogs and cats in the United States, although veterinary preparations are available in many other countries. Women who might be pregnant should handle all these drugs with great care.

#### **ESTROGENS**

Estrogens cause delayed transport of the embryo through the uterine tube, which results in degeneration of the embryo. Although some estrogens are effective in preventing pregnancy, their use has been discouraged for the following reasons. Pyometra develops in some bitches given estrogen during diestrus. Estrogens can prolong the duration of behavioral estrus, predispose to cystic ovarian follicle formation, and cause aplastic anemia. These effects are dose dependent, but aplastic anemia develops in some bitches given the recommended dose. If estrogens are used, they should not be administered during diestrus, as determined by vaginal cytologic findings. Estradiol cypionate (ECP) is no longer approved for use in dogs in the United States. Estradiol benzoate, 0.2 mg/kg, given intramuscularly 2 days after mating, prevented pregnancy in all 10 bitches in which it was administered. Animals were monitored for 75 days posttreatment. No uterine abnormalities were detected on ultrasound examination performed every 5 days, and no changes were found on CBCs performed every 12 days.

# **PROSTAGLANDINS**

After pregnancy has been confirmed, prostaglandins are administered until abortion is complete. This is determined by abdominal ultrasound. If treatment is stopped before the entire litter is aborted, the remaining fetuses may be carried to term. Prostaglandin  $F_{2\alpha}$  (0.1 to 0.25 mg/kg; Lutalyse, Pfizer) is administered to bitches subcutaneously, q12h to q8h daily, beginning 30 to 35 days after breeding and continuing until abortion is complete, which is accomplished in 3 to 9 days. In queens 0.2 mg/kg of natural PGF<sub>2 $\alpha$ </sub> administed subcutaneously, q12h for 5 days, beginning about day 45 of gestation, was effective in three of four queens. However, treatment was discontinued after 5 days because of side effects. Side effects include panting, salivation, emesis, defecation, urination, mydriasis, and nesting behavior. Intensive grooming behavior and vocalization may also be seen in the queen. Adverse reactions usually develop within 5 minutes of  $PGF_{2\alpha}$  administration and last for 30 to 60 minutes. The severity of reactions is directly related to the dose administered and inversely related to the number of days of therapy. Adverse reactions tend to become milder with subsequent injections.

Fewer side effects are reported for cloprostenol (Estrumate<sup>®</sup>, Schering-Plough); however, gastrointestinal signs still occur in 30% to 54% of bitches given the drug.

In bitches cloprostenol, 1.0 microgram/kg, is administered subcutaneously, q48h, beginning 25 to 42 days after breeding and continuing until abortion is complete. This occurs in 1.5 to 10 days, with a mean of 4 days. In those treated early, pregnancy ends by resorption. In those treated later, abortion occurs. A mucoid sanguineous discharge is present for 3 to 10 days. Given the fewer side effects and fewer injections, cloprostenol may be a better choice than prostaglandin  $F_{2\alpha}$ .

The dopamine antagonist cabergoline may be used with cloprostenol at a dose of 5 µg/kg orally, q24h. Gastrointestinal signs are the most common side effect of cabergoline (Galastop®, Ceva Vetem; Dostinex®, Pfizer).

Another protocol involves administration of one of the prostaglandins to bitches early in diestrus, before it is known if pregnancy exists. The advantage of early treatment is that fetuses are resorbed rather than expelled. Postabortion sequelae such as vulvar discharge are also minimal compared with those in bitches treated after day 30 to 35 of gestation. The disadvantage is that some animals will be subjected needlessly to treatment side effects. The protocol is begun no sooner than day 5 of cytologic diestrus, up to day 15 of diestrus. PGF<sub>2α</sub> is administered q12h for 4 days, or cloprostenol is administered q12h for 5 days using the dosages previously discussed. The serum progesterone concentrations are determined at the end of treatment. Fetal death is likely if the serum progesterone concentration declines and remains below 2 ng/ml (approximately 6.4 nmol/L) for 48 hours. If the progesterone concentration is greater than 2 ng/ ml after treatment, luteolysis is not complete, in which case the pregnancy status should be assessed with ultrasonography or a second course of treatment should be administered. In either case reevaluation by ultrasound and/or progesterone determination at 20 days is recommended. When treatment is stopped without confirming the success of pregnancy termination, about 15% of treated bitches will carry their litters to term.

# **ALTERNATIVE TREATMENTS**

Cabergoline can be used as a single agent. When given after 7 weeks of gestation in bitches, cabergoline (5  $\mu$ g/kg, administered orally q24h for 5 days) causes abortion in 3 to 5 days with few side effects. Unfortunately, at this late stage of gestation recognizable fetal parts or live fetuses that die shortly thereafter may be passed. Parturition (i.e., full-term pregnancy) was prevented in 12 of 14 feral cats given cabergoline in their feed at a dose of either 25  $\mu$ g/day for 5 days or 50  $\mu$ g/day for 3 days.

A single course of aglepristone (Alizine®, Virbac, Carros, France) has an efficacy of 97% in bitches and 87% in queens, when administered at any time from the day of copulation to day 45. The dose for bitches is 10 mg/kg, given subcutaneously twice, 24 hours apart. The dose for cats is 10 or 15 mg/kg, given subcutaneously twice, 24 hours apart. The only side effect reported for aglepristone is transient pain or swelling at the injection site. Massaging the injection site to help disperse the drug can minimize this reaction. Resorption or

abortion occurs 1 to 7 days after treatment. On the day of fetal expulsion animals may be somewhat lethargic. The postabortion discharge typically lasts for 1 to 5 days. The animals in which pregnancy is not terminated may deliver a live litter at term, give birth to dead fetuses, or retain them. For this reason the effect of treatment should be determined by posttreatment ultrasound. If fetuses remain, another dose of aglepristone may be tried or prostaglandins can be administered. Given its efficacy and safety, aglepristone is a good choice for early and midgestation pregnancy termination in dogs and cats.

# CHAPTER Postpartum and Mammary Disorders

# CHAPTER OUTLINE

#### POSTPARTUM DISORDERS

Metritis

Puerperal Hypocalcemia (Puerperal Tetany, Eclampsia) Subinvolution of Placental Sites

# MAMMARY GLAND DISORDERS

Mastitis

Galactostasis

Agalactia

Galactorrhea

Feline Mammary Hyperplasia and Hypertrophy

Mammary Neoplasia

# **POSTPARTUM DISORDERS**

#### **METRITIS**

Metritis is an acute postpartum bacterial infection of the uterus. It also may occur after abortion, dystocia, retention of placental or fetal tissues, obstetric procedures, or normal parturition. Bacteria that ascend from the vagina are the cause. Affected animals are febrile and have a fetid, septic uterine discharge. Dehydration, septicemia, endotoxemia, shock, or a combination of these can occur. One of the earliest signs of maternal illness is unthrifty, crying neonates that are being neglected by the dam. Metritis and mastitis are the two most common causes of fever and neonatal neglect in the postpartum bitch.

# Diagnosis

The diagnosis is based primarily on the historical and physical findings. Diagnostic imaging should be done to evaluate the uterine contents (e.g., fetal remnants) and assess the integrity of the uterus. Bacterial culture and sensitivity testing of the uterine discharge should be performed. The overall health of the dam can be further assessed with a complete blood count (CBC) and biochemical panel if indicated. The septic nature of the discharge can be confirmed

by cytologic examination. The uterine source of the exudate can be confirmed with endoscopic studies, but this is usually not necessary.

#### **Treatment**

For the sake of neonatal survival, metritis should be treated promptly and aggressively to minimize the hospital stay. Infected uterine contents can be removed surgically by ovariohysterectomy or medically with the administration of ecbolic agents. The decision to manage metritis medically or surgically is determined by the health of the bitch or queen, the integrity of the uterus, and the owner's desire for the animal to be able to reproduce in the future. Regardless of the approach taken, intravenous (IV) fluid therapy should be aggressive to correct existing deficits, maintain tissue perfusion, and provide for the additional demands of lactation, which are substantial. The antibiotic should be chosen on the basis of the results of a culture of the uterine exudate obtained from the anterior vagina. It is assumed that the antibiotic will reach the neonates through the milk; therefore the potential for deleterious effects on the neonates should be considered (Box 59-1). When future reproductive function is not important, in cases of potential uterine rupture, and in situations in which the dam is critically ill, ovariohysterectomy should be performed.

Medical, rather than surgical, management of metritis is appropriate for animals that are in stable condition. Drugs that cause myometrial contractions, such as the prostaglandin cloprostenol, are used to promote the evacuation of infected uterine contents, as described for the treatment of pyometra in Chapter 57. The luteolytic aspects of the drugs are not needed for the treatment of postpartum metritis because the corpora lutea (CLs) are no longer present, but they may be helpful in cases of postabortion metritis in which serum progesterone may still be high. Treatment should continue until the uterus is empty, as determined by ultrasound. This usually takes several days. Aglepristone (Alizine®, Virbac), which blocks the progesterone receptor, has also been successfully used to treat metritis in bitches. The dose of aglepristone is 10 mg/kg, administered subcutaneously once daily on days 1, 2, and 8.

#### **Antimicrobial Therapy for Neonates**

# **Drugs with Known Safety**

Amoxicillin-clavulanate Amoxicillin Cephalosporins Erythromycin Penicillins Tylosin

#### Safety not Established

Clindamycin Lincomycin

#### Drugs Known to Cause Undesirable Effects

Aminoglycosides Chloramphenicol Ciprofloxacin Enrofloxacin Nalidixic acid Nitrofurantoin Norfloxacin Polymyxin Sulfonamides Tetracyclines Trimethoprim

# PUERPERAL HYPOCALCEMIA (PUERPERAL TETANY, ECLAMPSIA)

Puerperal tetany is an acute, life-threatening hypocalcemia that occurs in the postpartum period. Clinical signs are a direct result of hypocalcemia and include muscle fasciculation and tetany but not true seizures. The cause of the hypocalcemia is usually undetermined, but it could result from such problems as maternal calcium loss to the fetal skeletons and to the milk, poor absorption of dietary calcium, and parathyroid gland atrophy caused by improper diet or dietary supplements. Clinical signs of puerperal hypocalcemia typically develop during peak lactation (i.e., 1 to 3 weeks postpartum) in small bitches that are nursing large litters. The dam is otherwise healthy, and the neonates are thriving. Puerperal hypocalcemia also can occur in cats, in any breed of dog, with any size litter, and at any time during lactation. Rarely, hypocalcemia occurs during late gestation in bitches and queens and may contribute to dystocia.

#### **Clinical Features**

The clinical signs are caused by hypocalcemia and include panting, trembling, muscle fasciculation, weakness, and ataxia. These early clinical signs quickly progress (e.g., within hours) to tetany with tonic-clonic spasms and opisthotonos. Heart rate, respiratory rate, and rectal temperature are increased, especially during tetany. Clinical signs are

rapidly progressive and may be fatal if the animal goes untreated.

# Diagnosis

Puerperal hypocalcemia is diagnosed on the basis of the typical clinical signs in a heavily lactating female. It can be confirmed by measuring the serum concentrations of calcium, which typically are below the reference range. Because the clinical signs in postpartum bitches are so suggestive, treatment is usually initiated before, or without, laboratory confirmation. Laboratory confirmation would be necessary in a prepartum animal. Although severe hypoglycemia could cause similar clinical signs, it is a rare postpartum disorder in the bitch or queen.

#### **Treatment**

Treatment consists of the slow IV administration of a 10% solution of calcium gluconate, to effect. The total dose is usually 3 to 20 ml, depending on the size of the bitch or queen. Because calcium is cardiotoxic, the animal's heart must be closely monitored for the development of dysrhythmias and bradycardia during treatment. Calcium administration must be stopped immediately if any cardiac abnormalities are detected. If additional calcium is still needed, it should be administered as soon as the cardiac rhythm has normalized, but the rate of administration should be much slower. The response to treatment is dramatic, and clinical signs resolve during IV calcium administration.

Puppies or kittens should then not be allowed to nurse for 12 to 24 hours. Oral calcium (gluconate, carbonate, or lactate), 1 to 3 g daily, should be administered for the duration of lactation. The dam's diet should also be adjusted to ad libitum feeding or at least feeding three times a day. The diet should be high-quality commercial food that is labeled as nutritionally complete, balanced, and appropriate for lactation. Some veterinarians also recommend that dams be given vitamin D supplementation, but this must be done with caution because hypercalcemia can occur in response to overzealous vitamin D supplementation. Usually, a balanced diet with additional oral calcium suffices to prevent hypocalcemia. If hypocalcemia recurs, the puppies should be weaned.

# **Prevention**

Several steps can be taken to prevent puerperal hypocalcemia in the bitch and queen. First, a high-quality, nutritionally balanced and complete diet should be fed to the bitch or queen during pregnancy and lactation. Second, oral calcium supplementation during gestation is contraindicated because it may worsen, rather than prevent, postpartum hypocalcemia. Finally, the bitch or queen should have access to food and water ad libitum during lactation. If necessary, the dam can be physically separated from the neonates for 30 to 60 minutes several times a day to encourage her to eat. Supplemental bottle-feeding of the litter with milk replacer early in lactation and with solid food after 3 to 4 weeks of age may be helpful, especially for large litters.

#### SUBINVOLUTION OF PLACENTAL SITES

In the bitch normal postpartum involution of the uterus occurs over 12 weeks. The placental sites and the entire endometrium slough. By the ninth week the uterine horns are uniformly contracted, and the surface sloughing is complete. Replacement of the endometrial lining continues until the twelfth postpartum week, at which time involution is complete. The sloughed material makes up the normal postpartum vulvar discharge known as *lochia*. Immediately after whelping, lochia contains large amounts of the placental blood heme pigment called *uteroverdin*. This makes the lochia dark green for the first few hours (<12 hours). Thereafter the lochia is reddish or red-brown and contains cellular debris and mucus. The volume of lochia diminishes quickly, and within a few weeks it is an intermittent (several times a day) spotting of reddish or red-brown mucoid material.

Subinvolution of placental sites (SIPS) results in persistent postpartum dripping of sangineous discharge for 12 or more weeks. SIPS is most common in primiparous bitches younger than 3 years of age, but it can occur in older multiparous animals as well. It has not been reported in cats. The cause is unknown.

# **Diagnosis**

Affected bitches are healthy and physically normal, except for a small amount of bloody vulvar discharge. The blood loss from SIPS is not severe. If the clinician is concerned, the CBC can be evaluated, keeping in mind the normal decline in the packed cell volume (PCV) that occurs during pregnancy. Vaginal cytology (see Chapter 56) can be used to differentiate the bleeding associated with SIPS from lochia and from the discharge associated with metritis. Cytologically, evidence of hemorrhage is found. Decidua-like multinucleated giant cells may also be seen. Ultrasound can be used to assess the degree of uterine involution. The diagnosis of SIPS usually is based on the historical, physical, and cytologic findings alone. It can be confirmed by histopathologic examination of the placental sites, but this is rarely necessary. Normally involuted placental sites and SIPS can be found in the same uterus.

Bitches with SIPS rarely require treatment. Recovery is spontaneous, and subsequent fertility is not affected. Ovariohysterectomy is curative. The administration of ergonovine maleate, oxytocin, or prostaglandin will cause uterine contraction and may diminish bleeding, but there is little published evidence that this hastens recovery from SIPS. Progestin therapy has also been suggested, but its undesirable effects on the endometrium outweigh any potential benefit in this situation. If anemia is severe enough to require treatment, a diagnosis other than SIPS should be considered.

# DISORDERS OF THE MAMMARY GLANDS

#### **MASTITIS**

Mastitis is a bacterial infection in one or more of the lactating mammary glands. It is a common postpartum disorder in bitches. It is rare in queens. Mastitis rarely occurs in bitches that are lactating because of false pregnancy. Whenever inflammation and/or abnormal secretions are present in nonlactating glands, mammary neoplasia should be strongly considered as the cause. The clinical signs of mastitis are variable in severity but include fever; anorexia; dehydration; and warm, firm, swollen, painful glands. Crying, unthrifty puppies may be what the owner notices first because bitches that are ill with mastitis may neglect them. In severe cases abscesses or gangrene of the glands can develop. Mastitis is the most common cause of postpartum fever. The diagnosis is made on the basis of these physical findings in a lactating female and on the septic appearance of the mammary secretions. Escherichia coli, staphylococci, and β-hemolytic streptococci are the organisms most frequently isolated.

The treatment of mastitis includes antibiotics, fluid therapy, and supportive care. It should be aggressive to ensure that the bitch can resume her maternal duties as soon as possible. Adequate water and caloric intake is crucial to ensure continued milk production. During lactation food and water needs are often double what they were during gestation. The additional fluid needs to support lactation must be taken into account when planning fluid therapy. Warm compresses applied to affected glands several times a day can reduce swelling and pain, and this should be included in the treatment of mastitis.

There are several factors to consider in the choice of antibiotics, including the susceptibility of the infecting organisms, the ability of the antibiotic to achieve high concentrations in milk, and the effects of the drug on the nursing neonate (see Box 59-1). Amoxicillin and cephalosporins can be used if the results of bacterial culture are not known because they are likely to achieve reasonable concentrations in the infected gland, they are likely to be effective against the most common organisms, and they are reasonably safe for neonates. Mammary abscesses and gangrene should be treated surgically.

It is recommended that pups continue nursing as long as the dam is willing and able to provide adequate nutrition. Monitoring the weight gain of the puppies, which should be about 10% per day, helps the clinican assess whether the puppies' needs are being met. The pups should also be watched closely for other signs of illness. If present, supplemental feeding or hand-rearing of the puppies should be considered.

#### **GALACTOSTASIS**

Galactostasis is the accumulation and stasis of milk within the mammary gland. This results in warm, firm, swollen, painful glands. Unlike mastitis, in galactostasis the mammary secretions are not infected and the dam is not ill. Milk is simply being produced faster than it can comfortably be stored. Galactostasis usually occurs at the time of weaning and occasionally at the time of peak lactation, when production transiently exceeds the needs of the neonates. Galactostasis may also occur with false pregnancy (see Chapter 58).

Treatment is not indicated for the transient galactostasis that occasionally occurs during the first 1 to 3 weeks of lac-

tation. If treatment is necessary for galactostasis that occurs at weaning, it is directed toward reducing milk production and relieving discomfort. Milk production diminishes as food and water intake is restricted. Therefore reducing the caloric intake to amounts appropriate to maintain ideal body weight and normal hydration during anestrus (i.e., neither pregnant nor lactating) is helpful in treating, as well as preventing, the galactostasis that occurs at weaning. Gradual, rather than abrupt, weaning is also helpful. Because massaging or expressing the mammary glands may stimulate prolactin release and promote continued lactation, these techniques are not recommended. Warm compresses may help relieve swelling and discomfort.

#### **AGALACTIA**

Agalactia is the absence of milk production or secretion. Normal milk production and secretion are dependent on many factors, including genetics, nutrition, psychological factors, and anatomic differences. Prolactin stimulates milk production. Oxytocin stimulates milk letdown. Primary agalactia refers to a situation in which the gland is incapable of producing milk or the ducts are incapable of flow. More commonly, the gland and ducts are normal but other factors have diminished the capacity for production or inhibited milk letdown. Animals that are in poor body condition may have difficulty establishing and maintaining lactation. Caloric and water needs during lactation are as much as double those needed during gestation. To ensure that the needs of both gestation and lactation are met, a high-energy diet, appropriate for reproduction and lactation, should be fed from the time of breeding onward. Unlike multiparous animals that may have colostrum that is easily expressed during the last week of gestation, primiparous animals may not produce colostrum at this time; however, colostrum is almost always present within 24 hours of parturition.

Anxiety will inhibit milk letdown. The nursing dam and her litter should be in a quiet location, with limited visitors, especially for the first several days. If necessary, sedation may be considered. Phenothiazines may increase prolactin secretion, which would be beneficial. Oxytocin, 0.5 to 2.0 U administered subcutaneously q2h, has also been suggested to promote milk letdown. It is available for this purpose in people in the form of a nasal spray. Puppies or kittens are returned to nurse 30 minutes after oxytocin is administered. Metoclopramide stimulates prolactin secretion and has been successfully used to enhance lactation. The dose is 0.1 to 0.2 mg/kg (administered orally or subcutaneously) q6-8h until lactation is adequate. The oral dose may be increased to 0.5 mg/kg q8h if needed. Treatment is usually needed for only a day or two. Meanwhile, nutritional and psychological factors must also be corrected.

# **GALACTORRHEA**

Galactorrhea refers to lactation that is not associated with pregnancy and parturition. It is the most common clinical manifestation of false pregnancy in the bitch. Galactorrhea of false pregnancy occurs at the end of diestrus, after the withdrawal of exogenous progestins, or after oophorectomy performed during diestrus. This galactorrhea is self-limiting and usually does not require treatment. See Chapter 58 for details of the condition.

# FELINE MAMMARY HYPERPLASIA AND HYPERTROPHY

Feline mammary hyperplasia (fibroepithelial hyperplasia, fibroadenoma, fibroadenomatosis) is characterized by the rapid, abnormal growth of mammary tissue. Hyperplasia of both epithelial and mesenchymal tissues is evident microscopically. It is most common in young, cycling queens that may or may not be pregnant (Fig. 59-1). It has also been observed in neutered male and neutered female cats that are receiving exogenous progestins. There is a strong temporal relationship between the onset of mammary hyperplasia and progesterone stimulation. Feline mammary hyperplasia is a benign condition, but its abnormal growth may mimic those of mammary neoplasia. Histologic evaluation of a biopsy specimen can be done if there is any doubt.

Treatment consists of removing the source of the progesterone. Although successful pregnancy and nursing of kittens were reported in one queen with mammary hyperplasia, ovariohysterectomy is usually recommended, irrespective of the pregnancy status. The surgery is often performed through a flank incision rather than through the usual midline approach, because of the massive size of the glands. The hyperplastic tissue resolves over several weeks following oophorectomy. The prognosis is excellent. In the unlikely event that there is no response to withdrawal of progestins or ovariohysterectomy, the progesterone receptor blocker aglepristone (Alizine®, Virbac), 20 mg/kg administered subcutaneously on one day or 10 mg/kg on two consecutive days once weekly, resolves the condition in 1 to 4 weeks. The only side effect is irritation at the injection site; however, aglepristone will cause abortion if the queen is pregnant. Mastectomy may be indicated if the abnormal mammary tissue has become necrotic.

#### MAMMARY DUCT ECTASIA

Mammary duct ectasia is a benign, sometimes painful condition in which the mammary collecting ducts are dilated by inspissated secretions. It occurs in neutered and intact bitches of any age, but the mean age at the time of diagnosis is 6 years. The clinical signs resemble those of mammary neoplasia. The cystic nature of the condition can often be appreciated on palpation. The inspissated material is yellow or bluish in color and is sometimes visible beneath the skin. Surgical excision is curative. The mass should be submitted for histopathologic evaluation because mammary neoplasia is the other likely differential diagnosis.

# MAMMARY NEOPLASIA

# Etiology

Mammary neoplasms account for about half of all tumors in bitches. Although they are less prevalent in queens,

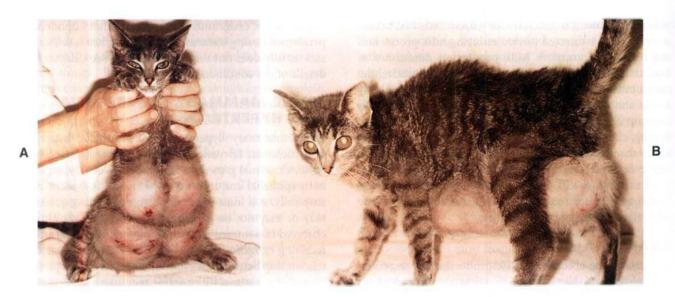

FIG 59-1 Mammary hyperplasia of 6 weeks' duration in a 5-month-old queen.

mammary neoplasms are still the third most common tumor type in cats. They primarily affect older animals, with a mean age of about 10 years. Most affected animals are intact females or females that have undergone oophorectomy after 1 or 2 years of age. Mammary tumors are rare in males and in young animals of either sex.

Early ovariohysterectomy is strongly protective against the development of mammary tumors. Bitches neutered before their first estrous cycle are at no greater risk for mammary tumors than are males. After 2.5 years of age or after the second estrous cycle, ovariohysterectomy is apparently no longer protective in bitches. Cats neutered before 1 year of age also have a significantly (86%) decreased risk of developing mammary carcinoma. The progestins used to suppress estrus promote hyperplastic and neoplastic changes in the feline and canine mammary glands. Benign mammary tumors are found in more than 70% of bitches receiving long-term progestin treatment. About half of mammary tumors in bitches are benign, whereas feline mammary tumors are almost always malignant.

#### **Clinical Features**

Mammary tumors are usually discrete, firm, and nodular. They may be found anywhere along the mammary chain. The size is extremely variable, ranging from a few millimeters to many centimeters in diameter. Multiple glands are involved more than half of the time. The tumors may adhere to the overlying skin but usually are not attached to the underlying body wall. Malignant tumors are more likely than benign tumors to be attached to the body wall and covered by ulcerated skin. About 25% of feline mammary tumors are covered by ulcerated skin. Abnormal secretions can often be expressed from the nipples of affected glands. Inflammatory carcinoma of a mammary gland may have a physical appearance similar to that of mastitis. However, inflammatory carcinoma is most likely to occur in geriatric animals, and there

is no association with lactation. The regional lymph nodes (axillary or inguinal) may be enlarged if metastasis has occurred. The remainder of the physical examination findings are often unremarkable. There may be evidence of tumor cachexia in animals with advanced neoplasia.

# **Diagnosis**

Mammary neoplasia is the most likely cause of any kind of nodule in the mammary gland of an older female. Excisional biopsy is the method of choice to confirm the diagnosis. Cytologic examination of specimens obtained by fine-needle aspiration often yields equivocal results. Before excisional biopsy is performed, radiographs of the thorax should be evaluated for evidence of pulmonary metastasis. If evidence of pulmonary metastasis is found, a grave prognosis is justified, even in the absence of histologic confirmation of mammary neoplasia. Malignant mammary tumors frequently metastasize to the regional lymph nodes and to the lungs. Less commonly, hepatic metastasis occurs. Metastasis to distant sites can also occur, but this rarely happens in the absence of local lymph node or pulmonary involvement. Diagnostic imaging and careful palpation are used to evaluate the tumor burden. The animal's overall health is assessed with a CBC, biochemical panel, and urinalysis.

## **Prognosis**

Approximately half of the mammary tumors in bitches are benign. Some of these benign tumors show evidence of cellular atypia within the parenchyma and are considered precancerous. Precancerous changes in bitches are associated with a ninefold increase in the risk of mammary adenocarcinoma developing at a later date. Animals with nodules of normal cellular characteristics are at no greater risk than animals with no previous mammary nodules. In contrast, benign mammary tumors are rare in cats. More than 80% of feline mammary tumors are classified as adenocarcinomas.

Adenocarcinoma is the most common malignant mammary tumor in bitches and queens. If the neoplastic cells are confined to the duct epithelium (carcinoma in situ), the prognosis after surgery is good. The prognosis is somewhat worse if neoplastic cells are found beyond the boundary of the duct system but not in blood or lymphatic vessels. The prognosis is worse if neoplastic cells are found in blood or lymphatic vessels. If neoplastic cells are found in the regional lymph nodes, the disease-free interval after surgery is significantly shortened. Nuclear differentiation affects the recurrence rates, even within the same stage of invasion. The recurrence rate 2 years after mastectomy in bitches with poorly differentiated (i.e., anaplastic) tumors is 90% versus rates of 68% and 24% in animals with moderately differentiated and well-differentiated tumors, respectively.

In queens mammary tumors are almost exclusively carcinomas. In bitches other malignant tumors of the mammary gland, such as inflammatory carcinoma, sarcomas, and carcinosarcomas, are occasionally found, but they are much less common than are adenocarcinomas. Inflammatory carcinoma is a fulminant malignant disease associated with a grave prognosis in bitches and queens.

#### **Treatment**

The treatment of mammary neoplasia is surgical excision of all abnormal tissue. Controversy persists as to the preferred surgical technique: nodule excision, simple mastectomy, or radical mastectomy. If nodulectomy is chosen, apparently normal surrounding tissue should always be included and submitted for histopathologic evaluation for evidence of tumor invasion. If there is evidence of extension beyond the nodule, mastectomy should be performed. There is no difference in the survival times after simple versus radical mastectomy in bitches and queens; however, the disease-free interval may be longer in cats that have undergone radical mastectomies. Excised mammary tumors should always be submitted for histopathologic examination because the tumor type determines the prognosis. The prognosis for inflammatory carcinoma is grave.

Because the surgical excision of malignant mammary tumors is not curative, the effectiveness of adjunct therapies has been investigated. There is no doubt that estrogen and progesterone play a role in mammary neoplasia. Mammary tumors express estrogen receptors or progesterone receptors (or both), which explains why some mammary masses appear to be hormone sensitive and others do not. The effects on survival of endogenous and exogenous hormones

continues to be of interest. To fully assess the therapeutic benefits of hormonal manipulation, the clinician must know the estrogen- and progesterone-receptor status of the tumors. In many veterinary studies that has not been the case.

Ovariohysterectomy performed at the time of mastectomy has no effect on 2-year survival rates in bitches. There also appear to be no differences in survival among bitches that undergo ovariohysterectomy before mastectomy, bitches that undergo ovariohysterectomy at the time of mastectomy, and bitches that undergo mastectomy alone, although data are conflicting. Tamoxifen competitively binds estrogen receptors with a combined antagonist-agonist effect. Its antiestrogenic effects are helpful in the treatment of mammary neoplasia in women. Tamoxifen has primarily estrogenic effects in dogs. In a study of the use of tamoxifen as adjunct therapy for canine mammary neoplasia, no beneficial antitumor effects were proved but 56% of the treated dogs showed adverse estrogenic effects. Although at present there is little published evidence of beneficial effects of chemotherapy as an adjunct to the surgical treatment of mammary tumors in bitches and queens, clinical investigations continue.

# NORMAL SEXUAL DEVELOPMENT AND BEHAVIOR

#### **DEVELOPMENT**

Sexual differentiation into a male or female has three components: chromosomal, gonadal, and phenotypic sex. The major genetic components that direct the development of a male are located on the short arm of the Y chromosome in the sex determining region, or Sry gene. Together with certain factors elsewhere on the sex chromosomes and on some autosomes, the Sry gene directs the development of the sexually indifferent fetal gonads into testes. Testicular differentiation is observed in the canine fetus at day 36 of gestation. The many hormones produced by the fetal testis cause continued sexual differentiation into the male phenotype. In the absence of these influences, the phenotype will become female. Fetal Sertoli cells produce Müllerian inhibiting substance, which causes regression of the Müllerian ducts that would otherwise have developed into the oviduct, uterus, and cranial vagina. Müllerian duct regression is complete by day 46 of gestation in dogs. Fetal Leydig cells produce testosterone, which causes the Wolffian ducts to develop into the ductuli deferentes and epididymes. Dihydrotestosterone, a metabolite of testosterone, causes the urogenital sinus, the genital tubercle, and the genital swelling to differentiate into the urethra and prostate, penis, and scrotum, respectively. The male external genitalia can be recognized by ultrasound between gestation days 38 to 43 in the feline fetus (Zambelli et al., 2006a). Factors produced by the fetal testis also cause the testis to descend from its fetal position near the caudal pole of the kidney, through the inguinal canal, into the scrotum. Normal testicular descent is a prenatal event in cats and is normally complete by 10 to 42 days of age in dogs. Although later descent is possible, a diagnosis of cryptorchidism should be considered if the testes are not palpable within the scrotum by 8 to 10 weeks of age.

The Leydig (interstitial) cells are stimulated by luteinizing hormone (LH) to produce testosterone and, in much lesser amounts, estradiol. In addition to the development of the ductus deferens and epididymis, testosterone initiates and maintains all aspects of spermatogenesis; supports libido; and, via negative feedback, regulates hypothalamic secretion of gonadotropin releasing hormone (GnRH) and pituitary secretion of LH and follicle-stimulating hormone (FSH). Testosterone is also the prohormone for dihydrotestosterone (DHT) and estradiol, which are formed in the testis and also in peripheral tissues, by the action of the enzymes  $5\alpha$ reductase and aromatase, respectively. DHT promotes the maturation of the prostate and the external genitalia and the development of the secondary sexual characteristics at puberty (see Fig 56-4). Only a small amount of estradiol is secreted by the testes. Most of the circulating estradiol in adult males is formed in the extragonadal tissues by the aromatization of circulating testosterone.

The Sertoli cells and spermatogonia (germ cells) are located along the basement membrane of the seminiferous tubules. Cytoplasmic processes from Sertoli cells extend from the lamina propria of the seminiferous tubules to the tubular lumen and surround the developing germ cells. Sertoli cells are regulated by FSH and testosterone to produce several substances that are necessary for spermatogenesis and normal spermatid maturation. In fact, spermatogenesis is regulated via the effects of FSH on Sertoli cells, not by

direct effects of FSH on germ cells. Specific functions of Sertoli cells vary according to the developmental stage of the germ cells they surround. These may also vary depending on the species of animal.

Sertoli cells convert testosterone, produced by the Leydig cells, to estradiol. This is especially apparent in prepubertal animals. Most of the testicular estradiol in adults appears to originate from Leydig cells. The role of estradiol in male reproduction is unclear. Along with testosterone, it is involved in the regulation of gonadotropin secretion. In some instances, estrogens augment the effects of androgens, such as in the canine prostate, where estradiol regulates the number of DHT receptors. In the mammary gland estrogens seem to have antiandrogenic effects. Sertoli cells also produce a substance known as androgen-binding protein, which is thought to moderate the effects of testosterone. It may also be involved in the transport of testosterone within the testis and epididymis. Sertoli cells also produce the hormones inhibin and activin. Inhibin causes a decrease in FSH secretion by the pituitary. Activin has the opposite effect on FSH secretion.

Spermatogenesis refers to the maintenance of spermatogonia and the differentiation of spermatogonia into spermatozoa within the seminiferous tubules. Both proliferating and noncommitted spermatogonia are located nearest the tubular basement membrane. As the germ cells mature into spermatocytes and eventually spermatids, they move toward the tubular lumen, such that the most differentiated cells are nearest the lumen. Eight to 10 stages of sperm development, or cellular associations, have been identified in dogs. They represent maturation of spermatogonia, then several stages of maturing spermatocytes, and finally several stages of maturing spermatids. A cross-section of any given normal seminiferous tubule contains all stages of the developing spermatozoa.

In addition to the proliferating spermatogonia, there is a population of noncommitted spermatogonia that are called  $A_0$ -spermatogonia. These spermatogonia remain in reserve and, unlike proliferating spermatogonia, are quite resistant to damage by toxins and radiation. The recovery of spermatogenesis that occurs after testicular injury results from the repopulation of the germinal epithelium by the progeny of the A<sub>0</sub>-spermatogonia. In dogs approximately 62 days elapse from the time A<sub>0</sub>-spermatogonia begin to differentiate into mature spermatogonia until the time mature spermatozoa are released into the tubular lumen. It then takes approximately 14 days for spermatozoa to become fully mature and motile in the epididymis. Frequent ejaculation does not influence daily sperm production in the testes, but it does diminish the number of sperm ejaculated by depleting the extragonadal reserves from the epididymis and ductus deferens.

Sexual maturity and physical maturity are closely related. Puberty occurs around 9 to 10 months of age in tomcats. The same is generally true for dogs, but the large and giant breeds mature more slowly. The onset of puberty is signaled by the development of masculine physical characteristics, such as heavier muscling and thicker skin on the jowls, and

sexual behavior, such as territorial urine marking and mounting of other colony members. Semen quality and serum concentrations of testosterone gradually approach those of mature males, although prepubescent males may be fertile. Semen quality and libido tend to decline with advancing age, especially in geriatric males. Although males are fertile long past 6 years of age, they often are less active in breeding programs. This is primarily because they are replaced by younger males with similar or preferred phenotypic and genotypic qualities. Because other health problems often develop in older animals, their physical ability to mate may decline. Undesirable behavior is cited as a common reason for retiring older tomcats from breeding colonies.

#### **BREEDING BEHAVIOR**

Much of normal breeding behavior is learned by dogs and cats. Consequently, early breeding experiences help determine a male's future success as a stud. There is usually one dominant male in any specific territory. Even if all males are given equal opportunity, the dominant male will do most of the breedings. Establishing dominance and territory is usually a prerequisite to mating; therefore the standard practice is to bring the female to the male. Because successful studs must be physically, sexually, and socially mature, it is usually recommended that males not enter a breeding program until they are at least 12 months old, even though puberty may have occurred months earlier. Dogs that are used in an artificial insemination program may become so accustomed to semen collection that they are no longer interested in natural service.

Ideally, a sexually inexperienced male should first be exposed to a docile, experienced female in his own territory. Virgin males usually make many unsuccessful attempts to mount before achieving intromission. This first encounter should be short and well supervised so that the male does not become frustrated or exhausted by his unsuccessful attempts to copulate or, worse, become intimidated or actually injured by an aggressive female. The tomcat typically grasps the queen's neck near her shoulders and straddles her with his front feet. The neck grasp is thought to be necessary to restrain the female and to properly position both animals' rear quarters to allow intromission to occur. The rear quarters are then straddled, and intromission occurs (Fig. 60-1).

FIG 60-1 Feline breeding behavior.

To insure adequate copulatory stimulation to induce ovulation in the queen, three breedings per day for the first 3 days of estrus are recommended (see Chapter 56). When semen is collected from cats three times per week, the volume and number of sperm are fairly constant from collection to collection. When semen is collected daily, by the fourth day the volume and number of sperm drop to less than half of that on the first day and then remain fairly constant at 14 to 45 million sperm per ejaculate. Libido and sperm motility and morphology did not change with frequent collection, other than an increase in the number of immature spermatozoa (Zambelli, 2006b).

Because the canine os penis maintains rigidity, intromission can and does occur before the penis is actually erect. During erection the bulbus glandis of the canine penis swells twofold to threefold, filling the vestibule and preventing separation of the breeding pair. Ejaculation of the first two seminal fractions begins shortly after intromission, during the rapid pelvic thrusting. Soon after its pelvic thrusting subsides, the dog dismounts and faces away from the bitch, but the erect penis, having turned 180 degrees in a horizontal plane, remains in the bitch. This is known as the postcoital lock or tie (see Fig. 56-2). Ejaculation, primarily of the third fraction, which consists of prostatic fluid, continues during the tie. The tie persists until the dog's erection subsides 15 to 30 minutes or more later. If the dog's penis is erect before intromission, the size of the bulbus glandis prevents complete intromission and a tie will not occur when the dog dismounts. Some dog owners refer to this as an outside tie. In this situation the entire ejaculate may not have been deposited in the bitch.

Two breedings during the fertile period are recommended for dogs because doing so has been shown to increase both whelping rates and litter size. When breeding is performed at the most optimal time during the fertile period, whelping rates are not significantly higher with two breedings than with one, although litter size is larger. Three breedings during the fertile period do not increase whelping rates above two breedings, but there may be a slight increase in litter size. Daily cjaculation diminishes sperm numbers dramatically by the second day, whereas semen collection every other day does not have such a profound effect on sperm numbers. On average 4 to 10 days of ejaculation deplete the extragonadal sperm reserves in the epididymis and ductus deferens. Thereafter the number of sperm per ejaculate is substantially less than half the number collected on the first day. This could be an important consideration for a very popular stud and when semen is being collected for freezing. Results from breeding during the fertile period with semen of good quality are optimized when bitches are 6 years of age or younger and dogs are 8 years of age or younger.

#### **Artificial Insemination**

Artificial insemination (AI) is used in dogs primarily when natural breeding cannot be accomplished. Transporting semen, rather than live animals, to distant geographic locations is a great advantage of AI over natural service. AI is also used when behavioral problems, such as partner preference, or physical problems, such as vaginal prolapse, prevent copulation of the desired pair. Some dog breeders prefer AI because they believe that the risk of breeding trauma is minimized and that the stud is less likely to be exposed to infectious diseases carried by the bitch. In addition, a single ejaculate with sufficient numbers of spermatozoa can be divided and used to inseminate several bitches. The success of AI is determined by several factors, including the reproductive health of the animals, the quality of the semen, the timing and the number of inseminations, intravaginal versus intrauterine insemination, and the technical skills of the person performing the insemination.

It is important to document semen quality before insemination because the success of the insemination will be no better than the quality of the semen. Knowing that semen quality is poor, the owner may wish to use a different stud. Although pregnancies are occasionally achieved using fresh semen of inferior quality, the litter size is usually smaller. Usually, no litters result if frozen-thawed semen of poor quality is used. In addition, once inseminated, the bitch should not be bred to a different male during that cycle because paternity is uncertain unless DNA testing is done. Two inseminations should be performed at the optimal time during the fertile period, as discussed in Chapter 56. It has been shown that pregnancy rates from AI are improved when the semen is deposited directly into the uterus rather than into the cranial vagina. This is especially important when frozen-thawed semen is used because, relative to fresh or chilled semen, the frozen-thawed spermatozoa have a very short life span and poor ability to transverse the cervix. It has been estimated that to achieve similar pregnancy rates with frozen-thawed semen, at least 10 times the number of viable sperm are needed for vaginal AI than for intrauterine AI. Intrauterine insemination can be accomplished transcervically using specially developed catheters (Norwegian catheter; Norske Pelsdyrforlag A/L) or endoscopically. These transcervical insemination techniques are commonly referred to as TCI. Intrauterine insemination can also be accomplished via laparoscopy or through a mini laparotomy.

While the semen is being handled, it must be protected from sudden changes in temperature. Freshly ejaculated canine semen is most effectively protected against temperature shock by working at room temperature and inseminating promptly after collection. Pregnancy rates of 84% have been achieved with vaginal AI of fresh semen. Chilled and frozen semen are protected against damage during processing by the addition of a protective "semen extender" to the sample and by careful attention to the cooling, freezing, and thawing rates. Semen extenders have been formulated to provide nutritional support for the sperm cells, buffer pH changes that occur because of continued metabolic activity, maintain physiologic osmotic pressure, prevent bacterial growth, protect cells from cold shock during chilling, and limit cell damage during freezing and thawing.

The advantage of chilled extended semen over natural breeding or AI with fresh semen is that the semen, rather

than the animals, can be transported. The advantage of chilled semen over frozen semen is that the pregnancy rates are better. Pregnancy rates and the longevity of chilled semen vary tremendously according to the type of extender and processing methods used. Properly extended and cooled semen of good quality can be stored at 5°C for 12 to 24 hours and usually longer. Recently, new extenders have been developed that maintain sperm viability for 1 to 2 weeks at 5°C (www.canirep.com). It is important to follow the instructions for warming chilled semen before insemination because the methods will vary according to the extender used. Pregnancy rates of 50% to 70% are reported for the use of various extenders with chilled semen and vaginal insemination. Whelping rates can be improved from about 45% with vaginal AI to about 65% with intrauterine AI using chilled semen. Extender, equipment, and instructions for their use and for collecting, chilling, and inseminating semen are available from several commercial sources (Fresh Express ICG, Synbiotics; Cryogenetics Laboratory of New England; International Canine Semen Bank; Canine Cryobank; www. canirep.com).

The greatest advantage of frozen semen is that cryopreservation is the only way in which the genetic potential of valuable male animals can be saved indefinitely. Using frozen semen, litters can be sired by a dog long after his death. Another advantage is that semen can be collected and stored whenever it is convenient to do so, in contrast to fresh or chilled semen, in which the timing is determined by the availability of cycling females. Conception rates achieved using frozen semen vary according to the extender and the sperm-processing techniques used (pellets versus straws, freezing rates, thawing rates). Pregnancy rates achieved with vaginal insemination using frozen-thawed semen of good quality have been about 30%, whereas pregnancy rates of 50% to 80% have been achieved when intrauterine insemination has been performed. The frozen semen should be accompanied by information from the collection and storage facility regarding the number of sperm in each straw or vial and the recommendations for thawing the semen. The latter is important because the ingredients in the extender influence the ideal thawing rates and temperatures, which have a significant effect on the postthaw motility. For additional information on AI and regulations for international shipment of chilled and frozen canine semen, the reader should consult the International Veterinary Information Service (www.IVIS.org).

# DIAGNOSTIC TECHNIQUES TO ASSESS REPRODUCTIVE FUNCTION

# **SEMEN COLLECTION AND EVALUATION** Indications

Semen is collected and evaluated as a routine part of a breeding soundness examination, for evaluation of male infertility, when artificial insemination is to be performed, and when semen is to be preserved by chilling or freezing. Cytologic

evaluation of the ejaculate is also used to evaluate diseases of the prostate, testes, and epididymides.

#### **Technique**

Many factors affect semen quality, including the animal's age, testicular size, frequency of ejaculation, degree of sexual arousal, collection technique, and the amount of seminal fluid collected. Semen is easily collected from dogs, especially those with previous breeding experience. The collection area should be quiet and free from distractions, with secure footing for the animals. The dog is encouraged to ejaculate by rapid massage of the bulbus glandis through the prepuce. The presence of an estrous bitch will improve the quality of the ejaculate and the ease with which semen is collected (libido). It has been shown that prostaglandin  $F_{2\alpha}$  (Lutalyse<sup>®</sup>, Pfizer) 0.1 mg/kg, administered subcutaneously 15 minutes before collection, increases the number of sperm ejaculated, similar to the presence of an estrous bitch. It may also have a positive effect on libido. When prostaglandin F<sub>2n</sub> and an estrous teaser bitch are both used, the effects are additive and the number of sperm ejaculated may be increased by nearly 300% (Root Kustritz et al., 2007). Side effects of prostaglandin  $F_{2\alpha}$  are transient and mild but also common. They include salivation, defecation, and vomiting. Semen can also be collected by electroejaculation, but this is rarely necessary in domestic dogs. Semen is usually collected from cats by electroejaculation under general anesthesia, although some cats can be trained to accept an artificial vagina. Feline semen collection and evaluation are not usually performed in clinical practice, but assisted reproduction techniques are used extensively in the study of endangered feline species.

Canine semen is ejaculated in three fractions. The first fraction, or presperm fraction, is composed of a few drops of clear fluid that originates from the prostate. Although this is uncommon, certain dogs may ejaculate several ml of the presperm fraction. The second fraction is the sperm-rich fraction. The volume of the sperm-rich fraction varies from 0.5 to 5 ml, depending on testicular size and individual variation. The sperm-rich fraction appears cloudy and opalescent. Usually, no attempt is made to separate the first two fractions. The third and largest fraction is prostatic fluid, of which there may be as much as 30 ml. Normal prostatic fluid is clear and easily distinguished from the milky, sperm-rich fraction. For routine semen evaluation and artificial insemination, it is sufficient to collect only enough prostatic fluid to ensure that the entire sperm-rich fraction has been obtained.

There are a variety of sophisticated methods that can be used to assess the structure and function of spermatozoa. These include various staining techniques to evaluate viability, the integrity of the plasma membrane, the capacitation status, and the acrosome reaction. There are in vitro assays to assess sperm functions, such as the ability to stimulate the acrosome reaction, measuring the ability of sperm to bind to the zona pellucida, or determining the ability to penetrate the oocyte. Computer-assisted sperm analysis programs have

been adapted for use with canine semen. These programs can assess sperm motility and morphology. At this time uniform laboratory standards for adapting these procedures to canine semen have not been established, and the correlation of specific findings with in vivo fertility has not been determined. Nevertheless, these methods have important potential application, especially for semen freezing centers. Scanning and transmission electronmicroscopy continue to be useful for evaluation of sperm morphology.

In clinical practice semen evaluation focuses primarily on sperm numbers, morphology, and motility. These parameters are often referred to as the spermiogram. A complete cytologic evaluation of other cells (e.g., white blood cells, red blood cells, epithelial cells) in the seminal fluid is also important. In cases of azoospermia determination of seminal fluid alkaline phosphatase is indicated. Because feline semen is rarely evaluated in clinical practice, the interested reader is referred to Zambelli (2006b) and Johnston (2001) for additional information (see Suggested Readings). Semen must be handled carefully. All equipment should be clean and free of contaminants, including water and excessive lubricant. The sample must be protected against sudden changes in temperature. Normal dog semen can usually be handled at room temperature for 10 to 15 minutes without adverse effects. Nevertheless, the sample should be processed promptly. Slides and coverslips should be maintained at 37°C.

# Motility

Assessment of motility is usually the first step in semen evaluation because it must be assessed promptly after collection so that changing temperature does not slow motility. Although not a precise measure, assessment of motility is considered a critical part of semen evaluation because it gauges spermatozoal function and viability. Very poor samples can be distinguished from very good ones. A decrease in the percentage of motile sperm is one of the first detectable changes after testicular injury. Asthenozoospermia is the term used to denote low motility. The percentage of motile sperm and the vigor of the movement can be spuriously diminished if the sample is exposed to excessive heat or cold, contaminated equipment, inflammatory cells, or bacteria. Poor motility may also be found in the setting of incomplete ejaculation. The motility of sperm ejaculated after a long sexual rest may also be poor because of aging of the cells. In addition, sperm in semen that has been chilled or frozen usually does not regain its original motility when warmed. In the case of chilled semen, the percentage of motile sperm may be similar to that seen in the fresh semen, but the individual sperm usually move with less vigor. Both the percentage and the speed of motility are usually diminished in frozen-thawed semen. Side-to-side oscillation may be a reflection of cooling, or it may be an artifact, representing the jostling of nonmotile sperm by motile ones.

To assess spermatozoal motility, a drop of undiluted semen is placed on a warm slide, covered with a warm coverslip, and examined by phase-contrast or light microscopy using the 40× and 100× objectives. Very concentrated samples should be diluted with warm 2.9% sodium citrate or phosphate-buffered saline solution to permit careful evaluation of individual spermatozoa. The percentage of motile sperm and the vigor of their movement are then estimated. In the normal dog more than 70% of the sperm should show rapid, steady, progressively forward motility. Although normal parameters for the feline spermiogram have not yet been adopted, reports of semen collected by electroejaculation and artificial vagina describe 60% to 85% progressively motile sperm. Spermatozoa that move in circles or in another nonlinear manner usually do so because of morphologic defects in the tail or midpiece.

#### Morphology

The sperm head is composed of the nucleus, which is covered proximally by the acrosome. The equatorial segment of the head represents thinning of the acrosome. The postacrosomal sheath and cell membrane cover the sperm head distally. The sperm tail is composed of the neck, midpiece, principal piece, and end piece. Often, the principal piece and end piece are collectively referred to as the tail. The neck is composed of laminated fibers and implantation plates that connect the midpiece to the head at the implantation fossa. A mitochondrial helix surrounds the axoneme of the midpiece. The axoneme is composed of nine microtubule doublets surrounding a central pair of singlet microtubules. A fibrous sheath of nine outer dense fibers surrounds the axoneme of the principal piece. The outer dense fibers gradually dissipate, and the end piece begins where the fibrous sheath ends. During spermatogenesis residual cytoplasm is extruded at the level of the midpiece.

Teratozoospermia refers to abnormal spermatozoal morphology. Morphologic abnormalities are sometimes classified as being primary or secondary or as being major or minor. Primary abnormalities are usually attributed to abnormal spermatogenesis in the testicle, whereas secondary abnormalities are attributed to errors in epididymal maturation or improper sample handling. Because the morphologic abnormality does not always reflect the site of the lesion, the abnormality should be described specifically (e.g., bent tail). Abnormalities are also classified according to their likely effect on fertility as being of either major or minor importance (Table 60-1). Abnormalities in the size and shape of the head, acrosome, midpiece, or proximal tail, and proximal droplets are usually considered the most severe (Fig. 60-2). Loose or detached heads, or acrosomes that are otherwise normal, distal droplets, and bent tails are considered less severe, although they may be the first abnormalities noted after a testicular insult. These classifications were developed for evaluation of fresh semen. The relative significance of some abnormalities, such as the acrosomal reaction, may differ in frozen-thawed semen because they may then reflect irreparable damage during processing.

Morphology can be assessed in unstained samples using phase-contrast microscopy. Many abnormalities can also be seen in unstained samples using routine light microscopy with properly adjusted light intensity and low condenser

**TABLE 60-1** 

### Classification of Morphologic Defects in Canine Spermatozoa

CLASSIFICATION	LOCATION			
	HEAD	MIDPIECE	TAIL	
Major	Macrocephalic; microcephalic Pyriform (pear shape) Nuclear vacuoles (diadem or crater defect) Binucleate (ridged sperm) Double head Acrosomal condensation (knobbed, nipple)	Proximal cytoplasmic droplet Kinked Bent (reflex) Ruptured All abnormalities except distal droplet	"Dag" defect Double tails	
Minor	Detached, otherwise normal, heads Nuclear condensation Swollen or detaching acrosome	Distal cytoplasmic droplet	Bent Simple coiling

Morphologic appearance of canine spermatozoa.

position, but more information can be gained when the samples are stained. Although many stains can be used to evaluate sperm morphology, in veterinary medicine the most common are eosin-nigrosin stains (e.g., Society for Theriogenology morphology stain). In dogs and cats modified Wright's stain (Diff-Quik®, VWR Scientific Products) is a better choice because there is less chance of stain-induced artifact in canine semen, and the staining characteristics using Diff-Quik correlate well with biomarkers of feline spermatozoal health (Mota et al., 2006). Another advantage over eosin-nigrosin stains is that other cells, such as red blood cells and white blood cells, are also stained and easily recognized. Stained slides are examined microscopically under oil immersion. A minimum of 100, but preferably 200,

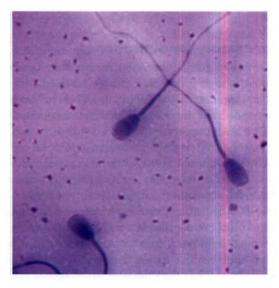

FIG 60-3 Canine sperm stained with Diff-Quik.

spermatozoa is classified as being normal or abnormal (Figs. 60-2 to 60-4). Fewer than 20% of the spermatozoa in semen samples from normal dogs have morphologic abnormalities. Electron microscopy may provide additional useful information in selected cases.

Bent tails deserve special mention because they may be artifactually induced by cold shock and by stain or diluent of improper pH or osmolality. Finding excessive numbers of bent tails in a sample previously assessed as having had normal motility strongly suggests the possibility that the bent tails were caused by the stain because sperm with bent tails usually cannot move with a straight, forward progression. Stain-induced abnormalities and those resulting from improper sample handling should not be found in subsequent, properly handled aliquots of the sample. Persistence of morphologic abnormalities is an indication for further diagnostic evaluation, including semen culture.

Canine spermatozoa with pyriform head and abnormal midpiece; phase-contrast microscopy. (Courtesy Dr. Patricia Olson, Morris Animal Foundation, Englewood, Colo.)

# **Spermatozoa Concentration**

The number of normal motile sperm has a direct effect on fertility. Although pregnancies can be achieved with fewer sperm, a minimum of 200 million motile sperm are usually recommended for intravaginal artificial insemination in dogs. Doing so is expected to yield normal pregnancy rates and litter size. Fewer numbers of sperm or samples with high numbers of abnormal sperm yield lower pregnancy rates and/or smaller litter size. The negative effects of some sperm defects can be overcome (compensated for) by increasing the number of sperm inseminated, whereas others cannot. In dogs the volume of the ejaculate and thus the concentration of sperm are influenced most by the volume of sperm-free prostatic fluid. For this reason the number of sperm in the total ejaculate, rather than the number of sperm per ml of semen, is assessed. The number of sperm is determined using a hemocytometer. The sample to be counted is usually diluted 1:100 using white blood cell/platelet dilution pipettes (Unopette; Becton-Dickinson and Co.). It may be unnecessary to dilute oligozoospermic samples before counting. To calculate the number of sperm per ejaculate, the number of sperm per ml as determined by the hemocytometer is multiplied by the total volume (ml) of the sample collected. Spectrophotometric methods may also be used to determine the sperm count. The number of sperm per ejaculate in normal dogs is  $300 \times 10^6$  to  $2000 \times 10^6$ . Average counts of 30  $\times$  10<sup>6</sup> to 300  $\times$  10<sup>6</sup> sperm per ejaculate are reported for cats.

There is great interdog and intradog variation in the number of sperm in any given ejaculate from normal fertile dogs. The breed of dog, size of the testes, degree of arousal, and frequency of ejaculation affect the number of sperm ejaculated. Because the spermatogenic potential is directly related to testicular size, smaller breeds of dogs are expected to have fewer sperm per ejaculate than large breeds of dogs. Although it has been stated that sperm production is also directly related to body weight, this holds only for animals

in normal body condition. The relationship between sperm production and body weight is lost in obese dogs. Daily ejaculation depletes extragonadal reserves from the epididymis and ductus deferens, causing an immediate and dramatic reduction in the number of sperm ejaculated, but in normal males the numbers are often still within the normal range. To minimize this effect, at least 1 day, and preferably 3 to 4 days, should elapse between collections. This is especially important for semen being collected for freezing and for subfertile males in any setting. As a general rule, a total number of less than  $200 \times 10^6$  sperm in any sample from a mature dog should be considered abnormally low (oligozoospermic), regardless of the breed of dog.

## **Volume**

The volume of seminal fluid, and therefore the concentration of the sperm, varies according to collection technique. Typically, electroejaculation yields higher volume and lower concentration than does the use of an artificial vagina. The seminal volume is determined directly from the calibrated tube into which the sample is collected. Volumes tend to be smaller in young dogs than in mature dogs. Volume does not usually correlate with fertility unless the animal fails to ejaculate an adequate amount of the sperm-rich fraction. For intrauterine AI in bitches, a volume of 4 ml or less is used. This is accomplished by centrifugation of the sample to concentrate the number of sperm/unit volume.

#### Color

The color is assessed by direct visualization. Dog semen is normally white to opalescent and opaque. Inflammatory cells and squamous epithelial cells may also cause the seminal fluid to be opalescent. Inflammatory cells can originate from anywhere in the urinary or genital tracts, including smegma from the preputial cavity. Yellow seminal fluid usually indicates the presence of urine. To avoid urine contamination, dogs should not be allowed to micturate immediately before semen collection. Some males urinate during ejaculation, which is not normal. They are usually subfertile. Red or redbrown semen usually contains blood. Blood in a canine ejaculate usually originates from the prostate, or it results from damage to the surface of the penis during collection. The latter source of hemorrhage can easily be excluded by prompt inspection of the penile surface. Complete cytologic evaluation of the semen is important, especially in cases of infertility and when the sample has an abnormal color.

#### Cytology

In addition to the spermatozoa, all cells in the semen sample should be evaluated. Cytologic examination of the third fraction of the ejaculate is very helpful in the evaluation of canine prostatic disorders. A finding of red blood cells indicates hemorrhage, whereas a finding of white blood cells and macrophages indicates inflammation somewhere in the urogenital tract. Fewer than 2000 white blood cells per ml, or up to 7 white blood cells per high power field, is considered normal in canine semen. Dogs with leukospermia should be

tested for *Brucella canis* (see Chapter 58), and the semen should be cultured for aerobes, anaerobes, and *Mycoplasma*. Some epithelial cells are normally present in dog semen, and their numbers increase with sexual rest. They are also present in the prepuce and on skin. Crystals may be found in samples contaminated with urine or with talc from the collection equipment. When excessive numbers of cells other than spermatozoa are found, further diagnostic assessment of the urogenital tract may be warranted.

# Seminal Alkaline Phosphatase

Alkaline phosphatase is produced in the canine epididymis and the feline testis and/or epididymis. Therefore the enzyme can be used as an indicator that epididymal fluid, which should contain high numbers of motile sperm, is present in the sample. The seminal alkaline phosphatase activity in whole semen from normal dogs may be as high as 4000 to 5000 IU/L or greater and greater than 100,000 IU/L in cat seminal plasma. Azoospermia with low seminal alkaline phosphatase activity may indicate bilateral obstruction distal to the epididymes, or ejaculation may have been incomplete. Azoospermia with high alkaline phosphatase indicates failure of sperm production or bilateral obstruction at the rete testis. Alkaline phosphatase activity in seminal fluid is determined by the same methods used to determine alkaline phosphatase activity in serum.

# Seminal pH

In some species changes in the seminal pH have diagnostic significance. The pH of canine seminal fluid and of prostatic fluid normally ranges from 6.3 to 7.0 and from 6.0 to 7.4, respectively, even in the presence of genital tract disease. Therefore determination of the seminal or prostatic fluid pH is rarely of diagnostic importance in dogs. Feline seminal fluid has a pH of about 6.6.

#### Interpretation of Semen Evaluation

The seminal characteristics thought to correlate best with fertility are the total number of sperm per ejaculate and the motility and morphology of spermatozoa. The quality of a canine semen sample is a reflection of (1) spermatozoal production during the past 62 days; (2) epididymal maturation during the past 14 days; (3) the extragonadal sperm reserves, which may take up to 7 days to be replenished in normal dogs; and (4) the spermatozoal output of that particular ejaculation. The finding of normal semen is not proof of normal fertility, however, because the male must also have normal libido and normal mating ability. Nevertheless, a dog with normal semen is expected to successfully impregnate a bitch if other factors are favorable. Likewise, the finding of abnormal semen does not necessarily indicate sterility unless there is persistent azoospermia or complete, true necrozoospermia. Even males with normal fertility, as demonstrated by breeding trials, may on occasion have a sample that is not within the expected normal ranges, particularly with regard to total sperm count. However, evidence shows that when fewer than 60% to 80% of the sperm are morphologically normal or when progressive motility is less than 50%, canine pregnancy rates are poor. Although it has been stated that prolonged abstinence contributes to poor semen quality because of spermatozoa senescence, it is unlikely that abstinence alone causes the quality of previously normal semen to diminish to the point of oligozoospermia and less than 60% normal morphology and motility. To help establish a prognosis or to resolve doubt about the cause of an unsatisfactory sample, the dog should be reevaluated several times over a period of at least 2 months. Recovery from a testicular insult may not be reflected by improved seminal quality for more than 3 to 5 months.

#### **BACTERIAL CULTURE OF SEMEN**

Quantitative and qualitative culture of the semen is indicated (1) as a routine part of the diagnostic evaluation of infertility in the male; (2) when excessive numbers of inflammatory cells are identified in the semen; and (3) in dogs with suspected bacterial prostatitis, epididymitis, or orchitis. Clinically significant growth of >10<sup>5</sup> colony-forming units (CFUs) of aerobic and anaerobic bacteria and Mycoplasma are recovered from more than half of normal fertile dogs that have no cytologic evidence of inflammation in the seminal fluid. Conversely, 30% of aerobic cultures from dogs with large numbers of white blood cells in the seminal fluid yielded no growth. For these reasons it has been recommended that semen culture be included as a routine part of the evaluation of canine infertility, irrespective of cytologic findings suggestive of infection. For culture results to be meaningful, an aseptic technique and sterile collection devices should be used. To limit contamination from the preputial cavity, the preputial orifice should be cleansed and smegma flushed off the surface of the penis before semen is collected. The spermrich fraction and the prostatic fraction of the canine ejaculate should yield fewer than 100 CFUs of bacteria per milliliter, whereas normal feline seminal plasma may contain more than 10,000 CFUs of bacteria. Results of semen cultures must be interpreted in conjunction with the clinical signs, the results of the cytologic evaluation of the ejaculate, and the variety of species of bacteria grown.

The normal bacterial florae of the prepuce and distal urethra are the same organisms most frequently isolated from normal canine and feline semen and from dogs with bacterial prostatitis, orchitis, or epididymitis. The normal florae of the distal urethra and prepuce consist predominantly of aerobic organisms, but anaerobic organisms are also found. Pasteurella multocida, β-hemolytic Streptococci, and Escherichia coli are the organisms most commonly isolated from dogs, whereas β-hemolytic E. coli, Pseudomonas aeruginosa, and Proteus mirabilis are the most common in cats (Boxes 60-1 and 60-2). The number of CFUs per milliliter of semen attributable to urethral contamination reportedly varies from 100 to 10,000. A separate culture of the material from a urethral swab, obtained before ejaculation, can be used to identify urethral organisms. Alternatively, the first fraction and the initial portion of the second fraction of the canine ejaculate can be discarded (i.e., not

submitted for culture). The number of urethral organisms contained in the later seminal fractions then tends to be reduced. Separately culturing each fraction of the canine ejaculate may help show whether the infection is in the testes and epididymis (second fraction) or in the prostate gland (third fraction). In most dogs the first fraction consists of only a few drops of fluid and is difficult to separate from the second fraction.

In dogs with epididymitis or orchitis, a culture specifically for *Brucella canis* should be requested (see Chapter 58). Specimens for anaerobic, *Mycoplasma*, and *B. canis* culture must be handled promptly and carefully because these organisms are sometimes more difficult to isolate than aerobes. The veterinarian should contact the microbiology laboratory to obtain specific recommendations concerning the submission of these samples. Special media, such as Anaerobic Culturette (Becton-Dickinson), is often recommended. Despite widespread concern among dog breeders, the role of *Mycoplasma* as a spontaneous cause of canine infertility remains to be fully clarified (see Chapter 58).

#### DIAGNOSTIC IMAGING

In the evaluation of male reproductive disorders, radiography is used primarily to assess the size of the prostate gland

and identify metastatic lesions in dogs with suspected prostatic adenocarcinoma. Ultrasonography is very useful to identify and characterize lesions within the prostate, testis, and epididymis; to help determine the cause of testicular or scrotal swelling; to assess the character of the spermatic cord in suspected cases of torsion; and to help establish the location of undescended testes. Ultrasonography is routinely used to guide biopsy needles for obtaining specimens from the prostate gland and focal lesions within the testis or epididymis.

# **HORMONAL EVALUATION**Testosterone

Testosterone is produced by the interstitial (Leydig) cells of the testes, under the control of LH and GnRH. It is secreted in a pulsatile manner that occurs about every 80 minutes in male dogs. In normal male cats the nadir concentrations may be below the levels of detection of some assay systems. There is also a diurnal rhythm, with the lowest serum concentrations in the morning and the highest at night. The serum testosterone concentration is most frequently measured to determine the presence and functional status of the testes. It is useful to differentiate previously castrated males from those with bilateral cryptorchidism or those in which an

intraabdominal testis was left after castration of a scrotal testis. It may also be of interest in evaluation of intersex animals. A single random determination is often not helpful because the nadir concentrations can be very low and values from intact animals may overlap with those for castrated males. Provocative testing is necessary to adequately assess testosterone production. This is done by measuring the serum testosterone concentration before and after the administration of human chorionic gonadotropin (hCG) or gonadotropin releasing hormone (GnRH).

Because the preferred protocols and the reference ranges vary greatly among laboratories, consultation with the laboratory is important. For example, in hCG stimulation protocols the serum testosterone concentration is typically measured before and 2 to 4 hours after the administration of hCG (40 to 50 IU/kg, administered intramuscularly in dogs and cats; or 250 IU per cat, administered intramuscularly). In GnRH stimulation protocols samples are typically obtained before and I hour after administration of GnRH (0.22 µg/kg, administered intravenously in dogs; 1.0 to 2.2 µg/kg, administered intramuscularly in dogs; 25 µg/cat, administered intramuscularly). Reference ranges for intact male dogs from a large veterinary diagnostic laboratory are 2.6 to 13.9 nmol/L and 13 to 17.3 nmol/L, before and after GnRH, respectively. Castrated male dogs and cats have serum testosterone concentrations of <0.5 nmol/L. In contrast, another veterinary diagnostic laboratory's ranges for intact male dogs are 0.19 to 26.3 ng/ml and 0.46 to 22.1 ng/ml and for castrated dogs 0.01 to 0.24 ng/ml and 0.02 to 0.42 ng/ml, before and after hCG, respectively; and the reference range for serum testosterone concentrations in castrated cats overlaps that of intact male cats (0.10 to 2.3 ng/ml versus <0.5 ng/ml, respectively).

Finding high serum concentrations of testosterone, with or without the administration of hCG or GnRH, indicates the presence of at least one testicle. Animals with only one testis and intersex animals may have testosterone values between those typically found in castrated and intact males after hCG or GnRH administration. Testosterone is sometimes measured in the evaluation of infertile males, but testosterone deficiency is rarely documented as a cause, or effect, of acquired infertility in dogs or cats. Congenital hypogonadism is characterized by abnormally small testes, which lack normal spermatogenesis and testosterone production.

Finding low serum concentrations of testosterone after hCG or GnRH administration in an otherwise healthy male almost always indicates previous castration because Leydig cells are quite resistant to thermal injury, toxic injury such as that caused by chemotherapeutic agents, and infectious agents, unless the entire testicle is destroyed by the process. Low testosterone concentrations could also indicate exposure to drugs such as ketoconazole that interfere with steroid hormone production or drugs that suppress GnRH or LH, such as gonadal steroids or GnRH antagonists (See the section on contraception in Chapter 56). Severe malnutrition can damage Leydig cells.

Because the development and maturation of the penile spines in cats and the prostate gland in dogs are androgen dependent, they serve as bioassays for the presence of DHT. Penile spines begin to appear in intact male cats at about 12 weeks of age; they regress by 6 weeks after castration. The finding of penile spines indicates the presence of testicular tissue and justifies a presumptive diagnosis of cryptorchidism in tomcats that do not have palpable testes in the scrotum. Finding a prostate gland in a supposedly castrated dog that is of normal size for a sexually intact dog indicates either prostatic neoplasia or the presence of a retained testicle. Administration of exogenous androgens would be another possible explanation in both species.

# Gonadotropins: Follicle-Stimulating Hormone and Luteinizing Hormone

The gonadotropins FSH and LH are produced by the pituitary under the control of hypothalamic GnRH (see Chapter 56; Fig. 56-4). They are secreted in a pulsatile manner. LH pulses occur about every 100 minutes during daylight hours and approximately every 80 minutes during darkness. FSH supports Sertoli cell function and spermatogenesis. LH stimulates testosterone secretion by the Leydig cells of the testis. The gonadal hormones, in turn, feed back to the hypothalamus and pituitary. After gonadectomy this negative feedback control of the gonadotropins is lost, and serum concentrations of LH and FSH are persistently elevated. This could also occur with the rare condition of gonadal dysgenesis. Serum LH concentration in normal male dogs reportedly

ranges from 0.2 ng/ml to less than 20 ng/ml. Normal FSH concentrations in healthy dogs reportedly range from 20 to 293 ng/ml.

To avoid unnecessary laparotomy, serum concentrations of LH can be measured to determine the presence or absence of gonads in animals with unknown reproductive status, such as those newly acquired by shelters or private owners. Males with very high LH have been castrated. Males with low LH have one or both testicles. If the testes are not in the scrotum, the male is cryptorchid. Much less likely causes of low LH would be exposure to exogenous sex hormones or a hypothalamic-pituitary lesion causing hypogonadotropic hypogonadism. Males with hypogonadism have abnormally small testes with diminished (or absent) spermatogenesis and testosterone production. The secretory capacity of the pituitary gonadotropins can be assessed by determining LH and/or FSH before and after administration of GnRH. A point-of-care, semiquantitative immunochromogenic assay for LH (ICG Status-LH®, Synbiotics) has been intermittently available. Few commercial laboratories offer validated quantitative assays for LH or FSH for veterinary species at this

#### **TESTICULAR ASPIRATION AND BIOPSY**

Testicular biopsy or aspiration and epididymal aspiration are usually reserved for animals that have been thoroughly investigated by other noninvasive means but in which no cause of infertility has been identified. Aspiration, biopsy, or both are indicated early in the evaluation of animals with discrete, focal lesions or in those with marked changes in the consistency of the testis or epididymis. The cytologic evaluation of testicular aspirates can identify inflammatory cells, sperm, neoplastic cells, and infectious agents. Testicular aspiration is usually reserved for the evaluation of discrete lesions rather than the assessment of spermatogenesis because tissue architecture is not preserved and the progression of spermatogenesis cannot be assessed. Fine-needle (i.e., 25 gauge) aspiration of the testes is performed in a manner similar to the aspiration of other masses. Sedation may be required in some dogs and is usually recommended for animals undergoing epididymal aspiration. In the absence of equipment to collect semen from cats, cytologic evaluation of a testicular aspirate could be used to confirm the presence of sperm.

Seminiferous tubule architecture, the progression of spermatogenesis, and interstitial and Sertoli cell numbers can be evaluated in specimens obtained by biopsy. Histopathology can also be used to determine whether there is inflammation or neoplasia within the testicular parenchyma. It has been shown that biopsy of a normal testis has no deleterious effect on semen quality in normal dogs. General anesthesia is required for animals undergoing testicular biopsy. The initial surgical approach is similar to that used for open castration except that the testis is not lifted out through the skin incision. When the proper vaginal tunic and the adherent tunica albuginea are incised, normal testicular tissue promptly bulges through the incision site. This bulging testicular tissue is excised for histopathologic and microbiologic evaluation.

The proper vaginal tunic/tunica albuginea is closed. Then the common vaginal tunic is closed, the testis is replaced in the scrotum, and the closure is as in a routine castration. Alternatively, the skin is incised with a scalpel, the testis is immobilized, and a biopsy needle is pushed through the tunic into testicular tissue. Incisional biopsy provides larger tissue specimens than does needle biopsy, but this method also causes greater damage to testicular parenchyma. Testicular tissue for histopathologic evaluation must not be fixed in formalin because artifacts are produced. Zenker's, Bouin's, glutaraldehyde, and Karnovsky's fixative are recommended, depending on whether tissues are to be embedded in paraffin or plastic. Some clinicians prefer glutaraldehyde over Bouin's for the epididymis. It is recommended that the pathologist be consulted regarding the preferred fixative before obtaining the specimen.

Complications from testicular aspiration or biopsy are not common if a careful, gentle, and aseptic technique is used. However, some of the potential complications could adversely affect the future fertility of the dog. These include swelling, local hyperthermia, infection, hemorrhage, and the formation of sperm granulomas. We routinely rinse away residual scrub solutions and apply an ice pack to the biopsy site while the dog is recovering from anesthesia to minimize swelling and local skin irritation. All pertinent noninvasive tests should be performed before biopsy is considered.

Noninflammatory, degenerative conditions of the testes vary in severity from diminished spermatogenesis to a complete absence of germ cells and collapse of the seminiferous tubules. Sometimes, only Sertoli cells remain. The less severe lesions are potentially reversible if the underlying cause can be eliminated. Unfortunately, the histologic appearance of testicular specimens obtained from animals with degenerative conditions of the testes rarely indicates the initiating cause. Chemical toxins and thermal and radiation injury can all cause testicular degeneration that may progress to testicular atrophy. The Leydig and Sertoli cells may be spared. Libido is maintained if the Leydig cells are not affected. Chronic testicular infection can also result in testicular degeneration. In this event evidence of the etiologic agents and inflammation may no longer be present.

Suppurative inflammation of the testes is characterized by infiltration of neutrophils. Macrophages and giant cells may also be found. Bacterial or mycotic infections are the usual cause. Viral orchitis, which occurs in some species, has not been reported in dogs. Immune-mediated reactions to sperm, mycotic infection, and *Brucella canis* infection are the most common causes of granulomas in the canine testicle.

If lymphocytes and plasma cells are found, the orchitis is usually thought to be immune mediated, but this does not exclude the possibility that infection was the initiating cause. For example, chronic *B. canis* infection is characterized by lympho-plasmacytic inflammation that is thought to be caused by antisperm antibodies produced as a result of the infection. Because the antigens that are unique to spermatozoa are usually not accessible to immune surveillance, any-

thing that disrupts the integrity of the seminiferous tubules or the blood-testis barrier has the potential to expose sperm antigens and incite an immune response. By this mechanism, testicular trauma, infection, or neoplasia may cause lymphocytic orchitis. Often, the cause of canine lymphocytic orchitis is not found, and sterility ultimately occurs. Foci of lymphocytes can be found in testicular biopsy specimens from apparently normal cats of all ages. The significance of these is unknown, but they are most prevalent in cats older than 8 to 9 years of age.

# DIAGNOSTIC APPROACH TO INFERTILITY

Normal seminal quality, normal desire to breed (libido), and normal ability to mate are all necessary for normal fertility in males. Therefore the diagnostic approach to infertility must investigate all three of these factors (see Fig. 60-5). Dogs achieving pregnancy rates of less than 75% when bred to apparently normal females using proper breeding management should probably be evaluated for subfertility because pregnancy rates of 85.4% ± 12.4% have been reported for privately owned, fertile stud dogs in which two matings per estrus were done. Pregnancy rates of greater than 90% are expected in well-managed commercial breeding colonies because individual animals with poor fertility are likely to be promptly culled.

The diagnostic approach begins with a complete history and physical examination. The history should assess the male's past breeding performance, breeding management, fertility of the females to which he has been bred, and current or previous health problems (Box 60-3). Some common drugs and metabolic disorders that are known to affect male fertility are listed in Box 60-4.

BOX 60-3

Vaginal cytology findings?

Ovulation timing?

4. Fertility of the female

Previously produced pups?

Subsequently produced pups?

5. Other health problems, test results, and medications

Assessment of the male's libido and mating ability can help narrow the differential diagnoses. A normal male may appear to lack libido if it is not in its established territory, if it is less dominant than the female or another male in the immediate vicinity, if it is inexperienced or frightened, or if it prefers a different partner. Some normal males show no interest until the female is actually in estrus, as opposed to proestrus. Dogs that are accustomed to semen collection may no longer be interested in natural service despite normal arousal and a willingness to ejaculate. Daily ejaculation, especially over a week or two, and ejaculation more often than once a day are other factors that can diminish the libido of normal male dogs. Frequent ejaculation does not diminish libido in tomcats. Excessive endogenous or exogenous glucocorticoids, stress, and pain also cause decreased libido in dogs. Libido also appears to decrease with advancing age.

Generally, mating ability is determined by physical, mechanical, and neurologic factors governing mounting, erection, intromission, and ejaculation. Orthopedic disorders of the rear legs; spine; and, less commonly, the front legs may prevent mounting or intromission but do not usually affect libido and ejaculatory ability unless they are painful. Semen collection and artificial insemination could be used

in such animals. Some animals may exhibit normal arousal and mount only to dismount before attempting intromission. It is often difficult to determine whether this behavior is caused by inadequate libido or by inadequate mating ability. This behavior is also often exhibited when a vaginal abnormality is encountered and also in some males accustomed to semen collection. Painful conditions often diminish libido as well as interfere with mating ability.

A complete physical examination should be performed to assess the animal's overall health and identify congenital or heritable abnormalities that should be grounds for excluding the male from the breeding program. Many metabolic and physical abnormalities can adversely affect spermatogenesis, libido, and mating ability. The testes and epididymes are palpated to determine their size, shape, consistency, and location. In situations of unilateral disease, there is urgency to establish and correct the cause before the condition affects the contralateral testis. This can occur by direct extension of the disease process itself or as a result of local swelling, pressure, and hyperthermia, all of which are deleterious. Finding abnormally small testes in an infertile male justifies a guarded prognosis for recovery of fertility, irrespective of the underlying cause. Testicular atrophy is common in dogs older than 10 years of age. The American Kennel Club will not register puppies sired by dogs 12 years of age or older without documentation of semen quality. The canine prostate is palpated per rectum and transabdominally. The penis and prepuce are palpated and inspected. Because the penis must be extruded from the prepuce for a thorough examination to be performed, as well as for semen to be collected in dogs, the two are often performed together. This is contraindicated if the history indicates the animal may have a penile lesion that could be aggravated by sexual arousal.

Anatomic abnormalities reported to cause difficulty in mating include phimosis, a persistent penile frenulum, an abnormally short os penis in dogs, and entanglement of the penis in preputial hair in cats. Tomcats that fail to grasp the queen's neck in the proper location may not be in the correct position for intromission. This is seen in some inexperienced males and in mating pairs with disparate body lengths. Male dogs are often reluctant to breed bitches with anatomic abnormalities of the vulva or vagina. Usually, neither shows outward signs of discomfort other than failure to mate; thus it may be difficult to discern whether intromission does not occur because of a female or a male problem.

A thorough neurologic and orthopedic examination should be performed. Neurologic disorders can interfere with mounting, erection, intromission, and ejaculation. For example, motor nerve dysfunction can cause difficulty with mounting and intromission, but semen collection for AI may be possible in such animals. Sensory or autonomic disturbances can cause difficulty with erection (and therefore with intromission in cats) and ejaculation. Semen collection by electroejaculation may or may not be possible in such animals, depending on the location of the lesion.

Semen evaluation is a crucial part of evaluating male infertility (Fig. 60-5). In addition, the semen of infertile

males should be submitted for aerobic, anaerobic, and *Mycoplasma* culture, and *B. canis* testing should be performed in dogs. Males with a history of infertility but that currently have normal semen, normal libido, and normal mating ability are now normal. Such males may have recovered from their previous infertility, the breeding management (e.g., timing of insemination) could have been inappropriate, or the female may have been infertile. Normal males should be bred again to fertile females using optimal breeding management. If the semen is abnormal, further evaluation of the reproductive tract is indicated. Semen is judged to be abnormal if inadequate numbers of sperm are found, if the motility of sperm is inadequate, if sperm morphology is abnormal, or if the semen contains excessive numbers of other cells (white blood cells, macrophages, red blood cells).

Abnormal motility (asthenozoospermia) and morphology (teratozoospermia) are often the first indicators of gonadal damage, irrespective of the cause. Morphologically abnormal sperm often do not have normal motility. Causes include primary testicular disease, metabolic and endocrine disorders, transient insults (e.g., fever), incomplete ejaculation, and iatrogenic causes. Sperm in semen from young dogs and dogs that have not mated for a long time may show poor motility, and the semen may contain more than the usual number of morphologically abnormal sperm. Iatrogenic causes include temperature shock, exposure of the semen sample to a stain of improper pH and osmolality, and exposure of the sample to latex rubber, plastics, and other spermicidal agents.

Infertile animals with abnormal semen should be reevaluated in 4 to 7 days or sooner if an iatrogenic cause is suspected. Care should be taken at that time to ensure that the entire sperm-rich fraction is collected and that improper handling does not damage the sample. If abnormalities persist, semen culture and ultrasound of the reproductive tract are indicated. A metabolic evaluation (e.g., complete blood count, serum biochemistry panel, urinalysis) is also appropriate. If no other abnormalities are identified, semen should be reevaluated in 2 to 3 months before additional testing is done. If the problem persists, additional testing is indicated, as discussed in the section on acquired infertility.

# OLIGOZOOSPERMIA AND AZOOSPERMIA

A decrease in the total number of sperm per ejaculate may occur with or without abnormalities in sperm morphology or motility. Sperm numbers may be less than normal (oligozoospermia), or sperm may be completely absent (azoospermia). The concentration of sperm per ejaculate may decline because of abnormalities in spermatogenesis or ejaculation. The clinician must always exclude the possibility that the entire sperm-rich fraction was not collected before proceeding further. This is ensured by repeat semen collection. In dogs an estrous bitch and the administration of prostaglan-

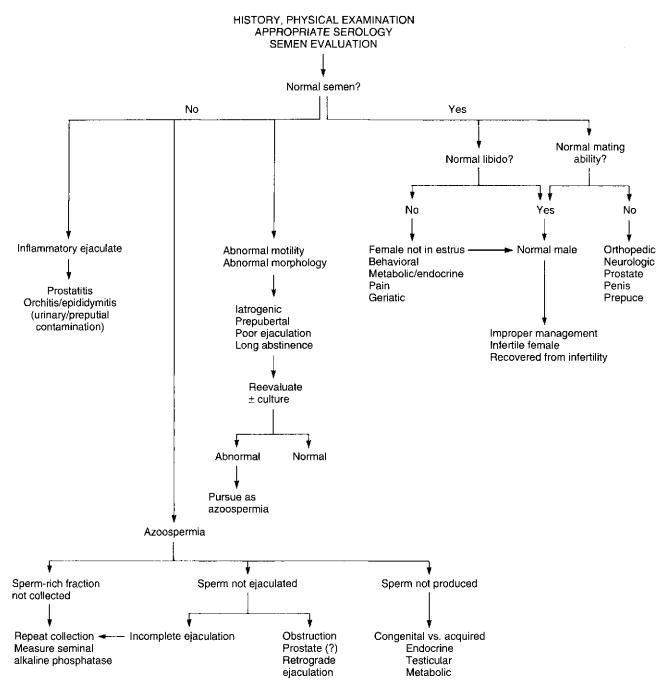

FIG 60-5 Diagnostic approach to male infertility.

din  $F_{2\alpha}$  should be used to maximize the number of sperm ejaculated (see p. 953). In cats another series of electrical stimulation should be given because the occasional azoospermic sample happens in normal males.

Spermatogenesis is a complex process that can be affected by environmental factors such as scrotal temperature; metabolic disorders, especially endocrinopathies; toxins and drugs; and infection. A thorough history taking and physical examination, ultrasound examination of the reproductive tract, semen culture, and standard laboratory tests help identify these possibilities. In addition, oligozoospermia and azoospermia may result from primary testicular failure or bilateral obstruction of the ductus deferens or epididymes. Because bilateral obstruction could occur at the level of the prostate gland, the prostate should be carefully evaluated. Measuring the seminal alkaline phosphatase activity (see p. 957) should help determine whether epididymal fluid was collected. High seminal alkaline phosphatase activity indicates that epididymal fluid, which should contain high numbers of motile sperm, was collected and that obstruction

to flow from the epididymes is apparently not the cause of the low sperm count.

Retrograde ejaculation of semen into the urinary bladder rather than out the urethra is another cause of oligozoospermia. This condition is thought to be neurogenic in origin, perhaps resulting from inadequate pressure in the proximal urethra or neck of the bladder. Some spermatozoa normally pass retrograde during ejaculation but substantially more do so during electroejaculation than during natural copulation. In the event of pathologic retrograde ejaculation, the volume of semen or the number of spermatozoa discharged is lower than normal. Retrograde ejaculation is diagnosed on the basis of finding excessive numbers of sperm in urine after ejaculation. Urine may be obtained by catheterization or cystocentesis. Some sperm are normally found in urine, but large numbers, especially approaching those in discharged semen, are considered abnormal. Treatment with α-adrenergic drugs (e.g., pseudoephedrine, 4 to 5 mg/kg, administered orally q8h or twice, 3 hours and 1 hour, before breeding) to increase urethral tone in dogs with retrograde ejaculation has been recommended, but experience with this treatment is limited.

The treatment of oligozoospermia and azoospermia depends on finding and eliminating the cause. Unfortunately, this is not always possible. Oligozoospermic males may be subfertile rather than infertile. It is assumed that sperm reserves and spermatogenesis are poor in oligozoospermic males; therefore they should be bred judiciously. This means allowing for adequate time between breedings so that sperm reserves can be replenished, performing insemination at the optimal time determined by ovulation timing, and breeding only to healthy, fertile females. Dogs with as few as  $20 \times 10^6$  to  $100 \times 10^6$  sperm per ejaculate have been reported to successfully impregnate normal, fertile bitches when ejaculation has been limited to twice, done at a 2-day interval. Intrauterine, rather than intravaginal, insemination may also be considered.

Oligozoospermia may or may not progress to azoospermia, depending on the cause. As a general rule, azoospermic males tend to remain azoospermic, especially if testicular size is abnormally small. The finding of small testes in an infertile male suggests the presence of congenital hypoplasia or acquired testicular atrophy or fibrosis, none of which is likely to be reversible. Because recovery from a testicular insult is slow and because canine spermatogenesis takes 62 days, the animal could reasonably be evaluated every 2 months for 6 to 12 months.

#### CONGENITAL INFERTILITY

Congenital causes of infertility should be considered in azoospermic animals that have no history of siring a litter or other reproductive activity. Abnormalities of the hypothalamic-pituitary-gonadal axis, such as hypogonadotropic hypogonadism; anatomic abnormalities of the Wolffian duct system, such as atresia; and disorders of sexual differentiation, such as intersex, are possible causes. Successfully correcting the congenital causes of infertility is unlikely. The diagnostic evaluation necessary to confirm a specific cause of congenital infertility can be quite extensive unless the external genitalia are abnormal or an infertile tomcat happens to have a calico or tortoiseshell coat color. The black and orange coat color each require an X chromosome to be expressed. Because male cats normally have only one X, they cannot express both coat colors. Therefore a male cat with calico or tortoiseshell color has either XXY or one of several reported chimeric states. Some of these cats are phenotypically normal males with normal spermatogenesis, presumably because of chimerism with the normal feline 38 XY karyotype in the gonadal tissue.

The phenotypic, gonadal, and chromosomal sex of the animal can be determined. The chromosomal sex can be determined by karyotyping. The phenotypic sex is determined by physical examination of the external genitalia. The internal genitalia (Müllerian and Wolffian duct derivatives) can be examined by ultrasonography, laparoscopy, or laparotomy. The gonadal sex can be assessed by endocrinologic evaluation (serum testosterone and LH concentrations) and gonadal biopsy. Otherwise, the diagnostic plan is the same as that for males with acquired infertility.

# ACQUIRED INFERTILITY

Animals with acquired infertility are known, or at least thought, to previously have had functionally and anatomically normal reproductive tracts. In some instances the onset of infertility or subfertility may be identified by a review of the breeding record, looking for a diminution in litter sizes and pregnancy/whelping rates. In other cases the time of onset of infertility is never determined. A thorough history should pay special attention to the possibility of toxin- or drug-induced infertility, excessive stress, or excessive frequency of ejaculation. A complete physical examination, semen evaluation and culture, ultrasonographic evaluation of the reproductive tract, and B. canis serology in dogs should be done. If these fail to establish the diagnosis, a thorough metabolic and endocrine evaluation should be done before more invasive procedures, such as testicular biopsy, are performed.

Bacterial infection of the testes, epididymides, or scrotum can cause alterations in spermatogenesis as a result of the destructive properties of the organisms themselves and as a result of local swelling and hyperthermia. *B. canis, Mycoplasma*, and herpes virus infections are discussed in Chapter 58. The role of bacterial prostatitis in canine infertility is unclear, but most theriogenologists consider bacterial prostatitis to be a common, potentially reversible cause of infertility. Appropriate antibiotic therapy should be initiated if the semen culture is positive for pathologic numbers of bacteria. Appropriate antimicrobial therapy should continue for a minimum of 2 to 4 weeks, or longer in the case of chronic bacterial prostatitis.

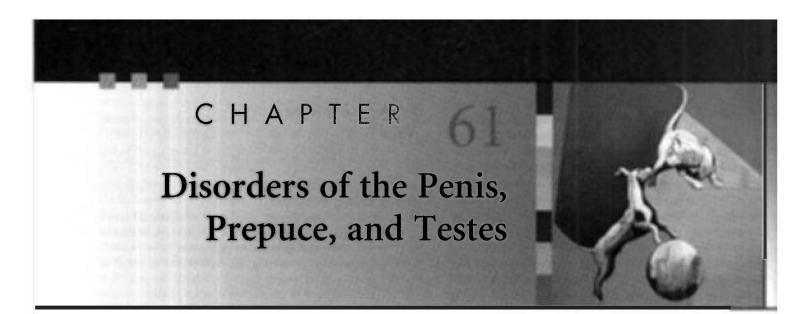

A variety of pharmaceutical agents have been empirically used to enhance semen quality in many species. The effect of drugs and nutriceuticals on the spermiogram depends on the cause of the problem. As discussed earlier, prostaglandin  $F_{2\alpha}$  has been shown to increase the number of sperm ejaculated and the ease with which semen is collected from normal dogs. In oligozoospermic and azoospermic dogs with pathologically high serum concentrations of estradiol and low serum concentrations of testosterone, treatment with an aromatase inhibitor corrected the hormonal concentrations and improved semen quality, although not to expected normal values. Treatment with vitamin E improved the spermiogram in dogs being given dexamethasone, presumably by protecting against oxidative stress. Whether vitamin E would improve semen quality in otherwise normal animals is not known because studies in rabbit, ram, and boar have yielded conflicting results.

There are anecdotal reports that treatment with GnRH or prolactin improved semen quality in dogs with abnormal spermiograms, but these reports lack evidence of the underlying pathophysiology, such as GnRH or gonadotropin deficiency or hyperprolactinemia. Glycosaminoglycans, omega-3 fatty acids, and vitamin C have also been tried. A dietary supplement containing docosahexaenoic acid (DHA), vitamin E, and selenium (PROSPERM®, Minitube America) has been used to improve semen quality in stallions and boars. Another antioxidant supplement (CellAdvance®, Vetri-Science Products) and a carnitine supplement (Motility Plus®, Platinum Performance) are also available. With few exceptions, there is not yet evidence of efficacy of these products in the treatment of canine infertility. Were these to be used, the duration of treatment would probably be at least 4 to 8 weeks because the canine spermatogenic cycle is about 60 days.

Testicular aspiration or biopsy should be considered when the abnormalities in the spermiogram have not improved after several months, especially in animals with normal testicular size. Testicular biopsy may be unwarranted in animals with testes that are already substantially smaller than normal because the testicular degeneration, atrophy, or fibrosis that cause small testicles are usually considered irreversible. Testicular biopsy specimens from cats older than 7 years show diminished spermatogenesis and degeneration of seminiferous tubules compared with the findings in younger cats. These are considered typical age-related changes. Testicular atrophy is common in dogs older than 10 years. A portion of the biopsy specimen should also be submitted for bacterial culture. The following histologic lesions have been identified in dog testes: neoplasia, suppurative and nonsuppurative inflammation, mycotic orchitis, lymphocytic orchitis, granulomatous orchitis, spermatogenic arrest, and testicular degeneration. There is limited information available on cats other than information on the testicular changes associated with aging.

#### PENILE DISORDERS

#### PENILE TRAUMA

Traumatic injury of the penis occurs in dogs and cats as a result of fighting, being hit by cars, mating inappropriately, and jumping through or upon, rather than over, barriers. Hematomas, lacerations (Fig. 61-1), and fracture of the os penis are injuries that may occur. Penile injuries are usually painful. Other clinical signs include swelling, bruising, and hemorrhage. The prepuce may or may not be similarly affected, depending on whether the penis was extruded (as it would be if erect) when the injury occurred. The diagnosis is made by visual examination of the penis and radiographic examination of the penile urethra and os penis. The integrity of the urethra should be evaluated by retrograde urethrography whenever significant penile trauma is identified. Ultrasonography and color-flow Doppler may help differentiate penile hematoma from priapism.

Treatment includes cleansing of the wounds and debridement if necessary. Lacerations may require surgical closure using absorbable sutures. An antibiotic cream should be

applied to the surface of the penis, and the penis should be protruded from the prepuce twice daily until the lesions are healed. This is done to prevent adhesions between the penis and the prepuce from forming. Sexual arousal and other types of excitement must be avoided until the penile lesion is completely healed because erection before then is likely to result in hemorrhage and possibly dehiscence.

Fractures of the canine os penis are very uncommon but are often associated with a urinary outflow tract obstruction or a urethral tear. In addition to the local signs associated with the trauma, these animals may have signs referable to a distended urinary bladder or postrenal uremia. The treatment adopted depends on the severity of the urethral damage and fracture displacement. As an emergency treatment, the urinary bladder may be decompressed by cystocentesis. An indwelling urethral catheter may be placed while the urethra heals. Urethral tears should be sutured if necessary. Urethrotomy or urethrostomy could be considered in some circumstances to temporarily or permanently divert urine flow. Systemic antibiotics should be administered to prevent urinary tract infection. Displaced fractures of the os penis can be immobilized with orthopedic wires. Immobilization is not required in animals with fractures that are not displaced because the penis itself provides adequate support. Occasionally, calluses that form during the healing of the os penis obstruct the urethra. It may be necessary to amputate the penis in the event of severe penile trauma.

#### **PRIAPISM**

Priapism is abnormal, persistent erection that is not associated with sexual arousal. The neurophysiology of erection includes sympathetic innervation via the hypogastric nerve, parasympathetic innervation via the pelvic nerve, and somatic and sensory input via the pudendal nerve. Parasympathetic innervation is considered to be responsible for stimulating erection, and sympathetic innervation is considered to be responsible for stimulating ejaculation. During the normal process of erection, relaxation of sinusoidal smooth muscle and increased flow through the arteries and arterioles facilitate rapid filling of the sinusoidal system, which in turn compresses the venous channels and occludes

FIG 61-1 Penile laceration in a Maltese.

outflow. During the process of detumescence, the trabecular smooth muscle contracts, enabling the venous channels to reopen, and the trapped blood is expelled.

Spinal cord lesions, general anesthesia, phenothiazine administration, and thromboembolism are reported causes of priapism. Venous occlusion at the base of the penis, due to any cause, could result in priapism. In many cases the cause of priapism is undetermined, but the outcome is occlusion of venous outflow and stagnation of blood that will eventually clot in the cavernous sinuses. In addition, ischemic necrosis is common. Fortunately, priapism occurs rarely in dogs and cats.

Some high-strung dogs transiently develop erections when they are excited for any reason. This is not priapism. These transient erections in highly excitable dogs usually diminish as the dog matures. If not, castration, with or without behavioral modification, is usually curative. Priapism is also different from the erection that occasionally persists in some dogs for longer than expected after copulation or semen collection. In these cases, if the estrous bitch is still present, she should be removed from the premises. The male dog should be taken out of the room in which copulation or semen collection took place. These distractions are often sufficient and the erection subsides. If not, sedation or application of cold water compresses could be considered. Priapism should also be differentiated from other causes of penile swelling, such as hematoma or edema. Penile hematomas usually form as a result of trauma or bleeding disorders. Edema usually occurs as a result of paraphimosis. Simple visual inspection and palpation of the penis are usually sufficient to differentiate the conditions. An ultrasound and/or color-flow Doppler examination may help differentiate hematoma from priapism.

During priapism clotting of the blood trapped in the cavernous sinuses, ischemia, and necrosis develop quickly. Therefore pharmacologic intervention, if it is to be successful, must be done within hours. Nonischemic priapism may respond to pharmacologic treatment with anticholinergic or antihistaminic agents, such as diphenhydramine and benztropine. Benztropine contains the active ingredients of atropine and diphenhydramine; a dose of 0.015 mg/kg intravenously has been suggested for dogs. The  $\beta$ -adrenergic

FIG 61-2 Priapism and paraphimosis in a German Shepherd Dog.

agonist terbutaline has also been used successfully in the treatment of priapism in men. Surgical drainage and intracorporeal lavage have also been reported as successful treatments. Unfortunately, many of the reported cases in dogs and cats were not presented to veterinarians until the condition had been present for days to weeks, by which time necrosis necessitated penile amputation or perineal urethrostomy.

During priapism (Fig. 61-2) the penis should be protected against additional damage or irritation that may perpetuate the problem or invite the development of sequelae, such as edema, thrombosis, fibrosis, penile paralysis, or necrosis. Physical treatments include cleansing the penis, applying antibiotic cream, and attempting to maintain the penis within the prepuce until the condition subsides.

#### MISCELLANEOUS PENILE DISORDERS

Vesicles, ulcers, pyogranulomatous lesions, warts, and neoplasia of the penis have been identified in dogs. The clinical signs are similar and include a preputial discharge, excessive licking of the prepuce or penis, or a mass protruding from the prepuce. These lesions are differentiated by visual examination, exfoliative cytologic studies, bacterial and fungal cultures, and biopsy. Transmissible venereal tumor (TVT) is the most commonly reported penile tumor in dogs (see Chapter 57). The macroscopic appearance of TVT and penile warts may be similar. In our experience, penile warts often resolve spontaneously after biopsy of the lesion (Fig. 61-3). The cause of vesicular lesions is uncertain. Canine herpes virus has been implicated but is usually not documented. Herpes virus infection is discussed in Chapter 58. Hyperplasia of the lymphoid follicles at the base of the penis may have a similar appearance to vesicles. Lymphoid follicular hyperplasia is thought to develop as a result of chronic irritation. Ulcers and pyogranulomatous lesions are uncommon, but when present they seem to be associated with infection and balanoposthitis.

Congenital penile disorders other than a persistent penile frenulum are rare. Penile hypoplasia has been noted in dogs and cats. Some affected animals have had an abnormal complement of sex chromosomes. In most the penile hypoplasia has been an incidental finding. In one dog it was associated with urine pooling in the preputial cavity. Diphallia, or duplication of the penis, has been reported in dogs and cats. Hypospadia is an anomaly in closure of the urethra that occurs because of a defect in the androgen

FIG 61-3
Penile warts in a geriatric Dachshund.

FIG 61-4
Hypospadia involving the urethra, penis, prepuce, and scrotum of an English Bulldog pup.

receptor(s). The result is one or more abnormal openings into the urethra anywhere along its length. The penis, prepuce, and sometimes the scrotum are simultaneously and similarly affected (Fig. 61-4). Hypospadia has been reported more often in dogs than in cats. Besides the abnormal appearance of the external genitalia, clinical signs include urinary incontinence and urinary tract infection. Affected animals may have additional congenital anomalies, such as cryptorchidism. Surgical correction may be considered.

## PERSISTENT PENILE FRENULUM

Under the influence of androgens, the surfaces of the glans penis and the preputial mucosa normally separate before or within months of birth, depending on the species of animal. If this separation does not occur, connective tissue persists between the penis and the prepuce. In dogs the persistent penile frenulum is usually located on the ventral midline of the penis (see Fig. 61-5). A persistent penile frenulum may cause no clinical signs, or it may be associated with preputial discharge or excessive licking of the prepuce. Persistent frenulum may cause the penis to deviate ventrally or laterally so that the dog is unable or unwilling to mate. The diagnosis is made by visual examination. Treatment is surgical excision, which can often be done using sedation with local anesthesia because the frenulum tends to be a sheer, avascular membrane.

Persistence of the adhesions of the prepuce and penis has been seen in male cats that are castrated between 7 weeks and 5 months of age, but the prevalence of this condition in the general cat population, irrespective of neuter status or age at castration, is unknown. Failure of the glans penis and preputial mucosa to separate prevents the penis from being fully extruded or causes deviation of the erect penis (see Fig. 61-5). The clinical significance, if any, of the failed penile-preputial separation seen in some cats neutered at very young ages remains to be determined.

A, Persistent frenulum in a dog. B, Failure of complete separation of the penile and preputial mucosa in a cat.

# BALANOPOSTHITIS

Inflammation or infection of the preputial cavity and penis, balanoposthitis, is very common in dogs and rare in cats. The offending organisms are usually members of the normal preputial flora (see Box 60-1), although infection with canine herpes virus and Blastomyces has also been reported. Balanoposthitis usually causes no clinical signs other than a purulent preputial discharge that is quite variable, from a scant white smegma to a copious green pus. The discharge associated with balanoposthitis is not sanguineous unless the cause is neoplasia or foreign material. The diagnosis of balanoposthitis is made by physical examination of the penis and preputial cavity all the way to the fornix, in a search for foreign material, neoplasia, ulceration, or inflammatory nodules. Cultures and cytologic studies are rarely performed, unless herpes virus or fungal infection is suspected because of the vesicular appearance of the lesions or the presence of similar lesions elsewhere on the body. The treatment of balanoposthitis is usually conservative. The hair should be clipped from the preputial orifice and from the surrounding area if discharge has been accumulating there. Flushing the preputial cavity with antiseptic solutions (e.g., chlorhexidine, povidone-iodine) seems to be helpful. Topical antibacterial medications may be instilled into the preputial cavity. Castration usually results in diminished preputial secretions. In persistent or refractory cases, cytology, culture, and endoscopic examination should be considered.

#### **PARAPHIMOSIS**

Paraphimosis is a condition in which the penis is prevented from retracting back into the preputial cavity. It occurs most frequently after an erection in dogs. Therefore it is seen quite often after semen collection and occasionally after copulation. Paraphimosis may occur in longhaired cats when the penis becomes entangled in the preputial hairs. Otherwise, it is uncommon in cats. The protruded penis usually becomes trapped because the prepuce has turned in on itself (see Fig. 61-2). Presumably, this occurs because the skin or hair at the preputial orifice adheres to the surface of the penis and is pulled into the preputial cavity as an erection subsides. The inverted preputial skin then compromises the circulation to the protruded penis.

The signs of paraphimosis depend primarily on its duration. Initially, the exposed penis is normal in appearance and nonpainful. However, after several minutes the exposed penis becomes edematous (see Fig. 61-6) and increasingly painful. In addition to the damage caused by continued poor circulation, the exposed penis is subject to trauma. The surface becomes dry, and fissures may develop. The urethra is usually not damaged. The unexposed penis and the uninvolved prepuce are normal and nonpainful. Long-standing paraphimosis may result in gangrene or necrosis.

Paraphimosis is diagnosed by visual inspection. The exposed penis may have become so painful that sedation or anesthesia is required, although this is not usually necessary

FIG 61-6
Correction of paraphimosis. Note edematous tip of penis.

early on. Treatment involves returning the prepuce to its normal configuration, restoring circulation to the penis, and replacing the penis in the preputial cavity. This is accomplished by gently sliding the prepuce in a posterior direction, such that more of the glans penis is protruded. The prepuce is thus retracted until the cranial aspect of the prepuce "unfolds" and the preputial orifice is exposed (see Fig. 61-6). Circulation to the penis usually improves immediately after the prepuce is restored to its normal configuration. Penile edema then begins to subside. The surface of the penis is cleansed or debrided as necessary. Topical antibiotic or an antibiotic-steroid cream may be applied if the penile mucosa has been damaged. Even though some penile edema may still be present, the prepuce usually slides easily over it and the penis is thus replaced in the preputial cavity. Water-soluble lubricant should be applied as necessary to accomplish this. If, even after circulation is restored, the edematous tissue is of sufficient magnitude that the prepuce cannot slide over it, application of pressure with a cool water compress is usually effective in resolving the edema.

Rarely is it necessary to enlarge the preputial orifice. If it is, an incision is made on the ventral midline of the prepuce, and after the penis is in place, the incision is closed in separate layers. The penis will usually stay within the preputial cavity, and penile swelling quickly subsides. The degree of swelling can be assessed by palpating the penis through the prepuce if there is concern that protruding the penis from the preputial cavity will be unduly painful. Rarely does the still-swollen penis protrude from the prepuce. The preputial orifice may be temporarily (1 to 24 hours) sutured closed, but there is the risk that urine will accumulate in the preputial cavity during this time. If the penis has become necrotic or gangrenous, penile amputation is indicated.

Conditions other than paraphimosis may also cause the penis to protrude from the prepuce. These include priapism, phimosis, an abnormally short prepuce in dogs, and a ring of preputial hair in cats. Penile trauma may cause penile hematomas to form. The swelling associated with the extravasation of blood may be sufficiently severe to cause the penis to protrude. Treatment is conservative and consists in

protecting the exposed penis from trauma. The preputial orifice may also be temporarily closed. If possible, the hematoma is allowed to resolve spontaneously; otherwise, it can be drained surgically. Foreign material within the preputial cavity or around the glans penis may also cause the penis to protrude.

#### **PHIMOSIS**

Phimosis is a condition in which the penis is trapped within the preputial cavity. It usually occurs as a congenital defect in which the preputial opening is abnormally small and the penis cannot protrude. Phimosis is uncommon in cats and dogs. It may be recognized in young animals as a cause of a urinary outflow tract obstruction or of the dribbling of urine that has accumulated in the preputial cavity. Phimosis may be recognized in an affected male when it is unable to copulate. It is treated by surgically enlarging the preputial orifice. The preputial hairs of longhaired cats may entangle the preputial orifice, causing clinical signs similar to phimosis. It is treated by clipping the preputial hairs.

## **TESTICULAR DISORDERS**

#### CRYPTORCHIDISM

Cryptorchidism is the failure of one or both testes to descend into the scrotum. The condition may be unilateral or bilateral. The undescended or retained testicle may be located in the abdominal cavity, in the inguinal canal, or in the subcutaneous tissue between the external inguinal ring and the scrotum. On rare occasions a cryptorchid testis is found in the perineal subcutis dorsal or lateral to the scrotum. The testicular hormone insulin-like factor 3 (also called relaxinlike factor), which is produced by prenatal and postnatal Leydig cells, mediates the transabdominal testicular descent from the caudal pole of the kidney to the inguinal canal. It induces growth and differentiation of the gubernaculum from the caudal suspensory ligament. The transabdominal migration of the fetal testis is independent of androgens, whereas the inguino-scrotal descent is mediated by testosterone. Testosterone causes regression of the cranial suspensory ligament. During the inguino-scrotal phase of migration, there is shortening of the gubernaculum and eversion of the cremaster muscle. The normal time of testicular descent has not been firmly established in dogs or cats. In cats testicular descent appears to be a prenatal event. In dogs testicular descent is complete by 10 to 42 days of age. Although later descent is possible, a diagnosis of cryptorchidism is likely if the testes are not palpable within the scrotum by 8 to 10 weeks of age. Because the testes are so small and mobile in infant animals, some veterinarians have recommended that a diagnosis of cryptorchidism not be made until a dog is 6 months old.

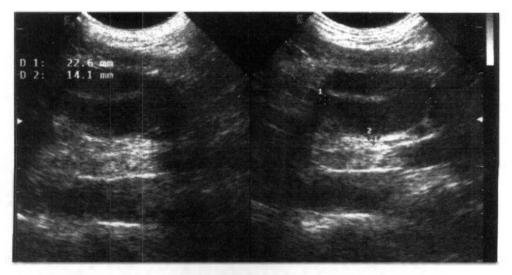

Unilateral cryptorchidism is more common than bilateral cryptorchidism in both dogs and cats. The undescended testis is found in the abdomen or in the subcutaneous tissues in the inguinal area with about equal frequency. Bilaterally

undescended testes are most often found in the abdomen. There is no apparent difference in the prevalence of right- or left-sided unilateral cryptorchidism in dogs or cats. True monorchidism (congenital absence of one testis) is extremely rare. The incidence of cryptorchidism in the general animal population is unknown. Of 1345 cats presented for castration, 23 (1.7%) were cryptorchid, which is similar to the findings in 3038 feral cats trapped for neutering, of which 35 (1.2%) were cryptorchid and 46 (1.5%) were thought to have been previously castrated. The prevalence of cryptorchidism in dogs in various hospital populations is reported between 1.2% and 5%. Cryptorchidism was found in 44 (2.6%) of 1679 dogs from a pet store.

Although the specific mode(s) of inheritance is not known in either species, cryptorchidism is generally believed to be associated with family lineage. Therefore the prevalence is likely to vary with breed and species. For example, the incidence of cryptorchidism in 2929 boxers was 10.7% (Nielen et al., 2001). The simplest model consistent with the evidence available is a sex-limited, autosomal recessive mode of inheritance. The expression of the trait is limited to males, but the genetic defect is not linked to the sex chromosomes. Therefore both males and females carry the gene and can pass it on to their offspring, but only the homozygous males are phenotypically abnormal (cryptorchid) and readily identifiable. Females cannot express the trait regardless of their genotype. Heterozygous (carrier) males have normal phenotype; in other words, they are not cryptorchid. Therefore, with the exception of a homozygous × homozygous cross, which would produce cryptorchid male puppies, some litters are likely to contain all phenotypically normal males, whereas other litters from the same dam and sire will have affected males. However, the inheritance of cryptorchidism is known to be more complex than that explained by the simple autosomal recessive, sex-limited model, providing yet another possible explanation for why each litter from the same breeding pair does not always have the same phenotypic result.

The undescended testis is not normal, Spermatogenesis is usually completely absent, especially in intraabdominal testes, because of the higher temperature. Spermatogenesis does not fully recover, even if the testis descends into the scrotum at a later time. Because interstitial cells continue to produce testosterone, libido and secondary sex characteristics are normal. Bilaterally cryptorchid animals are sterile, which effectively removes them from the gene pool. Although the number of spermatozoa in the ejaculate of animals with unilateral cryptorchidism is less than that of normal animals, they are expected to be fertile. Therefore unilaterally cryptorchid males will perpetuate the trait if allowed to breed.

There is no known medical treatment that can reliably cause cryptorchid testes to descend. Favorable results occasionally have been noted in male dogs and in boys treated with human chorionic gonadotropin. However, it is generally believed that the apparent success is actually the result of the coincidental spontaneous descent of mobile testes that were located very near the scrotum. There appear to be no reports of the successful medical management of intra-

**FIG 61-7**Sonogram showing an intraabdominal cryptorchid testis in a dog. (Courtesy Dr. Gustavo Sepulveda, East Lansing, Mich.)

abdominal cryptorchidism in any species. Castration of cryptorchid dogs is recommended primarily because of the increased risk of testicular neoplasia in retained testes. Ultrasonography may be helpful in locating the retained testis (Fig. 61-7).

In dogs testicular neoplasia is as much as 13 times more likely to develop in undescended than in descended testes. Because testicular neoplasia, even in scrotal testes, is so common in older dogs, this represents a significant risk. Castration of cryptorchid dogs while they are young is therefore recommended. Sometimes the cryptorchid testis is difficult to find. If, at the time of surgery, the ductus deferens, testicular vessels, or epididymis are found, it is highly likely that the ipsilateral testis also exists. True monorchidism is extremely rare. After unilateral castration, suspected monorchidism should be confirmed with appropriate hormonal testing, such as determining serum testosterone concentrations before and after gonadotropin releasing hormone (GnRH) or measuring serum luteinizing hormone (LH) concentrations. Testicular neoplasia is also more common in cryptorchid testes in men. Even after orchiopexy, the standard treatment for cryptorchidism in people, the previously ectopic testis is at greater risk for testicular cancer than the descended testis. The risk of testicular cancer in cryptorchid men treated with orchiopexy after puberty (age 13 years) is approximately twice that of men treated before the age of 13. Testicular neoplasia is rare in cats, although it has been reported in cryptorchid testes.

#### **TESTICULAR NEOPLASIA**

Testicular tumors are very common in dogs older than 10 years of age, second only to skin tumors. In most dogs testicular tumors are found incidentally during physical examination, castration, or necropsy. Testicular tumors are rare in cats. In dogs Sertoli cell tumors, Leydig cell (interstitial cell) tumors, and seminomas occur with about equal frequency

BOX 61-1

kopenia

Depressed spermatogenesis

Testicular atrophy

except in intraabdominal testes, in which the most common neoplasm is Sertoli cell tumor. The most important risk factors for testicular neoplasia are age and cryptorchidism. Testicular tumors are rare in dogs younger than 6 years of age. Testicular cancer is diagnosed almost 11 times more often in cryptorchid testes than in scrotal testes. Certain gene expressions and carcinogens are also risk factors.

# **Diagnosis**

The most common clinical sign of testicular neoplasia is enlargement of the testis. Sertoli cell and interstitial (Leydig) cell tumors can produce hormones, particularly estrogen, that cause paraneoplastic syndromes. These include atrophy of the contralateral testis, bone marrow suppression, pendulous prepuce, gynecomastia, alopecia and hyperpigmentation, and squamous metaplasia of the prostate (Box 61-1). The gynecomastia and pendulous prepuce have been referred to as *feminization*. The bone marrow suppression induced by estrogen is characterized by anemia, thrombocytopenia, and/or leukopenia. Some of the clinical signs may be related to anemia or bleeding as a result of the thrombocytopenia.

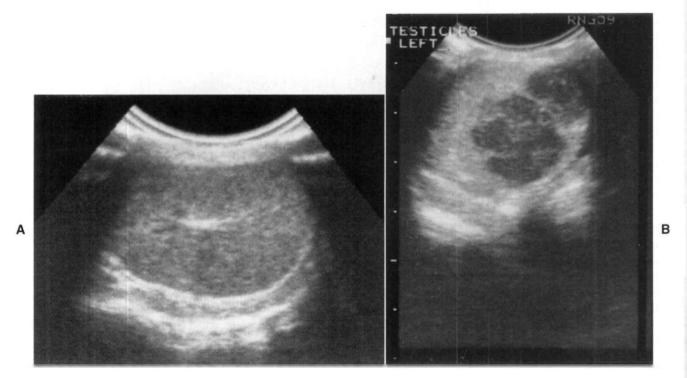

FIG 61-8
Sonogram of normal right testis (A) and left testis (B) with a seminoma in an infertile, 9-year-old English Bulldog. After hemicastration the dog sired a litter of nine pups. Hatch marks are 1 cm.

Intraabdominal testicular tumors of sufficient size may cause interference with other abdominal organs. Uncommonly, dogs with testicular tumors may be presented because of infertility, but most affected animals are past their breeding years.

The diagnosis of testicular neoplasia is usually straightforward. It should be suspected as a possible cause for any testicular mass and also feminization. The index of suspicion is highest in old, cryptorchid males. The diagnosis is most challenging in dogs that do not have scrotal testes because they may erroneously be assumed to have previously been castrated. Exfoliative cytology of the preputial mucosa may confirm the presence of excessive estrogen, which causes it to cornify like the vaginal epithelium (see Chapter 56). A testicular tumor is by far the most likely source of hyperestrogenism in a male dog, although pathologic production of sex hormones by the adrenal gland has been reported in dogs with hyperadrenocorticism. Ultrasonography is helpful in evaluating the testes of animals in which testicular neoplasia is suspected but not palpable. They have a variable echo texture. Tumors less than 3 cm in diameter are usually hypoechoic (Fig. 61-8). The larger tumors tend to disrupt normal testicular architecture and may contain focal areas of ischemic necrosis; thus large testicular tumors usually have mixed echogenicity. Ultrasonography and radiology can be used to evaluate intraabdominal testes, but testes similar in size to the diameter of the small bowel may be difficult to identify.

Fine-needle aspiration of palpable testicular masses is easily performed, but it is rarely done when the index of suspicion of neoplasia is high because tissue specimens can be obtained at the time of castration. Nevertheless, cytologic examination of aspirated material can be very helpful in differentiating a testicular neoplasm from other masses, such as abscess or granuloma, or if owners are reluctant to consider castration without a definitive diagnosis. A complete blood count is indicated to assess the possibility of bone marrow toxicity. Because most affected dogs are geriatric, a preoperative biochemical panel and urinalysis are also reasonable.

Treatment for testicular tumors is castration. If the dog has value as a stud, unilateral castration could be performed. The clinical signs associated with hyperestrogenism usually resolve promptly, except for bone marrow toxicity and infertility. The latter is not surprising, given the age of most affected dogs. The testis should always be submitted for histopathologic evaluation. Because most canine testicular tumors are benign, it would be reasonable to delay complete staging of the tumor until histopathologic confirmation of malignancy. Intraabdominal metastasis is more common than pulmonary. Treatment options for malignant and metastatic testicular tumors should be considered in consultation with a veterinary oncologist.

#### ORCHITIS AND EPIDIDYMITIS

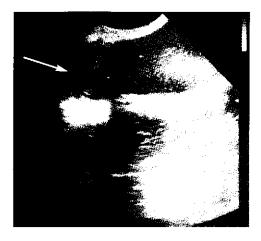

The testis or epididymis can become infected via the hematogenous route, through the ascension of pathogens from

elsewhere in the urogenital tract, or as a result of penetrating wounds. Extension or progression of infection from the epididymis to the testis, or vice versa, is common. Orchitis-epididymitis is more common in dogs than in cats. Aerobic bacteria are most often implicated. *Mycoplasma, Brucella canis* (see Chapter 58), *Blastomyces, Ehrlichia,* Rocky Mountain spotted fever, and feline infectious peritonitis are also reported to infect the testes, epididymides, or scrotum. Bacterial infection of the testes, epididymides, or scrotum causes alterations in spermatogenesis as a result of the destructive properties of the organisms themselves and as a result of local swelling, inflammation, and hyperthermia.

The clinical signs of orchitis-epididymitis vary with the chronicity of the infection. Acute infections are usually associated with swelling of the scrotum and scrotal contents and are painful. The affected epididymis or testis is enlarged, firm, and warm. The scrotal skin may be inflamed, and dogs may lick the scrotum excessively. Fever and lethargy may be present in animals with systemic infections. Conversely, some affected animals may show minimal discomfort, and the owner may not notice the acute phase. The scrotum is usually normal in animals with chronic orchitis-epididymitis. Eventually, the testis becomes soft and atrophic. Then the epididymis may seem more firm and prominent than usual. Infertility is common in animals with either acute or chronic orchitis-epididymitis, and it may be the presenting complaint.

#### Diagnosis

Orchitis-epididymitis is diagnosed on the basis of physical examination, ultrasonography (Fig. 61-9), cytology, and culture findings. Specimens for culture and cytology may be obtained by collection of semen or fine-needle aspiration of the testis. Semen from dogs with active orchitis-epididymitis contains many inflammatory cells (leukospermia) and abnormal spermatozoa. Bacteria or other infectious agents, however, are usually not seen during cytologic evaluation of

Sonogram of abnormal canine epididymis (arrow) typical of suppurative epididymitis. Normal-appearing testis is to the right.

semen. They are more commonly observed in specimens obtained by fine-needle aspiration. In animals with chronic infection and atrophy of the testes, the number of inflammatory cells and spermatozoa decreases, eventually resulting in azoospermia. Serologic tests for *B. canis* should always be performed in dogs with these clinical and cytologic findings. A thorough evaluation of the prostate gland is also warranted.

Semen cultures in dogs with active bacterial orchitisepididymitis usually yield more than 105 colony-forming units/ml of semen. However, culture results must be interpreted in light of the normal urethral florae and other clinical and cytologic findings (see Chapter 60). Microbiologic cultures may be negative in animals with chronic orchitisepididymitis. This is frequently the case in animals with chronic B. canis infection. Therefore negative culture results do not necessarily exclude infection as the inciting cause. The results of cytologic and microbiologic evaluation of semen from dogs with orchitis-epididymitis are indistinguishable from those of prostatitis. Further, prostatitis and orchitis-epididymitis may be concurrent. Therefore the prostate should always be thoroughly evaluated by palpation, ultrasonography, and cytologic evaluation of the third fraction of the ejaculate or specimens obtained by fine-needle aspiration of the prostate.

#### Treatment

Appropriate antimicrobial therapy should be initiated on the basis of culture results. Antibiotics to consider pending results of sensitivity testing are those that are usually effective against the common urogenital organisms. These antibiotics include enrofloxacin, amoxicillin, clavulanate-amoxicillin, chloramphenicol, and trimethoprim-sulfonamide, which are effective against either gram-negative or gram-positive organisms. Cephalosporins and tetracycline can also be considered. Antimicrobial therapy, determined on the basis of the results of culture and sensitivity testing, should continue for a minimum of 2 weeks. Soaking the scrotum in cool water may help to minimize the damage caused by hyperthermia and swelling. In cases of unilateral involvement, unilateral orchiectomy may be the best way to protect the apparently unaffected gonad. Antibiotics should be administered regardless of whether surgery is performed. The prognosis for recovery of fertility is poor in dogs or cats with orchitis and epididymitis, regardless of the causative organism. Orchiectomy effectively decreases the burden of infection and should be considered if fertility appears to be irreversibly lost.

# TORSION OF THE SPERMATIC CORD

Torsion of the spermatic cord is often called *testicular torsion*. Torsion of the spermatic cord occurs more often in intraabdominal testes than scrotal testes (Fig. 61-10). The clinical signs are related to the acute abdominal pain that results. If torsion of a scrotal testis occurs, pain is also the major clinical sign. There is also scrotal and testicular swelling, which can be quite pronounced. Often, the thickened spermatic

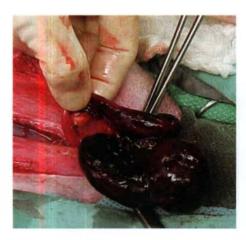

FIG 61-10 Spermatic cord torsion of an abdominal cryptorchid testicle in a dog.

cord can be palpated. Ultrasonographic examination of the affected testis and spermatic cord usually reveals the spiral course of the spermatic vessels. Treatment is unilateral orchiectomy because spermatogenesis is irreparably damaged as a result of ischemia within 1 to 2 hours of testicular torsion. Although some recovery is possible, fibrosis usually occurs.

# MISCELLANEOUS TESTICULAR AND SCROTAL DISORDERS

Whenever a lesion is found in one testis, both testes should be thoroughly evaluated. Differentiating focal lesions such as tumors, granulomas, spermatoceles or cysts can be accomplished with ultrasound and fine-needle aspiration. Spermatoceles are caused by stasis and accumulation of sperm. They occur more commonly in the ductus deferens or epididymal ducts than in the seminiferous tubules. They may be congenital or acquired as a result of trauma, including fine-needle aspiration or biopsy. They may be the result, or the cause, of local inflammation and the development of sperm granulomas. They may also be incidental findings. Cysts may arise in the seminiferous tubules or the rete testis. They are usually incidental findings during ultrasound, but, like spermatoceles, they may cause a mass or obstruction to the flow of sperm.

People often assume that an enlarged scrotum is due to testicular enlargement. Other causes of scrotal enlargement include epididymal or spermatic cord enlargement (e.g., scirrhous cord), herniation of omentum or small bowel into the scrotum, scrotal edema, or hydrocele. Hydrocele is the accumulation of fluid between the visceral and parietal

tunics of the scrotum. It may be a transudate, hemorrhage, or exudate. To differentiate among these causes, careful palpation and ultrasound of the scrotal contents are necessary. The scrotal skin is susceptible to contact irritant dermatitis. Self-mutilation of the scrotal skin sometimes occurs as a result of underlying gonadal disease. Otherwise, the considerations for problems with the scrotal skin are the same as for skin elsewhere on the body.

ACUTE BACTERIAL PROSTATITIS AND PROSTATIC
ABSCESS
CHRONIC BACTERIAL PROSTATITIS
PARAPROSTATIC CYSTS
PROSTATIC NEOPLASIA

# **OVERVIEW OF PROSTATIC DISEASE**

Disorders of the prostate gland are common in dogs but very rare in cats. They include benign prostatic hyperplasia, squamous metaplasia, bacterial prostatitis, prostatic abscess, prostatic and paraprostatic cysts, and prostatic neoplasia. Clinical signs of prostatic diseases are similar because each causes some degree of prostatic enlargement or inflammation (Box 62-1). The most common clinical signs include tenesmus, blood dripping from the urethra independent of urination, and recurrent urinary tract infections. Blood is usually found in the urine and semen from dogs with prostatic disease. Additional, nonspecific signs, such as fever, malaise, and caudal abdominal pain, are often present in dogs with bacterial infections and neoplasia of the prostate gland. Prostatic adenocarcinoma may cause an animal's gait to be abnormal as a result of pelvic and lumbar vertebral metastatic lesions. Less commonly, prostatic diseases may cause urethral obstruction, infertility, or urinary incontinence.

# DIAGNOSTIC EVALUATION OF THE PROSTATE GLAND

A complete physical examination is performed. Palpation is done to assess the size, shape, symmetry, and consistency of

the prostate as well as to detect any discomfort. This is accomplished by both abdominal and rectal palpation. The enlarged prostate is rarely located completely within the pelvic canal. There is a positive correlation between prostatic size and age and also body weight. The clinical signs and physical findings will usually localize the disease process to the prostate gland, but they are not able to differentiate among the various prostatic conditions.

Diagnostic imaging, prostatic cytologic studies, bacterial culture, biopsy, or a combination of these studies is usually required to differentiate the specific prostatic disorders. Culture results from normal prostatic fluid should yield less than 100 colony forming units (CFUs)/ml. Abdominal radiographs help define the size, shape, and position of the prostate. Prostatic length of greater than 70% of the distance from the sacral promontory to the pelvic brim on the lateral abdominal radiograph is indicative of prostatomegaly. The radiographic appearance of the sublumbar lymph nodes, lumbar vertebrae, and bony pelvis should be examined for evidence of metastasis. A positive-contrast cystourethrogram can be performed if it is difficult to differentiate an abnormal prostate from the urinary bladder and to assess the prostatic urethra. Ultrasonography provides additional information about the homogeneity of the prostatic parenchyma, the urethral diameter, and the diffuse or focal nature of the disease (Fig. 62-2). The finding of urethral invasion or destruction during diagnostic imaging is highly suggestive of prostatic neoplasia. As can be seen from the similarities of the figures in this chapter, radiographic and ultrasonographic findings do not differentiate cysts from abscesses or hyperplasia from metaplasia, prostatitis, or diffuse neoplasia.

Prostatic material for cytologic and microbiologic examination can be obtained by several methods. The rationale for prostatic massage or brush techniques is that material from the prostate may be recovered via the urethra. The accuracy of the results will depend on whether the prostatic lesion communicates in some way with the urethra. Prostatic massage is performed by placing a urethral catheter and removing urine from the bladder. An aliquot of urine is saved for future comparison. The catheter is then withdrawn

# BOX 62-1

## Clinical Signs of Prostatic Disease

#### **Common Signs**

Blood dripping from urethra without micturition Tenesmus Recurrent urinary tract infections Hematuria and hemospermia

#### **Less Common Signs**

Pain Fever Urethral obstruction Infertility Gait abnormalities

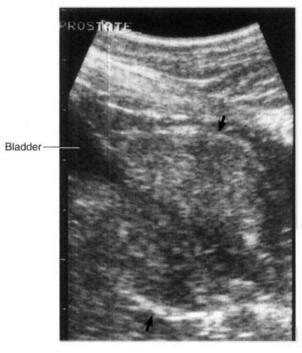

FIG 62-1 Sonogram of normal canine prostate (arrows) of an English Setter. Hatch marks represent 1 cm.

to the level of the prostate, as determined by rectal palpation; the prostate is thoroughly massaged by way of the rectum; and additional material is aspirated through the catheter. The prostatic urethra can be lavaged with sterile saline solution if an inadequate volume is recovered. The premassage and postmassage specimens are analyzed and compared. A urethral brush may also be used to obtain material for cytologic and microbiologic evaluation. In this method the brush is passed through a urinary catheter to the level of the prostate, as determined by rectal palpation. The prostatic urethra is then "brushed."

Prostatic massage is easily performed. There is a risk of rupturing prostatic abscesses or liberating septic emboli during massage. Because prostatic fluid normally refluxes into the urinary bladder, urinary tract infection is usually present whenever there is bacterial prostatitis. Conversely, urinary tract infection can exist in the absence of prostatitis. If a urinary tract infection is present, microbiologic and cytologic examination of the prostatic portion (third fraction) of the ejaculate to confirm the presence of bacterial prostatitis is more accurate than examination of specimens obtained by massage. Neoplastic cells may not be recovered in specimens obtained by prostatic massage or brush unless there is urethral invasion.

Fine-needle aspiration is an excellent method to obtain prostatic specimens for cytology and culture. Fine-needle aspiration is usually performed percutaneously, preferably with ultrasound guidance. A transrectal approach for fine-needle aspiration has also been described. The percutaneous approach is generally safe and simple if a careful technique, especially with ultrasound guidance, is used. Percutaneous ultrasound-guided biopsy of the prostate can also be performed. Prostatic biopsy is also performed via a celiotomy. After prostatic biopsy there may be mild, transient hematuria that resolves spontaneously.

#### BENIGN PROSTATIC HYPERPLASIA

Benign prostatic hyperplasia (BPH) is the most common prostatic disorder in the dog. Some degree of BPH is found in most intact male dogs older than 6 years of age. It occurs as a result of androgenic stimulation. Specifically, it is mediated by dihydrotestosterone, which causes symmetric prostatic growth. Why some males are affected and others are not is unknown. BPH is often a subclinical incidental finding on routine examination of older dogs. When clinical signs are present, the most common are tenesmus and prostatic bleeding reflected by blood dripping from the urethra in the absence of urination. This bleeding may be exacerbated by sexual arousal. Macroscopic or microscopic hematuria and hemospermia may also be found (see Box 62-1). Contrary to the situation in men, urine retention is a rare manifestation of BPH in dogs.

#### **Diagnosis**

The diagnosis of BPH is suggested when tenesmus, a sanguineous urethral discharge, hematuria, or a combination of these is found in an otherwise healthy, middle-aged or older, intact dog with symmetric prostatomegaly. Less commonly, dogs with BPH may be evaluated because of blood in the semen. The prostate gland is not painful when palpated. Radiologic studies confirm the presence of prostatomegaly (Fig. 62-2, A). Ultrasound studies should show diffuse, relatively symmetric involvement throughout the prostate (Figs. 62-2, B, and 62-3). Small, multiple, diffuse, cystic structures are commonly seen on ultrasound images obtained in dogs with BPH. Initially, prostatic enlargement is due primarily to glandular hyperplasia. This progresses to cystic hyperplasia. Cytologic examination reveals evidence of hemorrhage and

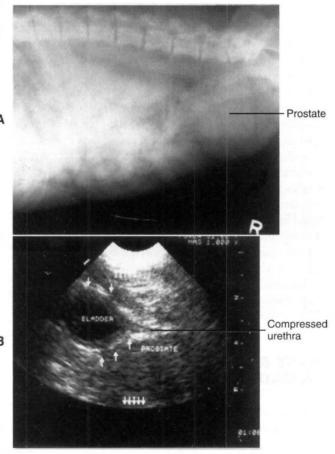

FIG 62-2
Benign prostatic hyperplasia. Radiograph (A) and sonogram (B) from the same dog showing urethral compression. Single arrows, bladder; multiple arrows, prostate.

perhaps mild inflammation but no evidence of sepsis or neoplasia. The diagnosis of BPH could be confirmed by histopathologic studies of biopsy specimens, in which hyperplastic changes, often with microscopic cysts, are found; however, biopsy is rarely necessary.

#### **Treatment**

Treatment is not necessary for asymptomatic BPH, but castration is the treatment of choice for dogs showing clinical signs of BPH. Prostatic involution is usually evident within a few weeks of castration and is complete by 12 weeks after the source of androgens is removed. Prostatic bleeding usually resolves in about 4 weeks. Castration may not be a feasible treatment option for breeding males. Such animals can be treated with antiandrogens, but this is not as effective as castration in resolution of the clinical signs, and the results are temporary. However, it may be many months before signs recur. In addition to castration or antiandrogen therapy, cysts can be treated by fine-needle aspiration under ultrasound guidance. The fluid should be submitted for bacterial culture because many cultures are found to be positive for bacteria (see later discussion of chronic bacterial prostatitis).

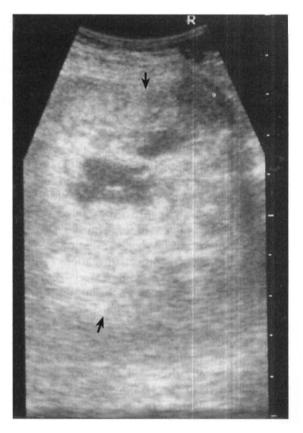

FIG 62-3 Sonogram of the cystic, hyperechoic prostate of a German Shepherd Dog with prostatomegaly  $(5.7 \times 4.6 \text{ cm})$  resulting from benign prostatic hyperplasia. Hatch marks represent 1 cm.

When castration is not a desirable option, antiandrogenic drugs may be considered. Estrogen therapy to reduce prostatic hyperplasia, although initially effective, is not recommended because estrogens can induce squamous metaplasia of the prostate, enhance the cystic changes within the prostate, and depress spermatogenesis. The dose-dependent and idiosyncratic toxic effect of estrogens on canine bone marrow is well known.

Progestins have antiandrogenic effects. At high doses they suppress spermatogenesis and spermatozoal motility, increase morphologic defects in spermatozoa, and suppress serum testosterone concentrations, despite having no apparent effect on serum luteinizing hormone (LH) concentrations. Progestins reportedly also have no apparent effect on libido in dogs, despite the fact that they suppress serum testosterone concentrations. Megestrol acetate at a dosage of 0.5 mg/kg orally, q24h for 10 days to 4 weeks, has been reported to cause the clinical signs of BPH to resolve without adverse effects on fertility in dogs, but its long-term use has not been evaluated. Delmadinone acetate is another progestin that is used to treat BPH. It is administered at a dose of 1.5 mg/kg subcutaneously at weeks 0, 1, and 4. This causes adrenal suppression for up to 21 days after the last dose but no changes in glucose tolerance or growth hormone. It is not as effective as castration in resolving prostatic bleeding. A

single subcutaneous injection of 3 mg/kg of medroxyprogesterone acetate (MPA) relieves the clinical signs of BPH for 10 to 24 months in most dogs treated (84%). Although serum testosterone concentrations were decreased after week 5, there were no apparent problems with semen quality or libido. The effects of progestins on adrenal function, growth hormone secretion, and insulin and glucose homeostasis (see Chapter 56) should be considered.

Finasteride (Proscar®; Propecia®; Merck) inhibits 5-αreductase, thereby inhibiting the conversion of testosterone to dihydrotestosterone. It is not labeled for use in dogs. Doses of 0.1 to 0.2 mg/kg q24h, or 5 mg/dog/day, orally have been studied. Relative to body weight, these doses are much higher than the 5 mg/day recommended for men with BPH. Treatment is continued for several months. Clinical signs begin to improve after 1 week of treatment. Prostatic size is demonstrably and significantly decreased by 8 weeks of treatment because of atrophy of the prostatic epithelium and fibromuscular stroma. Prostatic fluid volume will decrease; otherwise, there is no apparent effect on semen quality. Libido and ejaculation are unaffected. Serum testosterone concentration was unchanged, but serum dihydrotestosterone concentrations were significantly decreased. Although the changes induced by finasteride are reversed by 6 months after the termination of treatment, the prostate gland does not necessarily return to pretreatment sizes. At the 0.1 to 0.2 mg/kg doses, adverse effects were not reported. Finasteride is teratogenic. Therefore pregnant women must not handle the drug.

The concept of immunizing dogs against gonadotropin releasing hormone (GnRH) or LH has appeal for the treatment of BPH. Because GnRH and LH control gonadal function, blocking them would theoretically suppress testosterone production, which in turn would diminish dihydrotestosterone and prostate size. These effects might be maintained permanently or temporarily, depending on the duration of adequate antibody titers. An anti-GnRH factor product (Canine Gonadotropin Releasing Factor Immunotherapeutic®; Pfizer) is marketed in the United States for treatment of benign prostatic hyperplasia in dogs. Treatment also causes the testes to shrink and serum testosterone concentrations to decline, both of which would be deleterious to spermatogenesis.

An over-the-counter medicament made from an extract of the berry from the saw palmetto plant (*Serenoa repens*) has been marketed for relief of some of the urine retention symptoms of BPH in men. There is no evidence that it is beneficial in either dogs or men with BPH (Barsanti, et al., 2000; Bent, et al., 1998). No adverse effects were noted in the treated dogs.

# SQUAMOUS METAPLASIA OF THE PROSTATE

Estrogen-secreting testicular tumors are the most common cause of prostatic squamous metaplasia. Rarely, adrenal tumors and exogenous estrogen therapy also may cause squamous metaplasia of the prostatic epithelium and diminish the movement of prostatic fluid within prostatic ducts. The clinical signs and physical examination findings may be identical to those seen in the setting of BPH. Additional signs of hyperestrogenism (see Box 61-1) may also be present. A testicular mass may be palpable or cryptorchidism may be identified during physical examination. Increased numbers of squamous epithelial cells are often found in ejaculated or aspirated prostatic specimens. If necessary, the diagnosis can be confirmed by prostatic biopsy.

Squamous metaplasia is treated by removing the source of estrogen. This is accomplished by the castration of dogs with testicular tumors or the discontinuation of estrogenic drugs. In the absence of estrogenic drugs, the finding of prostatic squamous metaplasia in a castrated dog strongly suggests the presence of a cryptorchid testicle that was not removed. The effects of estrogen are potentially reversible. Unilateral castration might be considered for a dog that still has potential value as a stud, although it may take some time for the hypothalamic-pituitary-gonadal axis to recover.

# ACUTE BACTERIAL PROSTATITIS AND PROSTATIC ABSCESS

Bacterial infection of the prostate gland may be acute or chronic, and overt prostatic abscesses may develop in dogs with such infections. Normally, the prostate is protected against bacterial colonization by the local production of secretory IgA, the production of prostatic antibacterial factor, and the removal of organisms through frequent micturition. Presumably, the diseased prostate is more prone to infection than the normal gland. Indeed, when cultured, many of the cysts in BPH are found to have asymptomatic infection. The most common route of infection is the ascension of urethral flora. A hematogenous route of infection is also possible. The organisms most commonly isolated from the infected prostate are *Escherichia coli*, *Staphylococcus*, *Streptococcus*, and *Mycoplasma*. Occasionally, *Proteus* spp., *Pseudomonas*, or anaerobic organisms are found.

## Diagnosis

Animals with acute bacterial prostatitis or prostatic abscess usually have a history of an acute onset of severe illness, with abdominal pain and perhaps a hemorrhagic urethral discharge. Fever, dehydration, and pain on palpation of the prostate are usually present. The prostate may be normal in size or enlarged. Asymmetry, prostatomegaly, and fluctuant areas are usually palpable in animals with prostatic abscesses. Septicemia and endotoxemia can develop, in which case signs of shock may also be present. Bacterial prostatitis and prostatic abscess are diagnosed on the basis of the findings from physical examination and ultrasonography and cytology and culture of prostatic fluid. Ultrasonographic examination of the prostate identifies intraparenchymal, fluid-filled spaces consistent with abscesses (Fig. 62-4). A neutrophilic leukocytosis with a variable shift toward immaturity, signs

#### FIG 62-4

Prostatic abscesses in a 5-year-old male Mastiff treated for 1 year with intermittent antibiotic therapy for recurrent *E. coli* urinary tract infection. **A,** Precastration prostate size was  $7.0 \times 3.5$  cm. Largest abscess  $(9.9 \times 9.6$  mm) indicated by marks. **B,** 3 months postcastration prostate size was  $4.8 \times 2.6$  cm. Normal echotexture and all cystic structures resolved. (Notice different magnification of **A** and **B**.)

of toxicity in the neutrophils, and monocytosis are typically shown by a complete blood count in animals with acute infections or abscesses.

Prostatic fluid obtained by ejaculation is a good specimen for bacterial culture and antibiotic sensitivity testing. However, dogs with acute prostatitis or abscess usually are too ill or in too much pain to ejaculate. Prostatic specimens obtained by fine-needle aspiration, preferably with ultrasound guidance, are also acceptable. Cultures of prostatic specimens from dogs with bacterial prostatitis usually yield greater than 10<sup>3</sup> to 10<sup>5</sup> CFUs/ml. Culture of urine is an alternative to culture of prostatic material because normally some prostatic fluid refluxes into the bladder. Urinalysis usually shows hematuria, pyuria, and/or bacteriuria. When urinalysis findings are abnormal, urine should always be submitted for culture and sensitivity testing. Usually, cultures of urine and prostatic material grow the same organisms. Although specimens for culture can also be obtained by prostatic massage, extreme caution should be exercised when massaging the prostate of animals with acute bacterial prostatitis or prostatic abscess because of the risk of rupturing an abscess or the risk of a septic embolism developing. Cytologic evaluation of the prostatic material should be performed. This usually reveals inflammation with evidence of sepsis and hemorrhage, with macrophages found in animals with chronic infection. Unlike the situation in men, prostatic fluid pH, specific gravity, and cholesterol and zinc concentrations typically are not of diagnostic value in dogs.

#### **Treatment**

Acute bacterial prostatitis and prostatic abscesses are serious, life-threatening disorders. Treatment must be prompt and aggressive. Fluid therapy is necessary to correct dehydration and shock. Despite aggressive therapy, the morbidity and mortality associated with prostatic abscesses are high. Large prostatic abscesses are treated most effectively by surgical drainage and omentalization. The abscess may also be drained by fine-needle aspiration under ultrasound guidance. Pending the results of culture and susceptibility, treatment with a fluoroquinolone, ampicillin, or first-generation cephalosporin should be initiated. Antibiotic treatment for acute prostatitis and prostatic abscesses should be continued for a minimum of 4 weeks. Urine or prostatic fluid should be recultured a week after discontinuing antibiotic therapy and again 2 to 4 weeks later to be certain the infection has resolved. Castration should be considered. It can be performed whenever the dog's hemodynamic and metabolic status is stable enough for general anesthesia. Prostatic abscessation has been reported to recur in about 10% of treated dogs.

#### CHRONIC BACTERIAL PROSTATITIS

The primary sign of chronic bacterial prostatitis is recurrent urinary tract infection. Chronic bacterial prostatitis may be asymptomatic. Physical abnormalities are often limited to the urinary tract. Prostatic size and shape may be normal, or the prostate may be asymmetric and more firm than normal. It may or may not be painful to palpation. Ultrasonographic findings are nonspecific but typically will be of mixed echotexture with hyperechoic areas reflecting fibrosis. Confirmation of chronic bacterial prostatitis requires cytologic and microbiologic examination of urine and prostatic material, which may be obtained by fine-needle aspiration.

Chronic bacterial prostatitis may be difficult to eradicate because the blood-prostate barrier is quite effective in preventing many drugs from penetrating into the prostatic parenchyma. Erythromycin, clindamycin, oleandomycin, trimethoprim-sulfonamide, chloramphenicol, carbenicillin, enrofloxacin, and ciprofloxacin are the agents most capable of achieving therapeutic concentrations in the prostate. Antibiotic therapy should be based on culture and susceptibility results from urine and prostatic material. Treatment should be continued for at least 4 weeks. Cultures should be repeated during and for several months after discontinuing antibiotic therapy to ascertain whether resistance to antibiotics or persistent infection has developed. Castration hastens the response to treatment of chronic bacterial prostatitis.

#### PARAPROSTATIC CYSTS

Paraprostatic cysts apparently develop from remnants of the Müllerian duct or as a result of the tremendous enlargement of an existing cyst (prostatic retention cyst). In the former

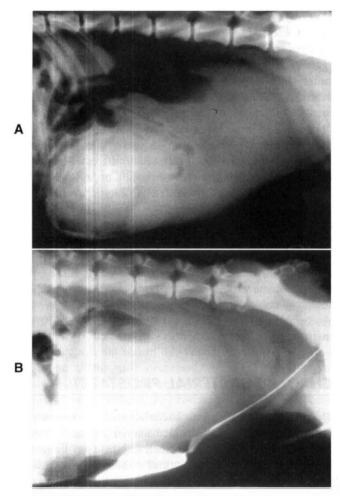

FIG 62-5
Very large, partially calcified paraprostatic cyst. Survey radiograph (A) and cystourethrogram (B) showing bladder displacement.

situation the rest of the prostate gland is essentially normal, whereas in the latter situation cystic benign hyperplasia usually exists. Often, the origin of the cyst is obscure. Paraprostatic cysts are located outside the prostatic parenchyma but are attached to the gland by a stalk or adhesions. These cysts can become extremely large and cause clinical signs, including tenesmus, stemming from mechanical interference with abdominal viscera. Otherwise, they are often asymptomatic.

The possibility of a paraprostatic cyst should be considered in the dog with a large caudal-abdominal mass. Diagnostic imaging will identify the mass as a cystic structure and will help differentiate the cyst from the urinary bladder (Fig. 62-5). Fine-needle aspiration of the paraprostatic cyst usually yields a sterile, yellow-to-serosanguineous fluid showing minimal evidence of inflammation. The treatment is castration and complete surgical excision of the cyst. In situations in which the cyst cannot be completely excised, omentalization is recommended. If this fails to resolve the problem, marsupialization could be performed, but this is a very poor alternative to extirpation or omentalization.

#### PROSTATIC NEOPLASIA

Prostatic adenocarcinoma is the most common neoplasm of the canine prostate. It occurs in older dogs, with a mean age of 10 years at the time of diagnosis. Transitional cell carcinoma arising in the urinary tract may also invade the prostate. The clinical signs and biologic behavior of both tumors in the prostate gland are similar. Prostatic adenocarcinoma is locally invasive and metastasizes to the sublumbar lymph nodes, bony pelvis, and lumbar vertebrae. The link between previous castration and the development of prostatic adenocarcinoma is unclear, but about 50% of affected dogs have been previously castrated. A benign prostatic adenoma has been reported in an intact male dog. Rarely, prostatic adenocarcinoma occurs in cats.

#### **Clinical Features**

Clinical signs include tenesmus and dyschezia, stranguria, pain, gait abnormalities, and weight loss. Palpation of the prostate usually elicits pain. The gland is usually not dramatically enlarged, but the shape may be irregular and the consistency somewhat firmer than normal. Because prostatic involution, resulting in a small gland, occurs within 12 weeks of castration, prostatic neoplasia should be the primary consideration in a previously castrated male dog found to have a "normal"-size or large prostate. Urinary obstruction rarely occurs in dogs as a result of prostatic diseases other than prostatic neoplasia, but it is fairly common in those with cancer.

#### Diagnosis

The diagnosis of prostatic neoplasia is suggested by the history, physical, and the findings of diagnostic imaging. Prostatic adenocarcinoma is usually hyperechoic relative to the normal prostate, but this is not pathognomonic. The finding of urethral invasion demonstrated by contrast radiologic studies or ultrasonography is highly suggestive of neoplasia. The diagnosis is confirmed by fine-needle aspiration or biopsy findings. Neoplastic cells may be found in specimens aspirated through a urethral catheter, especially if the tumor has invaded the urethra. Usually, neoplastic cells are not found in ejaculate specimens. The serum and seminal plasma concentrations of acid phosphatase and prostatespecific antigen are not different between normal dogs and dogs with prostatic disease. Although prostate-specific esterase concentrations are higher in dogs with prostatic disease than in normal dogs, this finding is not specific to the cause of prostatic disease.

# **Treatment**

The prognosis for dogs in which prostatic adenocarcinoma arose after castration is much worse than for dogs that are intact at the time. Prostatic adenocarcinoma in intact dogs is likely to be somewhat hormone responsive, and castration may be a beneficial part of the therapy. Prostatic adenocarcinoma in previously castrated dogs is likely to be refractive to hormonal therapy. To date, surgical (prostatectomy),

chemotherapeutic, and radiation therapy have been largely unsuccessful in improving the quality or length of life. Treatment with the nonsteroidal antiinflammatory drug piroxicam may offer some relief. Consultation with a veterinary oncologist is recommended.

# Drugs Used in Reproductive Disorders

(Note: Many of these drugs are extra-label use in small animals. Many dosages are micrograms, µg. Most have various sources, even if only one is listed herein.)

USE	DRUG	TRADE NAME	CANINE DOSE	FELINE DOSE
Abortifacient	Cloprostenol	Estrumate, Mallinckrodt	begin 25 days after LH, 1 μg/kg, SC, q48h, plus bromocriptine, 30 μg/kg, PO, q8h OR plus cabergoline, 5 μg/kg, PO,	
	A - l i - t	Ali-ina Vialana	q24h	10 15 /k-
	Aglepristone	Alizine, Virbac	10 mg/kg, SC, twice, 24 hours apart	10 or 15 mg/kg, SC, twice, 24 hours apart
	Cabergoline	Galastop, Beringer- Ingeheim; Dostinex, Pfizer	5 μg/kg, PO, q24h, 3-5 days, begin ≥ day 49	'
	$PGF_{2\alpha}$	Lutalyse, Pfizer	0.1-0.25 mg/kg, SC, q8-12h, begin ≥ day 35, until abortion complete <b>OR</b>	0.25-0.5 mg/kg, SC, q12h, begin day 45, until abortion
			0.25 mg/kg, SC, q12h, 4 days, begin during cytologic diestrus days 8-15, monitor progesterone	complete
Agalactia	Oxytocin	Various	0.5-2.0 U/dog, SC, 30 minutes before nursing for milk let- down	
	Metoclopramide	Reglan, Wyeth-Ayerst	0.1-0.2 mg/kg, PO or SC, q6- 8h for milk production	
Benign prostatic hyperplasia	Finasteride	Proscar and Propecia, Merck	0.1-0.5 mg/kg <b>OR</b> 5 mg/dog, PO, q24h	
	Anti-GnRH vaccine	Canine GnRF- immunotherapeutic, Pfizer	SC, at 0 and 4 weeks	
	Medroxyprogesterone	Depo-Provera, Pfizer	3 mg/kg, SC, once	
	Megestrol acetate	Ovaban, Shering	0.5 mg/kg, PO, q24h, 10 or more days	
	Delmadinone	Tarđak, Pfizer	1.5 mg/kg, SC, at 0, 1, and 4 weeks	

USE	DRUG	TRADE NAME	CANINE DOSE	FELINE DOSE
Dystocia*	Calcium gluconate IV	Various	10% solution, slow IV ≤ 0.2 <b>ml</b> /kg	
*No obstruction	Oxytocin	Various	maintain normal labor pattern 0.25-4.0 U/dog, IM maintain	
			normal labor pattern	
Estrus induction during anestrus	Cabergoline	Galastop, Beringer- Ingeheim; Dostinex, Pfizer	5 μg/kg, PO, q24h, until 2-5 days after onset of proestrus	
	Bromocriptine	Lactafal, Eurovet BV; Parlodel, Sandoz	5 or 20 μg/kg, PO, q12h, until onset of proestrus	
	Deslorelin	Ovuplant, Fort Dodge	1.05 or 2.1 mg, SC implant in vestibular mucosa in ventral commissure of vulva	
Estrus suppression	Megestrol acetate	Ovaban, Shering	Within first 3 days of proestrus, 2.2 mg/kg, PO, daily for 8 days, <b>OR</b> during anestrus, 0.55 mg/kg, PO, daily for 32 days	
	Medroxyprogesterone	Depo-Provera, Pfizer; Various	3 mg/kg, SC, once, <b>OR</b> 5 mg/bitch/day, PO, daily for 1-2 weeks	
	Testosterone- propionate	Various	110 mg, IM or SC, q7 days	
	cypionate methyltestosterone		2 mg/kg, IM, q14 days 25-50 mg, PO, twice weekly	
False	Deslorelin Banana printina	Ovuplant, Fort Dodge	6-12 mg, SC implant*	6 mg, SC implant
pregnancy	Bromocriptine	Lactafal, Eurovet BV; Parlodel, Sandoz	* may initially induce estrus 10 μg/kg, PO, q12h, 10-14 days	
, ,	Metergoline Cabergoline	Contralac, Virbac Galastop, Beringer- Ingeheim;	0.1 mg/kg, PO, q12h, 8 days 5 μg/kg, PO, q24h, 4-7 days	
Follicular ovarian cysts	GnRH	Dostinex, Pfizer Cystorelin, Abbott; Various	2.2 μg/kg, IM, q24h, 3 days	
Increase sperm ejaculated	$PGF_{2\alpha}$	Lutalyze, Pfizer	0.1 mg/kg, SC, 15 minutes before collection	
Induce parturition	Aglepristone	Alizine, Virbac	15 mg/kg, SC, twice on one day	
Infertility with short	Megestrol acetate	Ovaban, Shering	2 mg/kg, PO, 8 days, begin within first 3 days of proestrus	
interestrous interval	Chlormadinone	Various	0.5 mg/kg, PO, 8 days, begin within first 3 days of proestrus	
Mammary hyperplasia	Aglepristone* *will cause abortio	Alizine, Virbac in <b>if pregnant</b>	not applicable	20 mg/kg, SC once, <b>OR</b> 10 mg/kg, SC, 2 consecutive days
Ovulation induction	GnRH	Cystorelin, Abbott	50-100 μg/dog, IM, once, <b>OR</b> 2.2 μg/kg, IM, once	25 µg/cat, IM, once or twice, q24h
during estrus	hCG	Various	10-22 IU/kg, IM, once	250 IU/cat, IM, once or twice, q24h
Puerperal hypocalcemia	Calcium gluconate IV, followed by Ca	Various	10% solution, slow IV, to effect [3-20 ml]	10% solution, slow IV, to effect
Pyometra	gluconate, lactate, or carbonate PO See Box 57-2	Example: Tums	1-3 g, PO, q24h	500-600 mg, PO, q24h

# FUNCTIONAL ANATOMY OF THE NERVOUS SYSTEM AND LESION LOCALIZATION

The most important step in the diagnostic evaluation of dogs or cats with neurologic signs is establishing an accurate anatomic diagnosis (Box 63-1). A basic understanding of nervous system structure and function is essential to correctly interpret neurologic examination findings and localize lesions to clinically significant regions.

#### **BRAIN**

The brain consists of the cerebrum, the brainstem, and the cerebellum. The brainstem is further subdivided from rostral to caudal into the diencephalon (thalamus and hypothalamus), midbrain, pons, and medulla oblongata (Fig. 63-1). Neurologic abnormalities within the brain can usually be localized on the basis of clinical findings to one of three clinically important regions. These include (1) the forebrain (the cerebrum and diencephalon), (2) the pons and medulla, and (3) the cerebellum (Box 63-2).

#### **Forebrain**

The forebrain includes the cerebral cortex, cerebral white matter, basal nuclei, and the diencephalon. The cerebral cortex is important for behavior; vision; hearing; fine motor activity; and conscious perception of touch, pain, temperature, and body position (proprioception). The cerebral white matter transmits ascending sensory information and descending motor signals, and the basal nuclei are involved in maintaining muscle tone and the initiation and control of voluntary motor activity. Unilateral forebrain lesions result in a relatively normal gait but postural reaction deficits and increased muscle tone in limbs on the contralateral (opposite) side of the body. The diencephalon is important in the integration of sensory input, maintenance of consciousness and attention, and control of autonomic and endocrine functions such as appetite, thirst, temperature, electrolyte, and water balance. The olfactory nerve, cranial nerve 1 (CN1), projects onto the hypothalamus, and the optic nerve (CN2) and optic chiasm are on the ventral surface of the hypothalamus; therefore lesions in this region can result in loss of the sense of smell or contralateral visual deficits with normal pupillary light reflexes. Neurologic examination findings associated with forebrain lesions are listed in Box 63-3.

#### Pons and Medulla

The pons and medulla compose the portion of the brainstem that contains the regulatory centers for consciousness

# BOX 63-1

#### Steps in Neurologic Diagnosis

- 1. Describe the neurologic abnormalities.
- 2. Localize the lesion.
- 3. Describe any concurrent nonneurologic disease.
- Characterize the onset and progression of the neurologic disease.
- 5. Generate a list of differential diagnoses.
- Use ancillary tests, if needed, to make a diagnosis and gauge the prognosis.

(ascending reticular activating system) and normal respiration. This area provides a link between the spinal cord and the cerebral cortex through ascending sensory and descending motor tracts. These tracts cross in the rostral midbrain, such that while unilateral forebrain lesions result in contralateral limb deficits, unilateral lesions of the pons, medulla, or spinal cord cause ipsilateral (same side) deficits. Ten pairs of cranial nerves (3 to 12) originate in this region, with lesions reflecting motor or sensory dysfunction of individual nerves. Because vestibular nuclei are located in the medulla oblongata and the flocculonodular lobe of the cerebellum, lesions at this site commonly result in head tilt, disequilibrium, and nystagmus (see Chapter 68). Box 63-3 lists common neurologic examination abnormalities in patients with lesions of the pons and medulla.

## Cerebellum

The cerebellum controls the rate, range, and force of movements. It serves to coordinate muscular activity, regulate fine

## BOX 63-3

#### Signs Caused by Lesions in the Brain

#### Forebrain Lesions

Seizures

Altered mentation: depression, stupor, coma

Abnormal behavior: agitation, delirium, aggression, loss of

learned behaviors

Contralateral:

Blindness with normal pupillary light reflexes Subtle decrease in skin/facial sensation

Hemi-inattention syndrome

Normal gait

Circling, pacing towards lesion

+/- Postural reaction deficits in contralateral limbs

Normal or increased (contralateral) spinal reflexes

#### **Brainstem Lesions**

Altered mentation: depression, stupor, coma

Multiple cranial nerve deficits (CN3-CN12, ipsilateral)

Upper motor neuron tetraparesis or hemiparesis

(ipsilateral)

Postural reaction deficits ipsilateral limbs

Normal or increased (ipsilateral) spinal reflexes

Respiratory and cardiac abnormalities

#### Cerebellar Lesions

Normal mentation

Ipsilateral menace deficit +/-

Intention tremor

Hypermetric gait, truncal ataxia with normal strength

Normal knuckling and hopping (hypermetric ipsilateral)

Normal spinal reflexes

Possible paradoxical vestibular syndrome

movement, and modulate muscle tone. Lesions of the cerebellum result in a wide-based stance, ataxia (incoordination) with normal strength, and increased muscle tone (spasticity). The gait is hypermetric or exaggerated, with each limb being raised excessively during protraction and then returned more forcefully than normal to weight bearing. Cerebellar

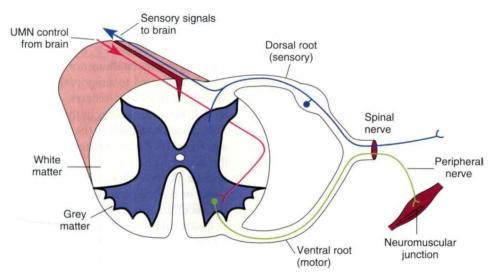

FIG 63-2 A single spinal cord segment.

lesions may also result in a fine tremor of the head that becomes more pronounced during voluntary movement such as reaching for food (intention tremor). Severe lesions of the rostral cerebellum result in opisthotonus with rigid extension of the forelimbs (decerebellate posture) (see the discussion of posture, p. 989). Box 63-3 lists the clinical signs caused by lesions of the cerebellum. Cerebellar disorders are discussed in Chapter 65.

# SPINAL CORD

The spinal cord resides entirely within the bony vertebral column. It is composed of a central H-shaped core of gray matter surrounded by white matter. Spinal cord gray matter contains the cell bodies of interneurons and lower motor neurons (LMNs). White matter is composed of nerve fibers organized into columns of ascending and descending tracts. These long tracts transmit ascending sensory information (proprioception, touch, temperature, pressure, and pain) and descending motor signals between higher centers in the brain and spinal cord neurons.

The spinal cord can be functionally divided into segments, with each spinal cord segment giving rise to one pair of spinal nerves (left and right), each of which has a dorsal (sensory) and ventral (motor) root (Fig. 63-2). The cell bodies for the LMNs supplying the thoracic limbs are in the ventral gray matter within a thickened region of the cord called the cervical intumescence (segments C6-T2), whereas the LMNs supplying the pelvic limbs originate in the lumbar intumescence (segments L4-S3; Fig. 63-3). After a neurologic examination, each limb should be characterized as normal or as having upper motor neuron (UMN) or LMN signs. This will allow localization of spinal cord lesions to one of four functional anatomical regions: spinal cord segments C1-C5, C6-T2, T3-L3, or L4-S3 (Box 63-4). Because the ascending and descending tracts to the rear limbs are located peripherally in the cord, it is common for dogs and cats with

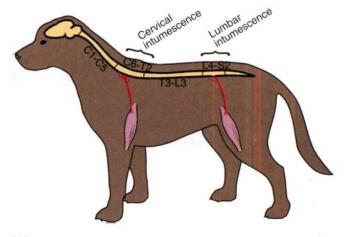

FIG 63-3
Spinal cord segments at the cervical intumescence (C6-T2) and the lumbar intumescence (L4-S3) give rise to the important peripheral nerves of the limbs.

compressive lesions of the cervical (C1-C5) cord to have more pronounced UMN deficits in the rear limbs than in the forelimbs. Also, lesions that affect only the center of the cord (central cord syndrome) in the cranial cervical (C1-C5) or caudal cervical (C6-T2) region will often produce profound UMN (C1-C5) or LMN (C6-T2) deficits in the forelimbs with minimal UMN deficits in the rear limbs.

## **Lower Motor Neuron signs**

The LMN is the efferent neuron that directly connects the central nervous system (CNS) to a muscle or gland (Fig. 63-4). Components of spinal LMNs include the nerve cell bodies within the ventral gray matter, the axons leaving the spinal canal as ventral nerve roots and spinal nerves, and the peripheral nerves formed by the spinal nerves that terminate at the neuromuscular junction in the muscle to produce

986

contraction (see Fig 63-2). Damage to any component of the LMN will result in the appearance of LMN signs in the muscles normally innervated by that particular LMN. LMN signs include flaccid paresis (weakness) or paralysis (loss of motor function), decreased or absent muscle tone, rapid muscle atrophy, and decreased or absent spinal reflexes (Table 63-1). When there is damage to the sensory component of the LMN (the peripheral nerve, spinal nerve, or dorsal nerve root), there may also be a loss of sensation in the skin and limb directly supplied by that LMN. Spinal cord lesions causing focal LMN signs are discussed in Chapter 70. Disorders affecting peripheral nerves and disorders causing diffuse LMN paralysis are discussed in Chapter 71.

### BOX 63-4

Dilated anus, fecal incontinence
LMN bladder +/-

UMN, Upper motor neuron; LMN, lower motor neuron.

### **Upper Motor Neuron Signs**

Those motor systems originating in the brain to control the LMN are UMNs (see Fig. 63-4). UMNs are responsible for initiating and maintaining normal movement, regulating the muscle tone used to support the body against gravity, and inhibiting myotactic reflexes. Components of the UMN include nerve cell bodies in the cerebral cortex, basal nuclei, and brainstem as well as the motor tracts in the brainstem and spinal cord white matter, which relay information from the higher centers to the LMN. These pathways cross the midline in the rostral brainstem so that forebrain lesions result in contralateral deficits in the limbs, whereas UMN lesions of the spinal cord, pons, or medulla oblongata result in ipsilateral deficits in the limbs (Fig. 63-5). Damage to the UMN nuclei or tracts will cause loss of voluntary motor function and a release of the inhibitory effect of UMNs on all LMNs caudal to the level of injury. The resultant UMN signs in all muscles caudal to the site of the lesion include spastic paresis or paralysis, increased extensor muscle tone, and normal to increased spinal reflexes (see Table 63-1). Associated sensory signs such as ataxia and decreased sensation in the skin and limbs caudal to the lesion reflect inter-

### FIG 63.4

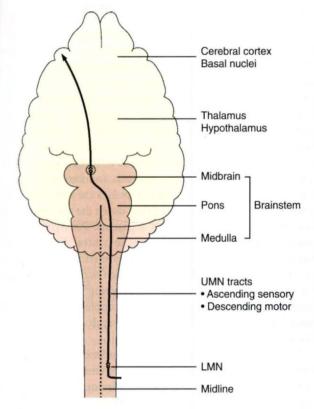

The upper motor neuron (UMN) and lower motor neuron (LMN) systems are responsible for mediating normal motor function.

**TABLE 63-1** 

### Summary of Upper Motor Neuron and Lower Motor Neuron Signs

CHARACTERISTIC	UPPER MOTOR NEURON	LOWER MOTOR NEURON
Motor function	Spastic paresis to paralysis in all limbs caudal to lesion	Flaccid paresis or paralysis at site of lesion
Postural reactions (knuckling)	Often delayed	Normal unless severe lesion
Gait	Wide-based stance, ataxic, long strides, delayed limb protraction	Short strides, limbs maintained under center of gravity
Muscle tone	Normal or increased	Decreased
Muscle atrophy	Late and mild—disuse	Rapid and severe—neurogenic
Spinal reflexes	Normal or increased	Decreased or absent

**FIG 63-5**Ascending (sensory) and descending (motor) upper motor neuron pathways cross midline in the rostral brainstem.

ruption of the UMN sensory tracts responsible for mediating proprioception (position sense) and pain perception.

### **Spinal Cord Sensory Pathways**

Sensory nerves that detect touch, temperature, and pain are distributed to the surface of the body and limbs. There are also sensory nerves responsible for proprioception that originate in the skin, muscles, tendons, and joints. The nerve cell bodies of most of these sensory nerves are located in the ganglia of dorsal nerve roots entering the spinal cord (see Fig. 63-2). Sensory tracts responsible for mediating sensation and conscious and unconscious proprioception ascend the spinal cord and brainstem to the brain. Most of these tracts ascend the ipsilateral spinal cord and cross over in the rostral brainstem to reach the contralateral cerebrum (see Fig 63-5). Patients with a unilateral forebrain lesion will typically experience hypalgesia (decreased sensation) in the limbs, trunk, and face on the opposite side. Damage to the sensory tracts in the spinal cord will disrupt the transmission of sensory and proprioceptive information to the brain (UMN), resulting in signs of ataxia, or incoordination, and the loss of conscious proprioception in all limbs caudal to the site of the lesion. With unilateral spinal cord lesions the deficits will be ipsilateral. If UMN spinal cord lesions are severe, there may also be some loss of superficial skin sensation caudal to the lesion. In addition to the sensory tracts responsible for relaying information to UMN centers regarding superficial sensation and proprioception, there are multisynaptic, small-diameter, bilateral crossing tracts deep in the white matter of the spinal cord that project to the cerebral cortex and are involved in the conscious perception of noxious stimuli (nociception, deep pain). The small diameter and deep location of these tracts make them very resistant to compressive injury, so loss of the ability to perceive a noxious stimulus (loss of deep pain perception) in the rear limbs of an animal with a T3-L3 lesion usually indicates a very severe transverse spinal cord injury.

Loss of sensation caused by damage to spinal cord dorsal gray matter, dorsal nerve roots, or the sensory portion of a peripheral nerve allows the LMN lesion to be precisely localized on the basis of skin sensation mapping. When there is a compressive or irritative lesion of the nerve root or peripheral nerve, there will sometimes be hyperesthesia (pain) at the site.

# **NEUROMUSCULAR SYSTEM Peripheral Nerves**

The peripheral nervous system consists of 12 pairs of cranial nerves originating in the brainstem and 36 pairs of spinal nerves originating in the spinal cord. Nerve fibers from the spinal nerves in the cervical and lumbar intumescences join together to form the peripheral nerves that innervate the muscles of the limbs. Spinal nerve or peripheral nerve lesions result in LMN motor signs in affected muscles and limbs and sometimes decreased, absent, or altered sensation. Box 63-5 lists the clinical signs caused by peripheral nerve lesions. Peripheral nerve disorders are discussed in Chapter 71.

### **Neuromuscular Junction**

At the neuromuscular junction (NMJ) electrical activity is transmitted from nerve axons to muscle fibers, resulting in muscular contraction. This process is mediated through the calcium-dependent release of the neurotransmitter acetylcholine (ACh) from the nerve terminal into the synaptic cleft. ACh diffuses across the synaptic cleft and binds to ACh receptors on the postsynaptic (muscle) membrane, inducing a conformational change and ion flux that result in muscular contraction. ACh is then rapidly removed from the synapse by acetylcholinesterase, readying the synapse for the next nerve impulse. Disorders that interfere with ACh release or inactivation and disorders that alter postsynaptic cholinergic receptor function will adversely affect neuromuscular transmission. Presynaptic neuromuscular junction disorders causing decreased release of ACh result in flaccid tetraparesis and decreased spinal reflexes (see Box 63-5) similar to diffuse peripheral nerve disorders. Myasthenia gravis is a postsynaptic disorder with reduction in the number of functional ACh receptors. The result is partial failure of NMJ transmission and exercise-induced weakness that may improve with rest but normal muscle tone and spinal reflexes. Disorders that interfere with acetylcholinesterase, the enzyme that normally inactivates ACh in the synapse, cause autonomic nervous system overstimulation and neuromuscular

BOX 63-5

Signs Caused by Lesions in the Neuromuscular System

# Peripheral Nerve Lesion: Signs Seen in Affected Limb/Muscle

Flaccid paresis/paralysis
Decreased to absent muscle tone
Rapid and severe muscle atrophy

Decreased or absent spinal reflexes

EMG suggests denervation

Skin sensation decreased or absent if sensory portion of nerve is affected

# Neuromuscular Junction Disorders: Signs Seen in All Limbs

Flaccid paresis/paralysis

Decreased to absent muscle tone

Decreased or absent spinal reflexes

EMG: decreased amplitude of muscle action potential
Normal postural reactions if able to move and weight is
supported

Normal sensation

Myasthenia gravis (post synaptic defect)

- · Paresis, often exacerbated by exercise
- Normal postural reactions
- Normal muscle tone and size
- Normal spinal reflexes

### **Muscle Disorders**

Paresis, may be exacerbated by exercise
Muscle atrophy, pain, or swelling +/Normal postural reactions if weight is supported
Normal spinal reflexes
Normal skin sensation

EMG, Electromyography.

weakness. Myasthenia gravis and other disorders of neuromuscular transmission are discussed in Chapter 71.

### Muscle

Skeletal muscle functions to maintain body posture and produce movement. Generalized weakness (tetraparesis), a stiff and stilted gait, and exercise intolerance are common clinical features in patients with muscle disease (see Box 63-5). Postural reactions and reflexes are normal. Some disorders cause muscle pain and muscle swelling, whereas others cause muscle atrophy and/or fibrosis. Muscle disorders are discussed in Chapter 72.

# NEUROLOGIC CONTROL OF MICTURITION

The physiologic control of micturition is complex and integrated centrally. The pelvic nerves originate in sacral segments S1-S3 and supply parasympathetic innervation to the bladder. Stimulation causes detrussor muscle contraction, bladder contraction, and bladder emptying. The striated skeletal muscle of the external urethral sphincter is under conscious and reflex control and is innervated by the puden-

dal nerve arising from sacral segments S1-S3. Sympathetic innervation to the bladder is supplied through the hypogastric nerves arising in the lumbar segments (L1-L4 in dogs, L2-L5 in cats). Sympathetic stimulation causes detrusor muscle relaxation (β-adrenergic) and contraction of the internal urethral sphincter (α-adrenergic). Sympathetic tone dominates during urine storage, allowing the bladder to distend with urine. As the bladder enlarges, sensory information from bladder wall stretch receptors is transmitted via the sensory portion of the pelvic nerve through ascending spinal cord pathways to the thalamus and cerebral cortex. When it is appropriate to void, impulses are sent from the cerebral cortex to the pons and then down the reticulospinal tract to the sacral spinal cord segments. Parasympathetic stimulation results in detrusor muscle contraction. There is normally simultaneous inhibition of sympathetic tone in the internal urethral sphincter and somatic (pudendal) input to the external urethral sphincter, allowing urine to flow. Damage to any component of this complex system or the connection with UMN centers will result in disorders of micturition.

Sacral spinal cord, nerve root, or pudendal nerve lesions typically result in urinary incontinence and a large bladder that is easily expressed and leaks continuously (LMN bladder). Perineal and bulbocavernosus reflexes are decreased or absent. Mild or moderate UMN lesions (spinal cord above the sacral segments) cause increased urethral tone, making it difficult for patients to void completely. With relatively mild lesions a syndrome of detrussor-urethral dyssynergia may result, wherein involuntary contraction of the urethral sphincter occurs during detrussor contraction, halting urine flow during voiding. Severe UMN spinal cord lesions causing severe paresis or paralysis typically result in a bladder that is enlarged and very difficult or impossible to express manually (UMN bladder). Occasionally, a reflex or automatic bladder will develop 5 to 10 days after acute UMN spinal cord injury, resulting in reflex detrussor contraction and spontaneous partial emptying of the bladder without cortical perception or voluntary control.

# SCREENING NEUROLOGIC EXAMINATION

A screening neurologic examination takes only a few minutes (Box 63-6). Abnormalities of mentation, posture, and gait are initially evaluated. Postural reactions are then evaluated. If abnormalities are detected, evaluation of muscle tone, spinal reflexes, urinary tract function, and sensory perception aids in lesion localization. Finally, cranial nerves are evaluated, and if necessary, localization of a lesion within the brain is attempted.

### MENTAL STATE

Owners should always be asked if they have noticed any changes in their pet's behavior because subtle changes are often not apparent to the examiner. A decreased level of

### BOX 63-6

consciousness, such as depression, stupor, or coma (Table 63-2), may occur with a metabolic disturbance or damage or disease affecting the cerebrum or brainstem. Delirium, confusion, or agitation suggests either cerebral cortical disease or a metabolic encephalopathy. Seizures occur with forebrain lesions or functional disturbances secondary to metabolic encephalopathies or intoxications. Aggression, compulsive pacing, loss of housebreaking, vocalizing, and head pressing can all be seen with a forebrain lesion. A behavioral syndrome in which animals with a structural unilateral forebrain lesion ignore all sensory input from the contralateral half of their environment has been called hemi-inattention syndrome.

FIG 63-6
Wide-based stance and excessive limb abduction indicative of ataxia in a 2-year-old Boxer with Neospora caninum meningoencephalomyelitis affecting the cervical spinal cord and cerebellum.

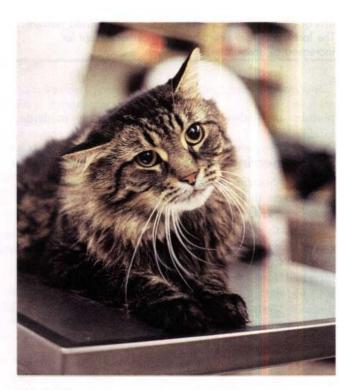

FIG 63-7
Right-sided head tilt in an adult cat with right-sided peripheral vestibular disease caused by otitis media/interna.

### **POSTURE**

A normal upright posture is maintained through the integration of multiple CNS pathways and spinal reflexes. Abnormal postures reflect a disruption of this normal integration. A wide-based stance is common in ataxic animals, particularly those with cerebellar or vestibular disease (Fig. 63-6). A continuous head tilt with resistance to straightening is usually associated with an abnormality of the vestibular system (Fig. 63-7). In recumbent animals

FIG 63-8

Schiff-Sherrington posture in a 9-year-old Lhaso Apso caused by traumatic fracture and luxation of the spine at T11-T12, with damage to the spinal cord at that site. There was a loss of proprioception, loss of voluntary motion, and loss of deep pain in the rear limbs, with increased reflexes. The forelimbs were neurologically normal except for increased extensor tone.

posture and other neurologic findings aid in lesion localization.

### **Schiff-Sherrington Posture**

The Schiff-Sherrington posture is observed in dogs when an acute, severe thoracic or cranial lumbar spinal cord lesion (usually a fracture/luxation, infarction, or hemorrhage) interferes with the normal ascending inhibition of thoracic limb extensor motor neurons by border cells in the spinal cord from L1 to L7 (most from L2 to L4). Forelimbs exhibit increased extensor tone with normal voluntary motion, strength, and conscious proprioception (Fig. 63-8). The rear limbs are paralyzed with normal to increased reflexes (UMN). This posture suggests severe spinal cord damage but does not have prognostic significance.

### **Decerebrate Rigidity**

This posture is most commonly observed when there is a rostral brainstem (midbrain) lesion. Affected animals are stuporous or comatose, all limbs are rigidly extended, and there is dorsal extension of the head and neck (opisthotonus; Fig. 63-9A).

### **Decerebellate Rigidity**

The rostral portion of the cerebellum is responsible for inhibition of excessive extensor muscle tone. A lesion in this region will result in increased thoracic limb extensor muscle tone, opisthotonus, and normal mentation. Rear limbs typically have the hips flexed forward as a result of increased iliopsoas muscle tone. This posturing can be episodic (see Fig. 63-9B and C).

### GAIT

Clinical evaluation of gait involves observation of the animal's movements during walking on a flat, nonslippery surface, with frequent turns and circling. If the animal is unable to walk unassisted, it should be supported with a harness or sling so that voluntary movement and gait can be better assessed. Each patient must be evaluated for paresis (weakness), ataxia, lameness, and circling.

### **Paresis**

Paresis is defined as weakness or inability to support weight or generate a normal gait. Paralysis is the term used to describe paresis so severe that all voluntary movement is lost (Table 63-3). Paresis occurs with LMN or UMN lesions, but the gait that results is markedly different between the two. Animals with LMN disease are usually profoundly weak, and they take small steps, always maintaining their feet under their center of gravity. Their short-strided gait is commonly mistaken for an orthopedic lameness, and they may tremble or collapse with minor exertion. Attempts to move quickly may result in a bunny-hopping gait. In contrast, animals with UMN lesions have a delay in the onset of protraction (the swing phase) and a longer than normal stride with a variable degree of spasticity or stiffness of the limbs. Animals with UMN lesions are ataxic as a result of disruption of the general proprioceptive (sensory) tracts that accompany the UMN tracts.

### **Ataxia**

Ataxia, or incoordination, is caused by lesions of the cerebellum, vestibular system, or the general proprioceptive (GP) sensory tracts in the spinal cord and caudal brainstem (Box 63-7). Animals with GP ataxia lose awareness of where their limbs are in space. They have a wide-based stance, long strides, excessive abduction of limbs during turning, exaggerated limb movements, and a tendency to scuff or knuckle affected limbs while walking. When affected animals are walking, their limbs may cross and the weight-bearing phase may be prolonged because of delayed protraction of affected limbs. Vestibular ataxia is manifested primarily as a loss of balance, reflected in a head tilt and a wide-based, crouched stance with a tendency to lean, drift, fall, or roll to the side. Vestibular ataxia is often accompanied by an abnormal nystagmus (see Chapter 68). Cerebellar ataxia reflects an inability to control the rate, range, and force of movement. Affected animals will have a wide-based stance, swaying of the body from side to side (truncal ataxia), and exaggerated (hypermetric) limb movements with normal strength and increased muscle tone (Fig. 63-10). A fine head tremor may be present (see Chapter 65).

### Lameness

Animals are lame when normal movement causes discomfort. If all limbs are equally painful, they may develop a stiff, short-strided gait, as seen in animals with polyarthritis. Animals with lameness affecting one limb have a short weight-bearing phase in the affected limb and a longer than

LMN, Lower motor neuron; UMN, upper motor neuron.

normal weight-bearing phase in the contralateral limb. In some cases the painful limb will be elevated or carried. Lameness affecting one limb is common in animals with orthopedic disease but can also be a prominent feature in animals with entrapment (pinching) of a spinal nerve or nerve root by a lateralized disk extrusion or nerve root tumor.

### Circling

Circling can be caused by lesions of the forebrain or the vestibular system. Dogs with unilateral forebrain lesions will usually walk or pace in wide circles toward the side of the lesion. Tight circling toward the side of the lesion is more often associated with vestibular disorders (Fig. 63-11). Most animals with vestibular disease also exhibit head tilt and nystagmus.

FIG 63-10

BOX 63-7

Localizing Ataxia

### Spinal Cord (Proprioceptive) Ataxia

Paresis of affected limbs
Imability to recognize limb position
Wide-based stance
Long strides
Excessive abduction of limbs during turning
Abnormal postural reactions
Normal mentation and cranial nerves

### Vestibular Ataxia

Head tilt
Wide-based, crouched posture
Balance problem
Peripheral: normal postural reactions
Central: abnormal postural reactions

### Cerebellar Ataxia

Normal strength
Wide-based stance
Hypermetric limb movements
Truncal sway
Normal postural reactions
Intention tremor of the head

### **POSTURAL REACTIONS**

The complex series of responses that maintain an animal in an upright position are called *postural reactions*. Postural reaction testing is used to determine whether animals can recognize the position of their limbs in space (conscious proprioception). Sensory receptors for proprioception originate in the muscles, tendons, and joints, and spinal cord

FIG 63-11
Tight circling and head tilt to the right in a 3-year-old Maltese with inflammatory disease affecting the right forebrain and brainstem.

proprioceptive tracts relay this sensory information to the cerebral cortex. Most proprioceptive tracts ascend the ipsilateral spinal cord and cross midline in the rostral brainstem (see Fig. 63-5). Abnormalities detected during the manipulations performed to test postural reactions do not provide precise localizing information but are sensitive indicators that suggest the presence of neurologic dysfunction somewhere along the neurologic pathway. A careful and systematic evaluation of postural reactions may permit the examiner to detect subtle deficits not observed during routine gait examination and to determine whether each limb is neurologically normal or abnormal. Postural reaction testing should include knuckling, hopping, wheelbarrowing, and hemiwalking (Fig. 63-12). When performed by an experienced clinician comparing the right and left limbs in an animal that has voluntary movement, hopping is the most sensitive and reliable postural reaction test. In animals with significant weakness it is important to support most of the body weight during postural reaction testing. Animals with neuromuscular disorders that still have normal sensation and the ability to voluntarily move their limbs will hop quickly (normal) as long as their weight is supported because their proprioception is normal. For the purpose of lesion localization, abnormalities of postural reaction testing are usually interpreted as UMN signs, which must then be confirmed with testing of muscle tone and spinal reflexes (see Box 63-4 and Table 63-1).

### FIG 63-12

Postural reaction testing. A, Conscious proprioception (knuckling) is evaluated by placing the dorsal surface of the animal's paw on the floor while the animal's weight is supported. The normal response is an immediate return to a normal position. B, Forelimb hopping. The animal is supported under the abdomen, and one thoracic limb is lifted from the ground. The animal is leaned and moved laterally toward the limb being evaluated. The normal animal responds by quickly lifting and replacing the limb under its body as it moves laterally. C, Pelvic limb hopping. The animal is supported under the chest, and one pelvic limb is lifted. The animal is leaned and moved laterally toward the limb being evaluated. The normal animal responds by quickly lifting and replacing its limb under the body as it moves laterally. D, Wheelbarrowing. The animal is supported under the abdomen and moved forward. The head may be elevated to remove visual input and accentuate proprioceptive abnormalities, as shown here. E, Hemiwalking. The front and rear limbs on one side are lifted, and forward and lateral walking movements are evaluated.

### MUSCLE SIZE/TONE

Muscle atrophy and muscle tone should be assessed by careful palpation and movement of each limb through a range of motion. Muscle atrophy can occur slowly as a result of disuse or rapidly as a result of a lesion of the LMN supplying a muscle (neurogenic atrophy). If focal muscle atrophy is detected in a limb, this can be used to precisely localize lesions of the peripheral nerve, nerve roots, or spinal cord gray matter because the spinal cord segments and peripheral nerves responsible for innervating each of the individual limb muscles are well known. Muscle swelling or enlargement is a feature of some myopathies. Muscle tone is generally decreased in animals with significant lesions of the LMN, whereas extensor muscle tone is usually increased with UMN lesions (see Table 63-1). Extreme alterations in muscle tone can be seen in animals with Schiff Sherrington syndrome and with decerebrate and decerebellar rigidity (see Figs. 63-8 and 63-9).

### SPINAL REFLEXES

Spinal reflex evaluation is the most reliable way to classify a neurological disorder as being UMN or LMN. Spinal reflexes and muscle tone will be diminished to absent in LMN disorders and normal to increased in UMN disease. Spinal limb reflexes are best assessed in a relaxed animal restrained in lateral recumbency. Each reflex is judged to be absent (0), decreased (+1), normal (+2), or increased (+3 or +4). Significant LMN lesions will reliably cause an absent or decreased reflex. UMN lesions cause an increased reflex that will not always be distinguishable from normal. In the absence of other neurologic deficits an exaggerated reflex means little and can be observed in an excited or nervous

animal. The limb reflexes that are most useful in dogs and cats include the patellar reflex, the sciatic reflex, the pelvic limb withdrawal (flexor) reflex, and the thoracic limb withdrawal (flexor) reflex. Because other reflexes are found inconsistently in normal animals, they are not routinely evaluated. The spinal reflexes and the spinal cord segments responsible for mediating each reflex are listed in Table 63-4.

### **Patellar Reflex**

With the animal restrained in lateral recumbency, the examiner evaluates the upper (nonrecumbent) limb by holding the stifle in partial flexion and striking the patellar ligament with the flat surface of the reflex hammer (pleximeter), stretching the fibers of the quadriceps muscle (Fig. 63-13). The normal response is a reflex contraction of the quadriceps muscle. This is a monosynaptic myotactic (stretch) reflex, with both sensory and motor components contained in the femoral nerve and the L4, L5, and L6 spinal nerves; nerve roots; and spinal cord segments. A weak or absent patellar reflex indicates a lesion of the femoral nerve or the L4-6 spinal cord segments or nerve roots. A lesion cranial to the L4 spinal cord segment will typically cause an exaggerated reflex. Although this is the most reliable tendon reflex for evaluation, it is sometimes difficult to interpret the response. Occasionally, a lesion of the sciatic nerve or the L6-S2 spinal cord segments will cause the patellar reflex to appear increased by decreasing tone in the muscles opposing stifle extension (pseudohyperreflexia). The patellar reflex can be difficult to elicit in animals with significant orthopedic disease of the stifle, and rarely it is decreased or absent in normal dogs (especially large-breed puppies).

TABLE 63-4

**Spinal Reflexes** 

REFLEX	STIMULUS	NORMAL RESPONSE	SPINAL CORD SEGMENTS
Thoracic limb withdrawal	Pinch foot of forelimb	Withdraw limb	C6, C7, C8, T1, (T2)
Patellar	Strike patellar ligament	Extension of stifle	L4, L5, L6
Pelvic limb withdrawal	Pinch foot of rear limb	Withdraw limb	L6, L7, S1, (S2)
Sciatic	Strike sciatic nerve between greater trochanter and ischium	Flexion of stifle and hock	L6, L7, S1, (S2)
Cranial tibial	Strike belly of cranial tibial muscle just below proximal end of tibia	Flexion of hock	L6, L7 (\$1)
Perineal	Stimulate perineum with pinch	Anal sphincter contraction, ventroflex tail	S1, S2, S3, pudendal nerve
Bulbourethral	Compress vulva or bulb of penis	Anal sphincter contraction	S1, S2, S3, pudendal nerve
Cutaneous trunci	Stimulate skin over dorsum just lateral to vertebral column	Twitch of the cutaneous trunci muscle	Response will be absent caudal to a severe spinal cord lesion. Used to localize lesions between T3 and L3

FIG 63-13
Patellar reflex. The straight patellar ligament is struck, resulting in a reflex "kick" extension of the stifle.

In tense patients the reflex may be decreased or absent in the upper limb but normal in the relaxed recumbent limb.

### Pelvic Limb Withdrawal (Flexor) Reflex

The examiner squeezes a digit with enough pressure to elicit flexion of the hip, stifle, hock, and digits (see Fig. 63-14A and B). If manual pressure is not adequate, the examiner squeezes the base of a toenail with a pair of forceps. The pelvic limb withdrawal reflex is complex. Sensory input is through the peroneal (dorsal, lateral) and tibial (ventral) branches of the sciatic nerve and the saphenous branch of the femoral nerve (medial). Motor output is through the sciatic nerve and its branches, the tibial nerve (digital flexion), and the peroneal nerve (tarsal flexion). Because hip flexion is mediated by the femoral nerve and the lumbar spinal nerves, this reflex can occur when the medial toe is stimulated even if the sciatic nerve and its branches have been destroyed. A decreased pelvic limb withdrawal response indicates an LMN lesion affecting the sciatic nerve (or branches) or the L6-S2 spinal cord segments or nerve roots. A lesion cranial to L6 results in a normal to increased reflex response. The withdrawal response is a segmental reflex that is not dependent on the animal's conscious perception of the noxious stimulus; functional transection of the spinal cord cranial to L6 will result in an increased reflex (UMN) but no ability to feel the stimulus.

### Sciatic Reflex

With the animal in lateral recumbency, the examiner palpates the notch formed by the greater trochanter of the

femur and the ischial tuberosity. Using the tapered end of the pleximeter to tap in this notch, the examiner elicits a brief flexion of the hock (Fig. 63-14C). The sciatic reflex requires that the sciatic nerve, spinal cord segments L6-S2, and the peroneal nerve (branch of the sciatic nerve) be intact. The reflex will be decreased with lesions of those components and normal to increased with UMN lesions cranial to L6.

### Thoracic Limb Withdrawal (Flexor) Reflex

The only reliable forelimb reflex is the withdrawal reflex. Because multiple nerves are involved, this reflex is used as a crude test of the entire brachial plexus (nerve roots and peripheral nerves) and cervical intumescence (C6-T2). The examiner squeezes a digit to elicit flexion of the shoulder, elbow, carpus, and digits (Fig. 63-15). Lesions involving the peripheral nerves, nerve roots, or spinal cord segments at that site will result in a decreased or absent reflex. Lesions above C6 in the spinal cord will cause a normal to increased (UMN) reflex response.

### **Crossed Extensor Reflex**

When the withdrawal (flexor) reflexes are elicited in an animal in lateral recumbency, a reflex extension of the limb opposite the one being stimulated is termed a *crossed extensor reflex*. The presence of this reflex in an animal that is not trying to rise or get away indicates that there is a UMN lesion to the limb being evaluated.

### Perineal Reflex and Bulbourethral Reflex

The perineal and bulbocavernosus reflexes are used to assess the pudendal nerve (sensory and motor) and sacral spinal cord segments S1-S3. In the perineal reflex the perineal skin is pinched with a hemostat, causing the anal sphincter to contract and the tail to ventroflex (Fig. 63-16). The same response should occur during digital rectal examination. The bulbourethral reflex causes anal sphincter contraction in response to gently squeezing the bulb of the penis or the vulva. LMN damage to the pudendal nerve or the S1-S3 spinal cord segments will cause a loss of both of these reflexes, urinary incontinence (LMN bladder), loss of tone in the internal and external anal sphincters, and resultant anal dilation and fecal incontinence.

### **Cutaneous Trunci Reflex (Panniculus)**

Pinching the skin of the dorsum causes a reflex contraction of the cutaneous trunci muscles bilaterally, producing a twitch of the overlying skin. This reflex can be very useful in the evaluation of patients with a severe spinal cord lesion localized to the T3-L3 region. Affected patients will have UMN signs in the rear limbs and normal forelimbs, but unless they have a painful site, it can be difficult to localize the lesion more precisely. When skin along the dorsum is pinched, the stimulated sensory nerve from that site enters the spinal cord and afferent sensory information ascends the spinal cord in sensory tracts. If the spinal cord is intact

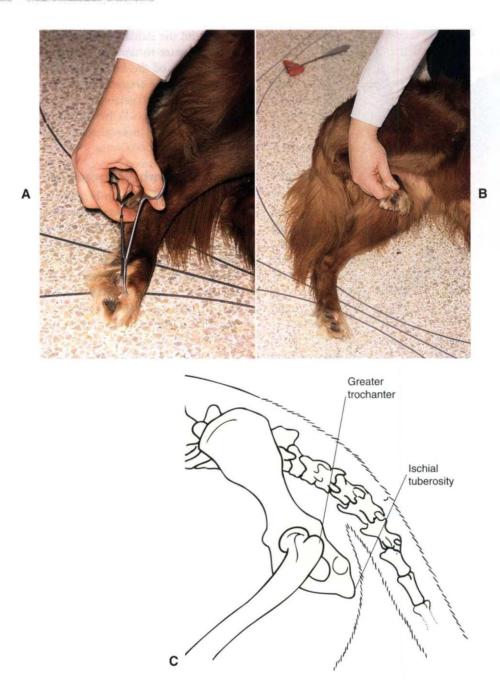

FIG 63-14
Assessing the sciatic nerve and spinal cord segments L6-S2. Pelvic limb withdrawal reflex: Pinch the toe (A), resulting in limb flexion (B). Assess flexion in all of the joints of the limb. It may be necessary to apply a forceps to the nail base to provide adequate stimulation. Sciatic reflex: Strike the sciatic nerve in the notch between the greater trochanter of the femur and the ischial tuberosity, resulting in limb flexion (C).

between the site of stimulation and the C8-T1 segments, a synapse occurs bilaterally at the C8-T1 spinal cord segments, stimulating motor neurons of the lateral thoracic nerve, which causes the cutaneous trunci muscle to contract. In spinal cord lesions causing paralysis the ascending pathway will be disrupted such that no panniculus reflex is elicited when the skin is pinched caudal to the level of the lesion, but stimulation of the skin cranial to the lesion elicits a response (Fig. 63-17). Testing is started at the level of the

ilial wings, although in many normal animals the reflex cannot be elicited until stimulation is applied at the midlumbar region. If a twitch occurs at the most caudal aspect, then the entire pathway is intact. If there is no response, then systematic stimulation of the skin just lateral to each vertebral body should be performed, progressing anteriorly until a twitch is observed. Because the sensory nerves that supply the skin enter the spinal cord one or two vertebrae cranial to the dermatome stimulated, the cord lesion is predictably

FIG 63-15
Thoracic limb withdrawal reflex: Pinch the toe (A), resulting in limb flexion (B). Assess flexion in all the joints of the limb.

FIG 63-16

slightly cranial to the site where the panniculus reflex is lost. The cutaneous trunci reflex can be lost unilaterally when there is a lesion of the ipsilateral brachial plexus or C8-T1 spinal cord segments, ventral nerve roots, or spinal nerves. In rare cases this reflex cannot be elicited in a normal dog.

### SENSORY EVALUATION

Evaluation of an animal's ability to feel a noxious stimulus such as a pinch (nociception) can be helpful in the localization of UMN and LMN lesions. When there is a transverse UMN spinal cord lesion, the animal's ability to feel a painful stimulus (skin or pinch with fingers or hemostat) may be decreased in the skin of the trunk and in the limbs caudal to the lesion because the ascending sensory tracts are disrupted in the damaged spinal cord. If minor stimulation (superficial pain assessment) in a paralyzed animal does not elicit a behavioral response such as turning the head, vocalizing, or trying to bite, then the animal's ability to perceive a more severe noxious stimulus such as a hemostat applied to the nail base (deep pain) should be tested. The spinal tracts that carry deep pain sensation are small, bilateral, and multisynaptic and located deep in the spinal cord white matter. Only a very severe bilateral spinal cord lesion will completely disrupt these tracts, making the ability to perceive deep pain an important prognostic indicator in animals with severe spinal cord injury (Fig. 63-18). It is important to remember that withdrawal of the limb indicates only an intact reflex arc (peripheral nerve and spinal cord segments), whereas a behavioral response requires that the sensory spinal cord tracts ascending to the brain also be intact.

When LMN paralysis of a limb is evident, mapping the boundaries of normal and diminished sensation can aid in lesion localization to specific peripheral nerves, dorsal nerve roots, or spinal cord segments. The skin should be pinched with a hemostat and regions of local anesthesia or decreased sensation identified (Fig. 63-19). These results can be compared with established maps of cutaneous regions deriving sensory innervation from individual nerves (dermatomes), allowing the LMN neurologic defect to be precisely localized (see Chapter 73).

### PAIN/HYPERPATHIA

The neck, spine, limbs, muscles, bones, and joints should be palpated and manipulated to detect painful areas or restricted mobility. Pain is usually most intense directly over a lesion, making this part of the neurologic examination important in lesion localization. Traumatic and inflammatory conditions are most likely to be painful, whereas degenerative and congenital conditions are rarely painful. Neoplastic condi-

FIG 63-17

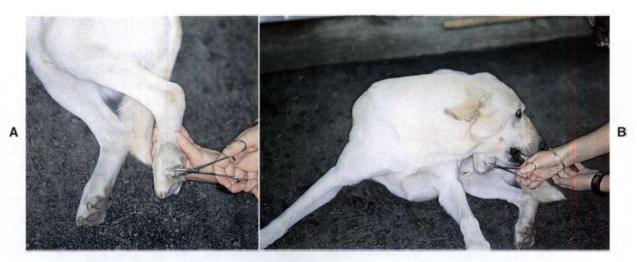

Cutaneous trunci reflex.  $\bf A$  and  $\bf B$ , Pinch the dorsal skin with a hemostat just lateral to the spine. If the spinal cord is not injured between the site of stimulation and the C8-T1 spinal cord segments, this will lead to a bilateral twitch of the cutaneous trunci muscle. The reflex may be absent caudal to a severe spinal cord lesion.  $\bf C$ , The spinal sensory nerves course caudally so that the dermatomes for skin sensation lateral to the vertebral column are caudal to their own vertebral bodies. A spinal cord lesion at site a will therefore result in loss of the panniculus response caudal to site b.

tions causing distortion of tissues (meninges, nerve roots, or bone) will also be painful.

The animal's posture and gait should be observed. Animals with neck pain maintain a low head carriage, with their head and neck extended, and are unwilling to turn their neck to

look to the side; they will instead pivot their entire body. Animals with pain of the thoracic or lumbar spine stand with an arched back (Fig. 63-20). Animals with painful bones, joints, or muscles typically have a short-strided, stiff gait and are reluctant to exercise.

**FIG 63-18**Evaluation of deep pain. Pinch the toe **(A)** to assess whether this elicits a behavioral response **(B).** The absence of deep pain sensation indicates the presence of severe spinal cord damage.

FIG 63-19
Sensory loss in the dorsolateral foot (A) and distal rear limb (B) in a lemur after damage to the peroneal nerve by an intramuscular injection.

Neck pain is a sign commonly associated with compressive or inflammatory diseases of the cervical spinal cord, cervical spinal roots, or meninges. The neck should be gently manipulated in dorsal, lateral, and ventral flexion and resistance to movement or pain assessed. Deep palpation of the vertebrae and cervical spinal epaxial muscles may also be performed (Fig. 63-21). Anatomic structures that can cause neck pain include the meninges, nerve roots, intervertebral disks, facetal joints, bones, and muscles (Box 63-8). Neck pain has also been recognized as a clinical symptom of intracranial disease, particularly of forebrain mass lesions.

Pain in other regions of the vertebral column may help localize lesions caused by intervertebral disk disease, diskospondylitis, or neoplasia. Dogs and cats with disease of the thoracolumbar spine may experience pain when pressure is applied over the affected vertebrae. Because these animals may also resist abdominal palpation, vertebral or spinal hyperpathia may be misinterpreted as abdominal pain. Cauda equina compression that is caused by a tumor, disk, or ligamentous proliferation typically causes pain in the lumbosacral region (see Chapter 70). This can be demonstrated in affected dogs by applying direct pressure over the lumbosa-

FIG 63-20

Neoplasia

Infectious meningitis/meningomyelitis Granulomatous meningoencephalitis (GME) Steroid responsive meningitis arteritis (aseptic meningitis) Hemorrhage-induced inflammation

### **Brain**

Mass lesion (neoplasia, inflammatory)

cral junction or applying dorsal traction to the tail (see Fig. 70-20).

Muscular pain should be assessed by manipulating the limbs and palpating individual muscle groups. During palpation it is important to attempt to differentiate pain that originates within the muscle from that caused by bone or joint abnormalities. Muscle disorders that are associated with pain are primarily the inflammatory diseases, such as immune-mediated polymyositis, masticatory myositis, and infectious myositis caused by the protozoal organisms Toxoplasma and Neospora. Ischemic myopathy, as occurs in animals with thrombosis affecting the arterial blood supply to a muscle group, can also result in severe muscular cramping and pain on palpation.

### URINARY TRACT FUNCTION

Severe lesions of the spinal cord are often associated with urinary tract dysfunction. Bladder function should be assessed on the basis of the owner's or the clinician's observations of micturition, palpation of the bladder, and attempts to express urine. A flaccid, easily expressed bladder with absent or diminished perineal and bulbocavernosus reflexes and reduced anal tone is expected with lesions of the LMN (S1-S3 spinal cord segments, pudendal nerve, pelvic nerve). UMN lesions cranial to the sacral segments cause diminished voluntary control of urination and reflex hyperexcitability of the urethral sphincter. There can be incomplete voiding or detrussor-urethral dyssynergia. Severe UMN lesions will result in a tense distended bladder that is difficult to express.

### **CRANIAL NERVES**

Cranial nerve dysfunction may result from a disorder affecting a single nerve; a diffuse polyneuropathy affecting multiple nerves; or a cluster of abnormalities, as is commonly seen in animals with a disease affecting the middle and inner ear or the brainstem. Animals with brainstem disease causing cranial nerve dysfunction usually have additional signs such as postural reaction deficits, hemiparesis, quadriparesis or altered mentation.

Cranial nerve examination is not difficult. The cranial nerves that are most often affected can be evaluated quickly with a rapid regional neurologic examination (Table 63-5). If findings yielded by the preliminary examination indicate the presence of an abnormality, a more thorough examination of each individual cranial nerve can be undertaken (Table 63-6; see also Suggested Readings).

### **Evaluation of Menace Response, Vision,** and Pupils

The optic nerve (CN1) is an important component of the afferent pathways for the menace response, vision, and the pupillary light reflex. The examiner covers one eye and assesses the menace response in the opposite eye. Next, the examiner advances a hand or finger toward the eye being evaluated, taking care to avoid touching the eyelid or whiskers or generating an air current that will stimulate the

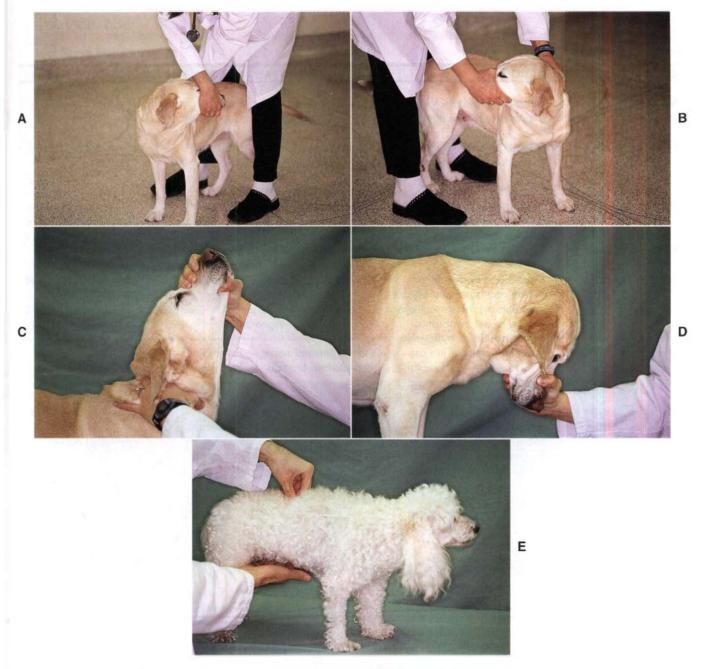

FIG 63-21
Testing for cervical and thoracolumbar spinal pain by (A to D) manipulating the neck through a full range of motion and (E) applying pressure through deep palpation of the vertebral bodies and spinal epaxial muscles.

cornea, which is innervated by the sensory portion of the trigeminal nerve (CN5). The menace response is a learned response and will not be present until 10 to 12 weeks of age in puppies and kittens. In addition to the menace response, the examiner should observe the animal's response to its environment by making sudden movements and dropping cotton balls to see if the animal follows the movement. It may be necessary to set up a maze of objects to assess vision in each eye. Pupil size should be examined at rest in a well-

lighted room and then in a dimly lit room and the two eyes compared. The examiner evaluates the ability of each pupil to constrict (parasympathetic function) and to dilate (sympathetic function) by shining a bright light in one eye, then swinging the light into the other eye to observe the response, and then swinging it back again. The parasympathetic axons of the oculomotor nerve (CN3) are responsible for pupil constriction. Loss of vision and pupillary abnormalities are discussed in Chapter 66.

TABLE 63-5

### Regional Assessment of Cranial Nerves

CRANIAL NERVE TEST	ACTION	SENSORY INPUT	INTEGRATION	MOTOR FUNCTION
Menace response	Threatening gesture towards eye; results in a blink	CN2-optic nerve	Forebrain Cerebellum Brainstem	CN7—facial nerve
Palpebral reflex	Touching medial or lateral canthus of eye results in blink	CN5—trigeminal nerve medial: ophthalmic branch	Brainstem	CN7—facial nerve
Pupillary light reflex	Shining a light in the eye elicits pupillary constriction	lateral: maxillary branch CN2—optic nerve	Brainstem	CN3—oculomotor nerve (parasympathetic)
Examine for head tilt	Evaluate head position	CN8-vestibulocochlear	Brainstem Cerebellum	_
Vestibulo-ocular reflex	Move head from side to side and dorsoventrally, evaluating for normal eye movements, strabismus and positional nystagmus	CN8vestibulocochlear	Brainstem	CN3—oculomotor nerve CN4—trochlear nerve CN6—abducent nerve
Stimulation of nasal mucosa	Inserting hemostat in nose to stimulate nasal septal mucosa; results in rapid withdrawal of head	CN5—trigeminal nerve (ophthalmic branch)	Forebrain Brainstem	_
Jaw tone	Assess jaw tone and ability to close the mouth	CN5—trigeminal nerve (mandibular branch)	Forebrain Brainstem	CN5—trigeminal nerve
Facial symmetry	Examine for facial symmetry, ability to blink, twitch lip, and move ears	CN2—optic nerve (menace) CN5—trigeminal nerve (palpebral, corneal reflex, lip pinch)	Forebrain Brainstem	CN7—facial nerve
Gag reflex	Manual stimulation of the pharynx induces contraction	CN9— glossopharyngeal CN10—vagus nerve	Brainstem	CN9—glossopharyngeal nerve CN10—vagus nerve
Tongue evaluation	Inspect the tongue for symmetry, observe tongue movements during eating and drinking	CN5—trigeminal nerve CN7—facial nerve CN12—hypoglossal nerve	Brainstem	CN12—hypoglossal nerve

# Examine for Strabismus, Nystagmus, and Head tilt

To check for strabismus, nystagmus, and head tilt, the examiner must determine whether the eyes are normally positioned in the orbits and whether there is any abnormal resting (spontaneous) nystagmus. Spontaneous nystagmus indicates either a central vestibular (medullary) lesion, a lesion of the vestibular portion of CN8, or a lesion of the cerebellum. A head tilt is common with a lesion in any of these locations. Abnormal eye position (strabismus) may indicate a vestibular disorder or damage to the innervation of the extraocular muscles (CN3, 4, 6) (Fig. 63-22). Oculomotor nerve (CN3) dysfunction can result in a ventrolateral strabismus and an inability to rotate the eye dorsally, ventrally, or medially. Lesions of the abducent (CN6) nerve cause a medial strabismus and an inability to look laterally,

and lesions of the trochlear nerve (CN4) cause a dorsolateral rotation of the eye. Lesions of these nerves (CN3, 4, 6) usually occur together, producing complete external ophthalmoplegia. Vestibular disorders commonly cause a ventral strabismus (eye drop) on the side of the lesion that may be evident only during head and neck extension. A quick assessment of the function of all these nerves can be accomplished by moving the head from side to side and eliciting the vestibulo-ocular reflex. As the head is turned slowly to the right, the gaze of both eyes should slowly drift left before jerking to the right to resume a central position. The examiner assesses these normal vestibular eye movements (physiologic nystagmus) while moving the head in each direction.

In addition to moving the head from side to side to determine whether the eye movements are normal, the examiner should hold the animal's head still in each lateral position to

TABLE 63-6

### Cranial Nerve Function

CRANIAL NERVE	SIGNS OF LOSS OF FUNCTION
I (olfactory)	Loss of ability to smell
II (optic)	Loss of vision, dilated pupil, loss of pupillary light reflex (direct and consensual when light shone in affected eye)
III (oculomotor)	Loss of pupillary light reflex on affected side (even if light shone in opposite eye), dilated pupil, ventrolateral strabismus
IV (trochlear)	Slight dorsomedial eye rotation
V (trigeminal)	Atrophy of temporalis and masseter muscles, loss of jaw tone and strength, dropped jaw (if bilateral), analgesia of innervated areas (face, eyelids, cornea, nasal mucosa)
VI (abducent)	Medial strabismus, impaired lateral gaze, poor retraction of globe
VII (facial)	Lip, eyelid, and ear droop; loss of ability to blink; loss of ability to retract lip; possibly decreased tear production
VIII (vestibulocochlear)	Ataxia, head tilt, nystagmus, deafness
IX (glossopharyngeal)	Loss of gag reflex, dysphagia
X (vagus)	Loss of gag reflex, laryngeal paralysis, dysphagia
XI (accessory)	Atrophy of trapezius, sternocephalicus, and brachiocephalicus muscles
XII (hypoglossal)	Loss of tongue strength

FIG 63-22

determine whether an abnormal (positional) nystagmus develops. The head and neck should then be extended and held in that position while the eyes are evaluated for a ventral strabismus and the development of nystagmus. When the head of a normal animal is held still, there will be no nystagmus. In most animals with severe or acute central or peripheral vestibular lesions, there will be a resting (spontaneous) nystagmus regardless of the position of the head. In less severe or compensated vestibular disorders the examiner will be able to elicit only a few beats of abnormal nystagmus when the animal's head is held in a certain position; this is called positional nystagmus, and it is abnormal. Positional nystagmus will sometimes be evident only when the animal is placed in dorsal recumbency with the head and neck extended (Fig. 63-23). The direction of nystagmus is defined as the direction of the fast phase of eye movements.

### **Evaluation of Trigeminal (CN5) Nerves**

The trigeminal nerve (ophthalmic and maxillary branches) supplies the sensory innervation to the skin of the face, the cornea, the mucosa of the nasal septum, the nasopharyngeal mucous membranes, and the teeth and gingiva of the upper jaw. The mandibular branch supplies sensory innervation to the mandibular portion of the face and oral cavity as well as motor function to the muscles of mastication. Sensory function is tested by assessing the corneal and palpebral reflexes, assessing the response to stimulation of the nasal septal mucosa, and pinching the skin of the face with a hemostat (Fig. 63-24). Motor function is assessed by evaluating the size and symmetry of the masticatory muscles and testing the resistance of the jaw when opening the mouth. Bilateral trigeminal motor paralysis results in a dropped jaw and inability to close the mouth (Fig. 63-25). Loss of corneal sensation

will decrease reflex release of tears and trophic factors, leading to keratitis (neurotrophic keratitis) and corneal ulceration in some dogs.

### **Evaluation of the Facial Nerves (CN7)**

The facial nerve provides motor innervation to the muscles of the face and sensory innervation to the rostral two thirds of the tongue (for taste) and palate. Parasympathetic fibers innervate the lacrimal glands and the mandibular and sublingual salivary glands and can be assessed with a Shirmer tear test. Motor function is assessed by examining the face for symmetry and observing spontaneous blinking and ear movements as well as by eliciting the corneal and palpebral reflexes, the menace response, and the ability to twitch the face in response to a pinch (sensory CN5). Because the facial nerve courses through the middle ear before distribu-

**FIG 63-23**Placing an animal in dorsal recumbency can reveal positional nystagmus or strabismus.

tion to the muscles of the face, middle ear lesions can cause dysfunction.

# Evaluation of the Glossopharyngeal (CN9), Vagus (CN10), and Hypoglossal (CN12) Nerves

The glossopharyngeal, vagus, and hypoglossal nerves are usually evaluated together as components of the gag reflex and normal eating and drinking. The glossopharyngeal nerve (CN9) provides motor innervation to the pharynx and palate and sensory innervation to the caudal third of the tongue and pharynx. It also provides parasympathetic stimulation to the parotid and zygomatic salivary glands. The vagus nerve (CN10) provides motor and sensory innervation to the larynx, pharynx, and esophagus and sensory innervation to the thoracic and abdominal viscera. The parasympathetic portion of the vagus provides motor innervation to most thoracic and abdominal viscera. The hypoglossal nerve (CN12) provides motor innervation to the tongue.

The swallowing or gag reflex (CN9 and CN10) can be evaluated by applying external pressure in the hyoid region to induce swallowing or by stimulating the pharynx with a finger to induce the gag reflex. This can also be evaluated by watching the animal eat and drink. The parasympathetic portion of CN10 can be tested by measuring the reflex bradycardia that normally occurs when applying digital pressure to both eyeballs (oculocardiac reflex). The hypoglossal nerve (CN12) can be evaluated by inspecting the tongue for atrophy or asymmetry (Fig. 63-26) and observing tongue movement during eating and drinking or when licking food paste placed on the nose.

### **LESION LOCALIZATION**

After the neurologic examination is completed, an animal's mentation, cranial nerves, posture, gait, forelimbs, rear limbs, perineum, anus, and bladder can be characterized as normal

FIG 63-24
The sensory distribution of the trigeminal nerve (CN5) can be assessed by pinching the skin of the maxilla (A) and by stimulating the nasal septal mucosa (B) with a hemostat.

FIG 63-25

**FIG 63-26**Deviation and atrophy of the tongue caused by left-sided hypoglossal nerve (CN12) paralysis.

or abnormal. If disease above the foramen magnum is present, clinical findings should allow a lesion to be localized to a specific region of the brain. In patients with spinal cord disease determining whether the neurologic abnormality in each limb is UMN or LMN in origin allows localization to a region of the spinal cord or specific spinal cord segments (see Box 63-4). When LMN signs are present in a single limb, the lesion can often be even more precisely localized by determining the muscles affected and, if sensory nerves are also affected, by testing sensation in dermatomes. Focal hyperpathia may also help to precisely localize a lesion. Whenever possible, the clinician should be able to explain all detected neurologic abnormalities on the basis of a single lesion. Occasionally, however, this will be impossible because the animal has multiple foci of disease or a diffuse disorder.

- N Neoplastic, nutritional
- Infectious, inflammatory, immune, iatrogenic, idiopathic
- T Traumatic, toxic
- V Vascular
- P Parasitic

### DIAGNOSTIC APPROACH

Once a neurologic lesion has been localized, it is necessary to generate a list of likely differential diagnoses. This list should take into account the signalment, historical data, the neuroanatomic location of the lesion, and the nature of the onset and progression of neurologic signs. It is important to consider all possible mechanisms or causes of disease that can affect the nervous system (Box 63-9). Once a list of likely differential diagnoses has been developed, diagnostic tests can be performed to confirm or exclude each.

### **ANIMAL HISTORY**

Patient age, gender, breed, and lifestyle may provide clues regarding the underlying disease. Young animals are most likely to be seen because of congenital or hereditary disorders; they are also at highest risk for intoxications and infectious diseases. Older animals are more susceptible to neoplastic diseases and many of the known degenerative disorders. Certain breeds are predisposed to particular disorders, and there are many congenital and inherited disorders that have been seen in only one or a few breeds. Dogs engaging in particular competitive or working activities (e.g., hunting, herding, racing, jumping) may be at increased risk for specific activity-related injuries. Potential exposure to trauma, toxins, and infectious disorders should be ascertained through careful history taking.

### **DISEASE ONSET AND PROGRESSION**

Evaluation of the onset and progression of neurologic signs is of primary importance in prioritizing the list of differential diagnoses (Box 63-10). The signs may be peracute and nonprogressive, or they may become progressively more severe with time. In peracute disorders the time of onset of the neurologic signs can be pinpointed exactly, with the animal going from being normal to abnormal within minutes or hours. Signs reach maximal intensity very rapidly and then remain static or improve over time. Examples include external trauma, internal trauma from intervertebral disk extrusion, vascular disorders such as infarcts or hemorrhage, and some rapid-acting intoxications such as strychnine. Rarely, animals with a typically slowly progressive disorder such as a tumor present with a peracute exacerbation of their

### **Chronic Progressive (Months)**

Most tumors Degenerative disorders

signs as a result of hemorrhage or fracture at the site of the tumor. A thorough history will often reveal that these animals were not entirely normal before the acute deterioration.

Neurologic disorders with fairly rapid deterioration over days to weeks are classified as subacute and progressive. Infectious and noninfectious inflammatory diseases and some of the more rapidly progressive neoplasms (e.g., lymphomas, metastatic malignancies) usually fall into this category. Metabolic and nutritional disorders and some intoxications can also cause subacute progressive signs. Animals with chronic progressive signs that develop very slowly over many weeks or months are most likely to have neoplastic or degenerative disease.

### SYSTEMIC SIGNS

Identification of concurrent systemic abnormalities may aid in the diagnosis of neoplastic, metabolic, or inflammatory nervous system disorders. A complete physical examination and ophthalmologic evaluation, including a funduscopic examination, should be performed in every animal with suspected neurologic disease. Laboratory tests and imaging modalities useful for specific evaluation of nervous system disorders are limited, so identification and characterization of associated abnormalities in other tissues can facilitate diagnosis. Ancillary diagnostic tests can then be performed to further evaluate animals with neurologic disease and thereby arrive at a specific diagnosis.

### MINIMUM DATABASE

Patients with disease confined to the central nervous system (CNS) often have no specific abnormalities on a minimum database consisting of a complete blood cell (CBC) count, serum biochemistry profile, and urinalysis. These tests can be useful, however, in the diagnosis of systemic disorders that have neurologic manifestations and in the identification

of the clinicopathologic abnormalities associated with some primary neurologic disorders.

Hematologic findings are rarely specific, but leukocytosis suggests inflammatory disease. Severe inflammation and a left shift are expected in patients with bacterial meningitis or encephalitis. Lymphopenia and inclusion bodies within red blood cells (RBCs) and lymphocytes are occasionally seen in dogs with acute canine distemper virus infection. Morulae may be seen within neutrophils in dogs with granulocytic ehrlichiosis. Microcytosis with or without thrombocytopenia is a common finding in dogs with portosystemic shunts. Red cell regeneration with or without accompanying anemia is seen in dogs with recurrent intraperitoneal hemorrhage caused by abdominal hemangiosarcoma. Occasionally, concurrent leukemia is detected in an animal with brain or spinal cord lymphoma.

A serum biochemistry profile is most useful in determining the likelihood of metabolic disorders as the cause of neuropathies, encephalopathies, and seizures. Diabetes mellitus, hypoglycemia, hypocalcemia, hypokalemia, and uremia can be eliminated from the list of differential diagnoses if the biochemistry panel is found to be normal. In dogs with peripheral neuropathy and a greatly increased serum cholesterol concentration, diagnostic tests for hypothyroidism should be considered (see Chapter 51). The finding of high liver enzyme activities (i.e., alanine aminotransaminase, serum alkaline phosphatase) or hypoalbuminemia in a patient with forebrain signs should prompt consideration of liver function tests to rule out hepatic encephalopathy (see Chapter 36). Hepatocellular enzyme elevations are also expected with some multisystemic disorders, such as toxoplasmosis and metastatic neoplasia. Serum creatine kinase is elevated in dogs and cats with muscle inflammation or necrosis. Urine specific gravity differentiates primary renal from prerenal azotemia. Hypernatremia is common when animals stop drinking or develop diabetes insipidus because of intracranial disease. Extremes of hyponatremia and hypernatremia and rapid correction of sodium imbalances cause brain dysfunction (see Chapter 55). Ammonium biurate crystals are occasionally found in the urine of dogs and cats with portosystemic shunts.

### **OTHER ROUTINE LABORATORY TESTS**

Additional biochemical tests are frequently performed during the diagnostic evaluation of patients with neurologic disorders. Preprandial and postprandial bile acids are routinely measured to rule out hepatic encephalopathy in animals with forebrain signs and to monitor liver function in animals being chronically treated with some anticonvulsants. Alternatively, provocative ammonia tolerance testing can be used to assess hepatic function in nonencephalopathic patients, and resting ammonia concentration can be measured in encephalopathic patients. Serum concentrations of anticonvulsants are routinely monitored (see Chapter 67). Whenever CNS hemorrhage is considered as a possible differential diagnosis, coagulation should be assessed by determining either the activated clotting time (ACT) or the prothrombin time (PT) and partial thromboplastin time (PTT). When abnormalities of calcium or glucose regulation are detected on the minimum database, further endocrinologic testing is recommended. Specific endocrine testing is also warranted when thyroid disease, hypoadrenocorticism, or hyperadrenocorticism could be responsible for an animal's neurologic signs.

### IMMUNOLOGY, SEROLOGY, AND MICROBIOLOGY

A number of special diagnostic tests can be performed in patients with neurologic disorders when infectious or immune-mediated diagnoses are being considered. Clinicians should routinely perform bacterial culture of the cerebrospinal fluid (CSF), blood, and urine in patients with inflammatory disease of the brain, spinal cord, or meninges. Concurrent systemic illness, potential for exposure, and vaccination status will determine what additional testing is warranted. When lesions outside of the CNS are identified, such as pneumonia or dermatitis, the most direct route to a diagnosis is usually by sampling those sites. Serum antibody or antigen tests are also available for many of the infectious agents that can affect the CNS. An increased titer of specific antibody in CSF relative to that in serum may be required to make a definitive diagnosis. Alternatively, immunohistochemical staining can be used to identify organisms in tissue (brain, spinal cord, or muscle). In some cases polymerase chain reaction (PCR) analysis is available for diagnosis of active infection by a specific organism.

Immune-mediated CNS disorders such as steroidresponsive meningitis-arteritis (SRMA) and granulomatous meningoencephalomyelitis (GME) are relatively common in dogs. Diagnosis requires finding typical clinical and clinicopathologic abnormalities and eliminating the possibility of infectious disorders, as previously. Dogs with SRMA commonly have elevated scrum and CSF IgA levels, and some have concurrent immune-mediated polyarthritis, which contributes to the diagnosis. In dogs with polyneuropathies, polymyositis, or apparent multisystemic immune-mediated

disease, it may be useful to measure antinuclear antibody (ANA) titers to support a diagnosis of systemic lupus erythematosus (SLE). Most dogs with acquired myasthenia gravis have detectable circulating antibodies against acetylcholine receptors, and some dogs with masticatory muscle myositis have serum antibodies directed against type 2M myofibers (See Chapter 72).

### RADIOGRAPHY

### RADIOGRAPHS

Radiographs of the thorax and abdomen can be useful as screening tests for infectious and neoplastic diseases and as a means of evaluating liver size. These are noninvasive tests that should be performed routinely.

Spinal radiographs are necessary and useful in the diagnosis of congenital malformations, fractures and luxations, disk disease, diskospondylitis, and primary or metastatic vertebral neoplasia. In most cases general anesthesia is required to obtain lateral and ventrodorsal radiographs of sufficient quality to permit the detection of subtle abnormalities. Radiographs should be centered on the region of clinical interest as established by the neurologic examination. Neoplasia of the soft tissues of the brain or spinal cord generally does not cause radiographic abnormalities. Although skull radiographs are a low-yield procedure, they are often performed in animals with disease above the foramen magnum, because finding an area of lysis, a region of tumor calcification, or an intranasal mass aids in diagnosis.

### CEREBROSPINAL FLUID COLLECTION AND ANALYSIS

### INDICATIONS

Analysis of CSF can be useful in the diagnostic evaluation of patients with CNS disease. Specific neurologic disorders often cause typical alterations in CSF cytology or protein concentration, aiding diagnosis. In addition, special techniques such as bacterial culture, organism identification, antibody determination, and PCR can be performed on CSF, leading to a definitive diagnosis in some patients with infectious CNS disease. CSF examination is indicated in most animals with certain or suspected neurologic disease in which a diagnosis is not readily apparent, once traumatic, metabolic, and congenital abnormalities have been excluded. Analysis of CSF is most likely to be diagnostic in dogs and cats with intracranial lesions causing progressive forebrain signs and in animals with fever and axial pain. In animals with evidence of spinal cord disease, CSF analysis should always be performed before myelography to rule out inflammatory disease.

### CONTRAINDICATIONS

If the proper technique is followed, the procedure for obtaining CSF is safe and simple. The animal is first placed under

general anesthesia, and the puncture site is prepared in a sterile fashion, thereby minimizing the risk of damage resulting from animal movement and the risk of iatrogenic infections. Spinal puncture should not be performed in an animal that is an obvious anesthetic risk or that has a severe coagulopathy. General anesthesia and collection of CSF should not be performed in any patient with suspected increased intracranial pressure (Box 64-1) without first taking steps to lower the intracranial pressure in order to decrease the risk of brain herniation (Box 64-2).

### **TECHNIQUE**

In dogs and cats the most reliable source of CSF for analysis is the cerebellomedullary cistern. The L5-L6 site may also be used, but it is more difficult to obtain a large volume of uncontaminated fluid from this site. Although it has been stated that CSF obtained from the cerebellomedullary cistern best reflects the nature of intracranial disease, whereas fluid from a lumbar tap is more useful in characterizing spinal cord disease, diagnostically the two are not significantly different. Lumbar CSF from normal dogs may have a slightly higher protein content and lower nucleated cell count than CSF obtained from the cerebellomedullary cistern.

### **Cisternal Puncture**

With the animal under general anesthesia, the clinician should prepare the back of its neck between the ears from the occipital protuberance to C2 for surgery. If the clinician is right-handed, the animal should be placed in right lateral recumbency with its neck flexed so that the median axis of the head is perpendicular to the spine. The nose should be elevated slightly so that its midline is parallel to the surface of the table. With the thumb and third finger of the left hand,

the clinician should palpate the cranial edges of the wings of the atlas and draw an imaginary line at their most cranial aspect.

The examiner can then use the left index finger to palpate the external occipital protuberance and draw a second imaginary line caudally from that site along the dorsal midline. The needle should be inserted where the two imaginary lines intersect (Fig. 64-1).

A 1<sup>1</sup>/<sub>2</sub>- or 3-inch (3.75 to 7.5 cm) long styletted spinal needle is then directed straight in through the skin, perpendicular to the spine, and into the underlying tissues. The needle is advanced 1 to 2 mm at a time, and the stylette is removed so that the clinician can look for CSF fluid. While the right hand is used to remove the stylette, the thumb and first finger of the left hand, which is rested against the spine for support, should grasp and stabilize the hub of the needle. A sudden "pop" may be felt as the dorsal atlantooccipital membrane and the dura mater and arachnoid mater are penetrated simultaneously (Fig. 64-2). This is not a reliable sign, however, and the level at which the subarachnoid space is reached varies greatly with the breed and individual animal. It is often very close to the skin surface in toy breeds and some cats.

If the needle strikes bone, it should be withdrawn, the patient position and landmarks reassessed, and the procedure repeated. If whole blood appears in the spinal needle, the needle should be withdrawn and the procedure repeated with another sterile needle. When CSF is observed, the fluid should be allowed to drip directly from the needle into a test tube. The clinician should check with the laboratory to determine the type of tube preferred for collection of CSF. The amount of CSF collected ranges from 0.5 to 3 ml depending on the size of the animal. Simultaneous jugular vein

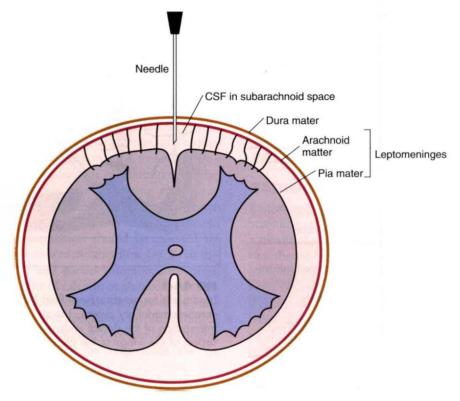

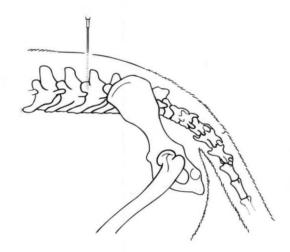

FIG 64-2

compression may hasten flow but will transiently increase intracranial pressure. Blood in the CSF may be the result of the disease or of the tap. If it is caused by the procedure, the amount of blood should decrease as the CSF drips from the needle. If this occurs, some of the less contaminated fluid should be collected in a second tube for cytologic evaluation. Mild CSF contamination with hemorrhage (<500 RBCs/µl) does not alter the CSF protein and leukocyte determinations. Grossly hemorrhagic CSF should always be collected into a tube containing ethylenediaminetetraacetic acid (EDTA) to prevent clotting.

### **Lumbar Puncture**

The animal is placed in lateral recumbency with its trunk flexed. Foam cushions are placed between its limbs and beneath the lumbar region to achieve true lateral positioning. A 3<sup>1</sup>/ -inch (8.75-cm) spinal needle is inserted on midline at the cranial edge of the dorsal spinal process of the L5 or L6 vertebra and directed ventrally into the ligamentum flavum (Fig. 64-3). The needle is passed in a smooth motion through or alongside the caudal spinal cord and cauda equina into the ventral subarachnoid space. The animal's tail and pelvic limbs may twitch when the cord is penetrated. Because CSF flow is slower from this site and more likely to be contaminated by blood, cerebellomedullary collection is usually preferred for diagnostic purposes.

Landmarks for cerebrospinal fluid (CSF) collection from a lumbar site. The needle is inserted at the cranial edge of the dorsal spinal process of the L6 vertebra.

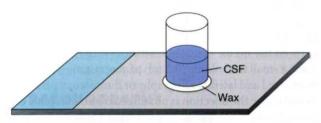

### **ANALYSIS**

Normal CSF is clear and colorless. A cell count should be performed and a cytologic preparation made for examination as soon as possible because white blood cells (WBCs) in the CSF deteriorate rapidly. If the sample must be stored

for longer than 1 hour before analysis, the specimen should be refrigerated to slow cellular degeneration. The addition of autologous serum (10% by volume of the sample) will preserve CSF so that cytologic analysis 24 to 48 hours after collection will yield reliable results, but a separate sample must be saved for protein analysis. Alternatively, one drop of buffered 10% formalin can be added for each 0.25 ml of CSF to preserve cytologic features without affecting the protein measurement.

Once the fluid is collected, a total cell count is performed and the concentration of RBCs and WBCs is determined. The normal range of values varies with each laboratory, but in general there should be fewer than five WBCs per microliter. An increased number of CSF WBCs is referred to as *a pleocytosis*. A pleocytosis should be further characterized by microscopic examination and differential cell count to determine the predominant leucocyte present. Cytologic analysis of CSF is necessary even if the WBC count is normal because there may be abnormal cell types or organisms present.

A concentration procedure is usually required to obtain sufficient cells for cytologic assessment if the CSF WBC count is less than 500 cells/µl. Cytocentrifuge concentration of CSF is available in most institutions and commercial laboratories, and results are best if samples are processed within 30 minutes of collection or if samples are preserved as described earlier. Alternatively, an in-clinic sedimentation technique can be used, in which 0.5 ml of CSF is allowed to sediment over a region of a slide within a sedimentation chamber that is attached to the slide with paraffin or petroleum jelly (Fig. 64-4). The CSF supernate is then gently aspirated with a needle and syringe and can be used for protein or antibody titer determination. Any remaining fluid is then removed by applying blotting paper to the fluid edge, and the slide is quickly dried by vigorously waving it in the air. Once the slide is dry, the remaining paraffin or petroleum jelly should be scraped off. Slides should be evaluated by a veterinary cytopathologist. If the slide cannot reach a commercial laboratory within a few hours, it should be fixed and stained with Diff-Quik Differential Stain Set (American Scientific Products) or Wright's or Giemsa stain.

### FIG 64-4

A sedimentation chamber can be made from a cut section of a glass vacutainer or plastic specimen tube that is attached to a glass microscope slide with paraffin or petroleum jelly. Cerebrospinal fluid (CSF; 0.5 ml) is placed in the chamber. After 30 minutes the supernate is gently aspirated with a needle and syringe and the slide is dried rapidly. The slide is then fixed, and the paraffin or petroleum jelly is removed with a scalpel.

Most of the cells in the CSF of normal dogs and cats are small, well-differentiated lymphocytes (60% to 70%). Minimally vacuolated, large mononuclear phagocytes normally compose up to 40% of the cells. Occasional neutrophils and eosinophils are present, but these cells should not normally make up more than 2% of the cell population. The typical CSF findings in some specific disorders in dogs and cats are summarized in Box 64-3. It is important to realize, however, that CSF cytologic findings must always be interpreted in relation to the signalment, history, and clinical findings.

If blood contamination is severe, it can influence the cytologic findings, but even grossly apparent iatrogenic contamination with peripheral blood will have only a minor impact on WBC count and protein analysis. To approximate the maximum effect blood contamination will have on the WBC count in CSF, one WBC per microliter can be expected for every 500 RBCs per microliter.

The protein concentration in samples collected from the lumbar site (<40 mg protein/dl) is normally higher than the protein content of CSF collected from the cerebellomedullary cistern (<25 mg protein/dl). The protein content of the collected CSF should be determined and, whenever possible, protein electrophoresis performed. An increase in the CSF protein content can occur in diseases that disrupt the bloodbrain barrier, cause local necrosis, interrupt normal CSF flow and absorption, or result in intrathecal globulin production. Information from CSF protein electrophoresis can be used to determine whether the high protein content in CSF is a result of blood-brain barrier disruption, the intrathecal production of immunoglobulin, or both (Box 64-4). CSF protein electrophoresis patterns typical of inflammation, degeneration, and neoplasia of the CNS have been established and can be used with some degree of accuracy to predict the mechanism of disease involved. The immunoglobulins in CSF can also be quantified, helping to differentiate inflammatory from noninflammatory disorders.

Whenever the CSF is cellular, it should be submitted for Gram's staining and anaerobic and aerobic bacterial culture. If infectious disorders are considered likely (see the discussion of meningitis, Chapter 69), specific culture techniques can be applied or, when available, PCR can be used to identify infectious agents in CSF. Antibody titers to a variety of infectious organisms can be measured in CSF, but leakage of antibodies from the serum to the CSF can be problematic. An immunogolobin G (IgG) index greater than 1 indicates that there is significant intrathecal production of immunoglobulin (see Box 64-4). Comparison of CSF and serum titers against a specific organisms can be performed, with a C-value greater than 1 indicating active CNS infection with an organism (see Box 64-4).

### ADVANCED DIAGNOSTIC IMAGING

### **MYELOGRAPHY**

In animals with clinical evidence of spinal cord disease or compression, myelography may be used to confirm, localize,

and characterize lesions. This procedure is particularly valuable for identifying compression of the spinal cord by herniated disks or tumors. Myelography is rapid and is more readily available and less expensive than other advanced imaging techniques, such as computed tomography (CT)

and magnetic resonance imaging (MRI), but it is also associated with a higher rate of complications.

To perform myelography, the clinician anesthesizes the animal and injects a nonionic contrast material into the subarachnoid space at the atlanto-occipital or lumbar (L5/6 or L4/5) space. The contrast material most commonly used for this purpose is iohexol (Omnipaque; Nycomed). Injection of iohexal (0.25 to 0.50 ml/kg of 240 or 300 mgl/ml contrast media) is associated with a relatively low (<10%) prevalence of postmyelographic adverse effects, such as seizure, hyperesthesia, and vomiting. Lumbar injections are technically more difficult but associated with decreased risk of iatrogenic spinal cord trauma and improved delineation of thoracic and lumbar compressive spinal cord lesions because the contrast material can be injected under increased pressure and forced around a site of severe compression.

Myelography should be performed only after it has been confirmed that the CSF is not inflammatory because contrast injection will worsen the inflammation and clinical symptoms in an animal with meningitis. Additionally, injection of contrast will cause mild inflammation, making diagnostic evaluation of CSF cytology very difficult for at least 1 week after myelography. CSF collection and analysis should always precede myelography.

In cisternal myelography the needle is inserted using the same technique and landmarks as for cisternal puncture for CSF collection (see Fig 64-1), and the bevel of the needle is directed caudally. The contrast material is injected slowly and allowed to flow caudally the length of the spinal subarachnoid space. Needle removal and elevation of the animal's head, neck, and thorax promote caudal flow, resulting in opacification of the caudal limit of the subarachnoid space within 10 minutes. During myelography the flow of the contrast agent is visualized fluoroscopically (when available), and lateral, ventrodorsal, and sometimes obliquely positioned radiographs are taken directly over each region of interest. In some instances dynamic views (traction, extension, and flexion) may be obtained. If contrast medium filling is inadequate in some regions, the animal is tilted and manipulated to allow gravity-assisted pooling of contrast medium at the site of interest.

Lumbar myelography is performed with the needle at the L5/L6 (large dogs) or L6/L7 (small dogs and cats) site. Needle insertion is as described for lumbar CSF collection, with the bevel of the needle oriented cranially. Once the needle is in place, a small test volume (0.2 ml) of contrast medium should be injected and lateral radiography or fluoroscopy performed to make sure the injection is not directed into the spinal cord parenchyma. If the needle is positioned correctly, the injection is completed during fluorosocopic visualization and then lateral radiographic views are taken with the needle in place. Once the spinal needle is removed, ventrodorsal, oblique, and dynamic radiographs should be taken rapidly because epidural leakage may occur through the puncture site.

Seizures occasionally occur in animals recovering from anesthesia after myelography. Seizures are most common in dogs larger than 29 kg, when cisternal myelography is per-

### Diagnostic Interpretation of Protein and Antibody Concentrations in Cerebrospinal Fluid

Albumin Quotient >0.3 indicates damage to the blood brain barrier and leakage of serum into the CSF.

Albumin Quotient = 
$$\frac{CSF \text{ albumin (mg/dl)}}{Serum \text{ albumin (g/dl)}} \times 10$$

lgG index >1 indicates significant intrathecal antibody production.

$$lgG index = \frac{lgG in CSF}{lgG in serum} \times \frac{1.0}{Albumin Quotient}$$

C-value >1 suggests intrathecal antibody production against a specific organism.

$$\label{eq:continuous} \text{C value} = \frac{\text{organism specific IgG in CSF}}{\text{organism specific IgG in serum}} \times \frac{\text{Total IgG in CSF}}{\text{Total IgG in serum}}$$

Antibody coefficient >1 is the most reliable indicator of intrathecal antibody production against a specific organism (organism A). Organism B is an organism normally expected to have serum antibodies detected.

$$Antibody = \frac{\text{organism A specific IgG in CSF}}{\text{IgG in serum}} \times \text{organism B specific}$$
 
$$Coefficient = \frac{\text{organism A specific IgG in serum}}{\text{IgG in serum}} \times \text{organism B specific}$$

CSF, Cerebrospinal fluid.

formed, and when more than two injections of contrast agent are administered. These seizures can usually be controlled with diazepam (5 to 20 mg, administered intravenously).

Neurologic deterioration occurs in some animals after myelography. Large-breed dogs with cervical spondylomyelopathy (Wobbler syndrome), dogs and cats with inflammatory CNS disease or extradural tumors, and dogs with degenerative myelopathy are most often affected. Fortunately, this deterioration is usually transient.

A normal myelogram will show contrast material filling the subarachnoid space. This appears as a column of contrast agent on each side of the cord on ventrodorsal views and in the ventral and dorsal columns on lateral views (Fig. 64-5). In normal myelograms a slight elevation and thinning of the ventral column of the contrast agent can be seen as it passes over each intervertebral disk space; however, a wide dorsal column remains, indicating that spinal cord compression is not present. Based on the features of the myelogram, a spinal cord lesion can be characterized as extradural compression, intradural extramedullary compression, or intramedullary swelling (Figs. 64-6 and 64-7).

### **ULTRASONOGRAPHY**

Ultrasound is not useful in routine imaging of the brain and spinal cord because these structures are normally encased in bone. This modality can, however, provide valuable information in the diagnostic evaluation of patients with neurologic disease. Abdominal ultrasound is recommended to search for a primary tumor whenever metastatic neoplasia is considered as a possible cause of neurologic signs. Ultrasound can also be used to identify portosystemic shunts in dogs and cats. Brain ultrasound through open fontanelles can be per-

formed to identify hydrocephalus in dogs and cats (Fig. 64-8). Ultrasound of the axilla in a sedated animal can be useful in the identification and biopsy of soft tissue masses within the brachial plexus.

# COMPUTED TOMOGRAPHY AND MAGNETIC RESONANCE IMAGING

CT and MRI are available for the diagnosis of neurologic disease at most major veterinary referral centers. These techniques are noninvasive and valuable in the localization, identification, and characterization of many brain and spinal cord lesions (Figs. 64-9 and 64-10). CT is most useful for identification and characterization of bony abnormalities of the vertebral bodies and skull. Contrast-enhanced CT will help identify soft tissue lesions that disrupt vascular endothelium. MRI can be used to determine very small density differences in soft tissues; therefore it is the imaging modality of choice for the brain, spinal cord, and peripheral nerves. These techniques allow precise topographic mapping of lesions, making them valuable tools in the evaluation of compressive lesions of the brain, spinal cord, or cauda equina when surgery is being considered.

### **ELECTRODIAGNOSTIC TESTING**

Electrophysiologic studies can be used to record electrical activity from muscle or neural tissue and aid in lesion localization and characterization. These tests are minimally invasive but usually require sedation or general anesthesia. The cost of the equipment and the experience needed to conduct the studies limit their use to academic and referral clinics.

### **ELECTROMYOGRAPHY**

Normal muscle is electrically silent. As a needle is inserted into normal muscle, a short burst of electrical activity is elicited, which stops when the needle insertion is stopped. Severance, destruction, or demyelination of the peripheral nerve supplying the muscle results in the development of spontaneous fibrillations and positive sharp waves (i.e., denervation potentials) and prolonged insertional activity in affected muscles 5 to 7 days after denervation. These changes may also be seen in some primary muscle disorders. Electromyography (EMG) is most useful to confirm a suspected diagnosis of a muscle or peripheral nerve disorder and to identify abnormal muscles for subsequent biopsy.

### **NERVE CONDUCTION VELOCITIES**

The conduction velocity of motor nerves can be determined by stimulating a nerve at two separate sites and recording the time it takes for an evoked muscle potential to occur. The motor nerve conduction velocity in that segment of nerve can be determined by measuring the distance between the two sites and the difference in the time it takes for the evoked potentials to appear. The conduction velocity of sensory nerves can be measured using a similar technique. Slow conduction times are seen in demyelinating disorders, allowing the diagnosis of peripheral neuropathies. Nerves that have been injured or avulsed and that have degenerated (onset typically 4 to 5 days after injury) do not conduct an impulse; thus nerve conduction velocity testing can also be used to diagnose and localize peripheral nerve injuries.

### **ELECTRORETINOGRAPHY**

An electroretinogram (ERG) is a recording of the electrical response of the retina to a flashing light stimulus. It is an objective way to evaluate retinal function, assessing both rod and cone receptors. The ERG is most useful for the evaluation of blind animals in which the retina appears normal on ophthalmic examination (e.g., diagnosing sudden acquired retinal degeneration) or in which the retina cannot be visualized (e.g., determining whether animals with cataracts have concurrent retinal degeneration). The ERG is abnormal with degenerative disorders of the retina, but it is normal if the

lesion causing visual dysfunction is located caudal to the retina (in the optic nerves, optic chiasm, optic tract, or cerebral cortex). The ERG can be performed under general anesthesia or under sedation if the patient is uncooperative.

# BRAINSTEM AUDITORY EVOKED RESPONSE

The brainstem auditory evoked response (BAER) depicts the response of nervous tissues to an auditory stimulus (a click). The response is a series of waveforms representing activity beginning in the cochlea and being relayed up the auditory pathway in the brainstem. Lesions of the outer, middle, or inner ear; the peripheral vestibulocochlear nerve; and the brainstem caudal to the midbrain cause characteristic changes in the response, aiding in lesion localization. This test has been most widely used for detecting unilateral and bilateral congenital deafness in dogs.

### **ELECTROENCEPHALOGRAPHY**

Electroencephalography provides a graphic record of the spontaneous electrical activity of the cerebral cortex. Results

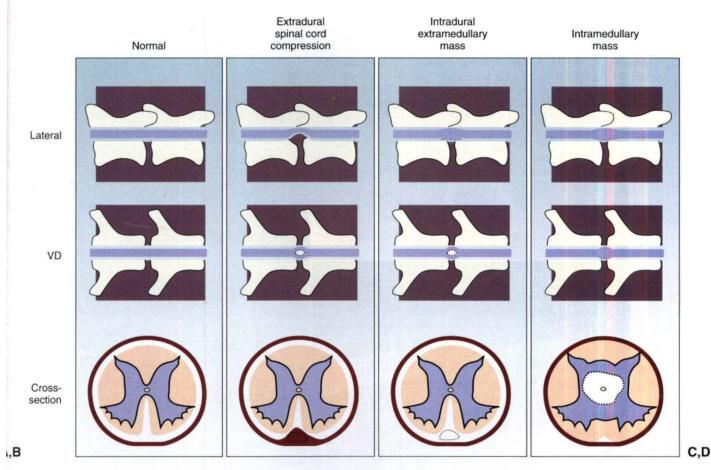

FIG 64-5

Lateral **(A)** and ventrodorsal **(B)** views of a normal myelogram of the thoracolumbar region in a dog. Multiple calcified intervertebral disks can be seen, but no spinal cord compression is evident. (Courtesy Dr. John Pharr, University of Saskatchewan.)

В

### FIG 64-6

The myelographic appearance of extradural, intradural-extramedullary, and intramedullary spinal cord masses. **A,** Normal myelogram. **B,** Ventral extradural spinal cord compression. The leading edge of the contrast material tapers toward the spinal cord, away from the bone on the lateral view. The dorsal column is thinned in this region. On the ventrodorsal view the spinal cord appears widened or flattened, resulting in narrow columns of contrast material. **C,** Ventral intradural, extramedullary spinal cord compression. The leading edge of the contrast material expands and outlines the lesion, tapering toward the spinal cord and toward the bony margin of the osseous canal, resulting in a filling defect at the site of the lesion and the appearance of a "golf tee sign." On the ventrodorsal view the spinal cord appears widened or flattened, resulting in narrow columns of contrast material. **D,** Intramedullary mass or swelling. The leading edges of the contrast material taper toward the bony margin of the osseous canal on both views, with diverging columns of contrast material indicating spinal cord enlargement.

may help determine whether a cerebral disorder is focal or diffuse. Some dogs with epilepsy will have abnormal electroencephalograms (EEGs) between seizures.

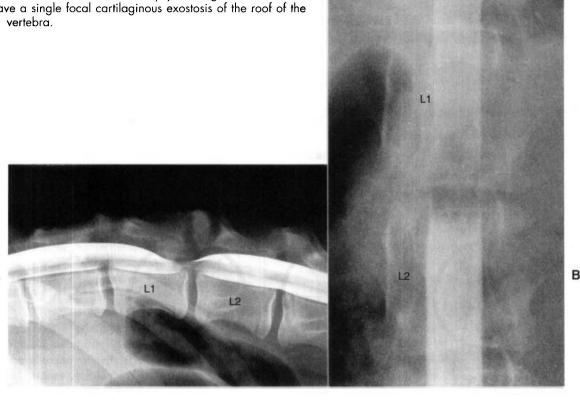

### **BIOPSY OF MUSCLE AND NERVE**

### **MUSCLE BIOPSY**

Muscle biopsy specimens should be evaluated when there is clinical and electrophysiologic evidence of muscular disease. A biopsy may provide a definitive diagnosis or indicate the nature of the disease process. For best results, muscle that is affected should be biopsied and in generalized disorders two different muscles should be sampled. For investigation of myopathic disorders, proximal limb muscles such as the vastus lateralis or triceps should be biopsied, whereas neuropathies are more evident in distal limb muscles such as the cranial tibial or extensor carpi radialis. Because complete histopathologic examination of muscle requires fresh-frozen tissue, most laboratories request that fresh muscle samples be wrapped in a saline-moistened gauze and shippped overnight under refrigeration. Whenever formalin-fixed samples are submitted, the sample should be attached to a splint, such as a tongue depressor, to prevent contraction during fixation.

FIG 64-7

Lateral **(A)** and ventrodorsal **(B)** views of a myelogram in a 5-month-old German Shepherd Dog with a 3-week history of progressive ataxia. A dorsally located extradural compression of the spinal cord within the caudal portion of the L1 vertebra can be seen. At necropsy the dog was found to have a single focal cartilaginous exostosis of the roof of the L1 vertebra.

Routine histologic studies may reveal inflammatory or neoplastic changes and the etiologic agent if the disease is infectious.

When fresh-frozen tissue is evaluated using a full range of enzymatic and immunohistochemical techniques, many characteristics of the muscle can be determined. Based on enzymatic staining characteristics, muscle fibers can be classified according to type and the proportion and distribution of myofiber types described. Some myopathies result in a selective loss of one fiber type. Denervation with reinnervation, as occurs in many neuropathies, results in "type grouping," wherein the normal checkerboard pattern disappears and large clusters of fibers of the same type appear. Muscle fiber shape and size, the presence of degeneration or necrosis, the location of nuclei, the presence of vacuoles or inclusions, and the presence of cellular infiltrates are all evaluated. Immunostains are also available to identify some parasites (Neospora) and evaluate muscles for normal structural components. Muscle samples should be sent to a laboratory with a special interest in muscle disorders to ensure that optimal results are obtained and accurately interpreted. Clinicians should consult the laboratory that will process the biopsy to learn the proper technique of obtaining and preparing specimens and the other procedures to be followed.

### **NERVE BIOPSY**

It may be useful to obtain nerve biopsy specimens in an effort to evaluate peripheral nerve disorders. Nerves are biopsied by transecting approximately one third of the width of the nerve and removing fascicles about 1 cm in length, leaving most of the nerve trunk intact. It is important to biopsy nerves that are affected. The common peroneal nerve and the ulnar nerve are the mixed (i.e., motor and sensory) nerves most commonly biopsied. As with muscle biopsy specimens, nerve biopsy specimens require special handling to ensure that maximal information is obtained. Samples should be laid out on a piece of wooden tongue depressor and pinned at each end to keep them oriented longitudinally, but they should not be stretched. They should then be fixed in 2.5% glutaraldehyde or buffered 10% formalin for light microscopy. Fresh nerve samples can be frozen in liquid nitrogen and stored for biochemical analysis.

Inflammatory Diseases (Encephalitis)

Inherited Degenerative Disorders

Geriatric Canine Cognitive Dysfunction

Neoplasia

### **HYPERMETRIA**

Congenital Malformations

Cerebellar Cortical Degeneration (Abiotrophy)

Neuroaxonal Dystrophy

Brain Cysts

**TREMORS** 

**DYSKINESIAS** 

### **GENERAL CONSIDERATIONS**

When the neurologic examination suggests that a lesion is located above the foramen magnum, a variety of disorders should be considered as differential diagnoses. Some of these disorders typically affect only one particular region of the brain, such as the forebrain or the cerebellum, whereas others can affect any location within the brain. Altered mentation is the first and most pronounced abnormality in most forebrain and brainstem disorders.

### ABNORMAL MENTATION

Abnormal behavior, delirium, compulsive behavior, and seizures can be seen in dogs and cats with lesions of the cerebral cortex and with intoxications or metabolic encephalopathies. Disorders affecting the brainstem can also cause severe depression, stupor, and coma.

When presented with a dog or cat with abnormal mentation, the clinician must first ascertain whether the problem is purely behavioral, the result of systemic illness, or an indication of an intracranial lesion. The history obtained from the owner regarding the animal's normal behavior, systemic signs, and the circumstances preceding the onset of signs may help identify a neurologic problem. Defined neurologic deficits confirm the existence of an abnormality within the nervous system. With some unilateral forebrain lesions animals turn or circle toward the side of the lesion and ignore all sensory input (touch, seeing, and hearing) on the side opposite the lesion (hemi-inattention syndrome). Although their gait will usually be normal, affected animals may exhibit postural reaction deficits on the side opposite the lesion. Brainstem lesions typically cause altered consciousness, multiple cranial nerve deficits, and ipsilateral upper motor neuron (UMN) paresis, ataxia, and postural reaction deficits.

### **INTOXICATIONS**

Intoxication with household toxins, insecticides, rodenticides, and prescription or illicit drugs must be considered in any dog or cat with an acute onset of abnormal mentation. Anxiety and delirium may precede severe depression, seizures, and other neurologic and systemic signs. Common toxic agents causing mentation changes and seizures in dogs and cats include strychnine, metaldehyde, chlorinated hydrocarbons, organophosphates, lead, and ethylene glycol (see Boxes 67-3 and 67-4). The clinical signs of intoxication are usually acute and severe, with rapid deterioration. A history of potential ingestion or exposure to a toxin and the finding of characteristic clinical signs lead to the diagnosis. Treatment must be initiated to remove the toxin, prevent further absorption, and expedite its elimination. Intoxications

resulting in scizures also require emergency treatment for seizures, as described for status epilepticus (see Box 67-7).

### **METABOLIC ENCEPHALOPATHIES**

Animals with abnormal mentation, diminished consciousness, or seizures should always be evaluated for metabolic disturbances such as hepatic encephalopathy, hypoglycemia, severe uremia, electrolyte disturbances, and hyperosmolality (e.g., untreated diabetes mellitus). Depressed mentation can also be a manifestation of severe systemic illness, sepsis, hypoadrenocorticism, or hypothyroid myxedema coma. More detailed information on the diagnosis and management of these metabolic disorders is contained elsewhere in this text.

### DIAGNOSTIC APPROACH TO ANIMALS WITH INTRACRANIAL DISEASE

Intracranial disorders that commonly cause abnormalities of mentation include external trauma, vascular disorders (e.g., hemorrhage and infarction), anomalies (e.g., hydrocephalus, lissencephaly), thiamine deficiency, inflammatory diseases (e.g., encephalitis), degenerative disorders, and primary or metastatic brain tumors. Evaluation should always include a complete physical and neurological examination as well as an ophthalmologic examination. When the cause of the neurologic signs is not readily apparent, animals should be screened for systemic manifestations of inflammatory or neoplastic disease using clinicopathologic tests, thoracic and abdominal radiographs, and abdominal ultrasound. If disease is restricted to an intracranial site, advanced neuroimaging (computed tomography [CT], magnetic resonance imaging [MRI]) and cerebrospinal fluid (CSF) collection and analysis may be required for diagnosis. Degenerative disorders are suspected if all test results are normal (Box 65-1).

### INTRACRANIAL DISORDERS

### HEAD TRAUMA

The outcome for animals with head trauma depends largely on the location and severity of the initial injury. Common causes of head injuries in dogs and cats include motor vehicle accidents and kicks and bites from larger animals. The initial trauma to the brain parenchyma is followed by secondary damage resulting from hemorrhage, ischemia, and edema. Because the brain is enclosed within the bones of the skull, as brain volume increases with edema or hemorrhage, there is an increase in intracranial pressure, leading to decreased cerebral perfusion and further brain damage.

Initial management of a patient with brain injury should focus on recognizing and treating systemic injuries and maintaining adequate circulation and respiration. Systemic hypotension further decreases cerebral perfusion, so fluids should be administered to maintain blood volume (Box 65-2). Administration of synthetic colloids (hetastarch, dextrans) allows rapid restoration of blood volume and pressure without the large volume of fluid required when crystalloids

### Diagnostic Approach to Animals with Abnormal Mentation

- 1. Perform a complete history, physical examination, and neurological assessment.
  - Focal or asymmetrical deficits suggest intracranial disease
- 2. Rule out metabolic encephalopathies. Hematology, serum chemistry profile, urinalysis Blood glucose: fasting, symptomatic, postprandial Liver function test
- 3. Evaluate for systemic inflammatory or neoplastic disease.

Complete ophthalmic examination Thoracic and abdominal radiographs Aspirates of lymph nodes (+/- spleen, liver, bone marrow)

- Serology when appropriate 4. Perform an intracranial examination.
  - Neuroimaging (computed tomography, magnetic resonance imaging)

Cerebrospinal fluid collection and analysis

BOX 65-2

Management of Intracranial Injury

### **Ali Patients**

Establish patent airway, administer oxygen. Examine, assess, and treat concurrent injuries. Treat shock: intravenous fluids, colloids. Maintain mean arterial blood pressure 80-120 mmHg. Monitor neurologic status every 30 minutes.

### If Severe Initial Injury or Deterioration

Elevate head 30 degrees.

Treat seizures if present (see Box 67-6).

Administer 20% mannitol: 1.0 g/kg, administered intravenously over 15 minutes (can repeat in 3 hours).

Administer furosemide: 1.0 mg/kg, administered intravenously.

If intubated, maintain PaCO2 at 30-40 mmHg.

alone are administered. Oxygen should be administered by mask or via nasal or transtracheal catheter. If the animal is unconscious, immediate intubation and ventilation may be required. Hyperventilation reduces intracranial pressure but causes cerebral vasoconstriction and decreased cerebral perfusion; therefore it must be used with caution. Whenever possible, a Paco<sub>2</sub> of 30 to 40 mmHg should be maintained. If seizures are evident, aggressive anticonvulsant therapy should be initiated as for status epilepticus (see Chapter 67) because seizure activity greatly increases intracranial pressure. Measures to lower intracranial pressure include elevating the head at a 30-degree angle from horizontal,

BOX 65-3

### Modified Glasgow Coma Scale

Motor Activity	
Normal gait, normal spinal reflexes Hemiparesis, tetraparesis, or decerebrate activity Recumbent, intermittent extensor rigidity Recumbent, constant extensor rigidity Recumbent, constant extensor rigidity with opisthotonus Recumbent, hypotonia of muscles, depressed or absent spinal reflexes	6 5 4 3 2
Brainstem Reflexes	
Normal pupillary light reflexes and oculocephalic reflexes Slow pupillary light reflexes and normal to reduced oculocephalic reflexes Bilateral unresponsive miosis with normal to reduced oculocephalic reflexes Pinpoint pupils with reduced to absent oculocephalic reflexes Unilateral, unresponsive mydriasis with reduced to absent oculocephalic reflexes Bilateral, unresponsive mydriasis with reduced to absent oculocephalic reflexes	6 5 4 3 2
Level of Consciousness	
Occasional periods of alertness and responsive to environment Depression or delirium; capable of responding, but response may be inappropriate Semicomatose, responsive to visual stimuli Semicomatose, responsive to auditory stimuli Semicomatose, responsive only to repeated noxious stimuli Comatose, unresponsive to repeated noxious stimuli	6 5 4 3 2

administration of intravenous mannitol as an osmotic diuretic (1.0 g/kg over 15 minutes), and administration of furosemide (0.7 mg/kg). Administration of high doses of methylprednisolone sodium succinate (SoluMedrol) during the first 6 hours after presentation has been shown to be beneficial in patients with spinal cord injury but may actually be detrimental in patients with serious brain injury.

Systemic and neurological assessment should be repeated every 30 minutes. A scoring system has been developed to allow grading of initial neurological status and serial monitoring. Using the modified Glasgow coma scale (Box 65-3), motor activity, brainstem reflexes, and level of consciousness are all assigned a score from 1 to 6. A total score of 8 or lower is associated with less than 50% survival, even with intensive treatment.

### VASCULAR ACCIDENTS

Spontaneous infarction and hemorrhage occasionally occur in the central nervous systems of dogs and cats. Older dogs;

dogs with renal failure, hyperadrenocorticism, hypothyroidism, or hypertension of any cause; and cats with renal failure, hyperthyroidism, or primary hypertension are predisposed. Intracranial hemorrhage and infarction may also occur secondary to septic emboli, neoplasia, thrombocytopenia, coagulopathies, heartworm disease, or vasculitis. With a vascular accident the onset of neurologic abnormalities is peracute. Results of physical examination, clinicopathologic evaluation, and thoracic radiography may be unremarkable, aside from the neurologic abnormalities, or may reflect the underlying disease process. Systemic blood pressure should be measured and an ocular exam performed to search for hypertension-related hemorrhage or retinal detachment. MRI is the most effective means of making an antemortem diagnosis. CSF analysis, when performed, may reveal increased protein concentration, a mild mononuclear or neutrophilic pleocytosis (<30 cells/µl), and occasionally erythrophagia suggesting prior hemorrhage. Short-term aggressive therapy to lower intracranial pressure as described for head trauma (see Box 64-2) may be indicated. Underlying disorders such as hypertension and coagulopathy should be managed. Most mildly or moderately affected animals show dramatic improvement during the first 3 to 10 days after the onset of signs, although some never return to a normal functional status.

### FELINE ISCHEMIC ENCEPHALOPATHY

Feline ischemic encephalopathy (FIE) is a syndrome of acute cerebral cortical dysfunction caused by cerebral infarction in young and middle-aged cats of any breed and either gender. The portion of the cortex supplied by the middle cerebral artery is most commonly affected. Most cases of FIE are diagnosed during the summer months, and the prevalence of this disorder is highest in cats living in the northeastern United States with access to the outdoors. Cats are presented because of a peracute onset of asymmetric neurologic abnormalities, including delirium, aggression, circling to the side of the lesion, ataxia, and seizures. There may be a loss of proprioception and hyperactive reflexes (UMN signs) in the limbs opposite the side of the lesion, and the cat may be blind but have normal pupillary light reflexes (cortical blindness) on the side opposite the lesion. FIE should be suspected in any cat with an acute onset of nonprogressive unilateral cerebral cortical dysfunction and no history of trauma or evidence of systemic illness or hypertension. Physical examination typically reveals no abnormalities other than the neurologic signs. Ophthalmologic examination, clinicopathologic evaluation, and skull radiography findings are also normal. CSF is normal cytologically, with a normal or only slightly increased protein content, making inflammatory disease unlikely. MRI is the best method of documenting the infarcted region.

Histopathology reveals extensive acute necrosis and edema of the cerebral cortex, resulting from acute infarction of the middle cerebral artery. Moreover, many cats show histopathologic features compatible with aberrant migration of Cuterebra fly larvae. The larvae apparently enter the brain

### **HYDROCEPHALUS**

euthanasia.

Hydrocephalus is a condition in which the cerebral ventricular system is enlarged secondary to an increased amount of CSF, with secondary compression or atrophy of the surrounding neurologic tissue. Most cases are congenital. Dog breeds at risk include the Maltese, Yorkshire Terrier, English Bulldog, Chihuahua, Lhasa Apso, Pomeranian, Toy Poodle, Cairn Terrier, Boston Terrier, Pug, Chow Chow, and Pekingese. Cats are occasionally affected.

sive behavior or recurrent seizures, often resulting in

Many affected animals have an obviously enlarged head and palpably open fontanelles (Fig. 65-1). Care must be taken not to overinterpret these findings, however, because domed heads and open fontanelles are very common in some toy breeds. Although most dogs with fontanelles that remain open at 9 weeks of age do have ventricular dilation, many will never develop clinical signs of hydrocephalus.

Animals with symptomatic hydrocephalus are slow learners and may be difficult to housetrain. They may seem dull or depressed. They may have episodic or constant abnormal behavior, delirium, and cortical blindness. Seizures may occur. Severely affected animals may exhibit tetraparesis and slow postural reactions. Some animals will develop a ventrolateral strabismus (see Fig. 65-1).

Hydrocephalus is suspected on the basis of characteristic signs and physical examination findings in a young animal of a typical breed. If fontanelles are open, ultrasound examination of the brain can be performed through the openings, and this can determine the size of the lateral ventricles and confirm the diagnosis (see Fig. 64-8). If the fontanelles are small or closed, ultrasound scanning is more difficult but may still be attempted through the temporal bone in young animals. Alternatively, CT or MRI can be performed to detect ventricular enlargement. Although historical studies have shown very little correlation between ventricular size and clinical signs, one recent report showed that ventricular enlargement (ventricle: brain [VB] ratio) was correlated

A and B, Hydrocephalus in a Chihuahua puppy. Note the greatly enlarged, domed skull and the divergent strabismus. C, The open skull sutures (fontanelles) are visible in this puppy after surgical drainage of the lateral ventricles with a ventriculoperitoneal shunt.

with severity of clinical signs in small-breed dogs and that all asymptomatic puppies with a VB ratio of >60% went on to develop neurologic signs related to their hydrocephalus.

Long-term medical management of animals with neurologic signs is directed at limiting CSF production and reducing intracranial pressure. Glucocorticoids are administered to decrease CSF production (prednisone, 0.5 mg/kg, administered orally daily, tapered weekly until 0.1 mg/kg q48h). Seizures may be controlled with anticonvulsant therapy, as described for epilepsy (see Chapter 67). The prognosis for a normal life is poor if neurologic signs are present. Surgical drainage and placement of a permanent ventriculoperitoneal shunt have been successful in a few cases.

Acute, severe, and progressive neurologic signs occasionally occur in dogs and cats with hydrocephalus, probably as a result of a sudden increase in intracranial pressure. Therefore it is important to rapidly lower intracranial pressure in these animals, as described for animals with head trauma (see Box 65-2). If fontanelles are open, a ventricular tap can be performed and a small volume of CSF (0.1 to 0.2 ml/kg) can be removed.

### LISSENCEPHALY

Lissencephaly is a rare condition in which the sulci and gyri fail to develop normally, resulting in a smooth cerebral cortex. Cerebellar hypoplasia may be seen in association with this malformation. Lissencephaly has been recognized primarily in the Lhasa Apso, Wire Fox Terrier, and the Irish Setter, Behavioral abnormalities and visual deficits are common. These animals are also very difficult to train and may not be housebroken. If seizures occur, they often are not prominent until the end of the first year of life. Definitive diagnosis requires MRI, brain biopsy, or necropsy.

### THIAMINE DEFICIENCY

Thiamine (vitamin B<sub>1</sub>) deficiency may occur in anorexic cats or cats fed uncooked all-fish diets that contain thiaminase. Thiamine deficiency is almost never seen clinically in dogs, except in racing sled dogs fed a diet high in raw fish. Thiamine deficiency results in abnormal glucose metabolism in the brain, encephalopathy, and hemorrhage of brainstem nuclei. Clinical signs initially include lethargy and ataxia followed by bilateral vestibular ataxia. Ventroflexion of the head and neck, blindness, dementia, head tilt, nystagmus, and seizures may be seen. The tentative diagnosis is based on the dietary history, signalment, and clinical signs and is further supported by the remission of signs within 24 hours of the administration of thiamine (2 to 4 mg/kg/day). Treatment is continued for 5 days or until the deficiency can be corrected.

### INFLAMMATORY DISEASES (ENCEPHALITIS)

Encephalitis resulting from most of the infectious inflammatory disorders discussed in Chapter 69 will result in abnormalities of mentation and seizures. Granulomatous meningoencephalitis (GME), a common noninfectious inflammatory disease in dogs, commonly affects the forebrain, brainstem, or cerebellum to cause a wide range of neurologic abnormalitis. See Chapter 69 for more information regarding the clinical manifestations, diagnosis, and therapy for intracranial inflammatory disorders.

### INHERITED DEGENERATIVE DISORDERS

Metabolic storage diseases are fatal neurodegenerative disorders resulting from an inherited deficiency of enzymes within the cells of the nervous system. Signs develop in young animals and are progressive. Seizures and severe alterations in consciousness may develop. The diagnosis of these disorders is suspected when a young dog of a susceptible breed develops a progressive neurologic disorder with characteristic features. Descriptions of the breed predispositions and clinical features of the inherited degenerative brain disorders can be found in Suggested Readings. Antemortem diagnosis requires brain biopsy or occasionally identification of inclusion bodies in hepatocytes or white blood cells. Histopathologic examination of biopsy specimens from affected organs sometimes reveals characteristic changes, but enzyme assays are required to establish the diagnosis. No treatment is currently available.

### **GERIATRIC CANINE COGNITIVE DYSFUNCTION**

Older dogs with degenerative brain disorders similar to human Alzheimer's disease may develop chronic progressive behavioral abnormalities, including loss of housebreaking, forgetting learned behaviors, altered sleep-wake cycles, and failure to recognize or interact with their owners. Because of the nonspecific clinical signs and the lack of a specific diagnostic test, this syndrome can be diagnosed only after extensive evaluation for other causes of intracranial signs. Older dogs should be carefully evaluated for metabolic disorders, brain tumors, encephalitis, and hypertension-related intracranial dysfunction. If no specific treatable abnormalities are found, administration of antioxidants, omega-3 fatty acids, and selegiline (L-deprenyl: 0.5-1.0 mg/kg/day, administered orally) as well as structured play and environmental enrichment have been recommended. It is difficult to objectively determine the benefit of this treatment.

### **NEOPLASIA**

Brain tumors are common in dogs and cats, usually resulting in a gradual onset of slowly progressive neurologic signs. Clinical signs may also develop acutely if tumors bleed. With the exception of brain lymphoma, most primary and metastatic brain tumors occur in middle-aged and older animals with a median age of 9 years in dogs and 11 years in cats. The most commonly affected breeds include Golden Retrievers, Labrador Retrievers, mixed-breed dogs, Boxers, Collies, Doberman Pinschers, Schnauzers, and Airedale Terriers.

Brain tumors cause signs by destroying adjacent tissue, increasing intracranial pressure, or causing hemorrhage or obstructive hydrocephalus. Seizures are the most common reason for presentation. Circling, ataxia, and head tilt are less

common. As intracranial tumors enlarge, they may cause an increase in intracranial pressure with progressive loss of consciousness and altered mentation; the owner may report that the dog or cat has recently become dull, depressed, and "old." Progressive subtle neurologic signs are sometimes present for weeks or months before the owner notices them.

Some animals with brain tumors are neurologically normal between seizures, but careful neurologic examination usually reveals evidence of asymmetric neurologic dysfunction. Compulsive circling toward the side of the lesion and abnormal postural reactions and vision on the side opposite the lesion are common with forebrain lesions.

Intracranial tumors may be primary (arising from the brain), or they may invade the brain from an adjacent site (e.g., the skull, nose, sinus) or metastasize to the brain from a distant site. A careful physical examination should be performed to identify potential sites of primary neoplasia. Particular attention should be paid to the nose, lymph nodes, spleen, skin, mammary chain, and prostate gland. A complete blood count (CBC), serum biochemistry panel, and urinalysis should be performed to rule out metabolic disease and look for evidence of neoplasia or a paraneoplastic syndrome. Radiography of the thorax and abdomen and abdominal ultrasonography should be performed to search for a primary tumor or extraneural metastases. Many patients with metastatic tumors in the brain have detectable pulmonary metastatic lesions.

Advanced imaging modalities such as CT and MRI are the most valuable imaging techniques for detecting and characterizing intracranial tumors. Although many tumors have characteristic anatomic and imaging features, the tumor type cannot be reliably determined without biopsy.

Because most intracranial tumors are poorly exfoliative, CSF collection and analysis rarely provide a definitive diagnosis. The identification of neoplastic cells in CSF is diagnostic, but this is an unusual finding, except in patients with central nervous system lymphoma, carcinomatosis, and choroid plexus tumors. The classical finding is normal CSF cytology with a slightly increased CSF protein content, but many dogs with brain tumors have completely normal CSF. Some dogs with brain tumors (especially meningiomas) have cellular CSF changes consistent with mixed inflammation, complicating differentiation from disorders such as granulomatous meningoencephalitis.

Treatment for brain tumors depends on the tumor type, tumor location, growth history, and neurologic signs. Once identified with CT or MRI, some small, superficially located, well-encapsulated, benign cerebral tumors; dorsal cerebellar tumors; and bony tumors of the skull are amenable to surgical removal. In particular, there has been some success in the removal of feline cerebral meningiomas. Canine cerebral meningiomas are similarly superficially located and histologically benign, but they are not well encapsulated, making complete surgical removal more difficult. Median survival after surgical removal of primary brain tumors in dogs is approximately 140 to 150 days, with significant risk of mortality within the first 30 days after surgery. For meningiomas,

median survival times are longer (240 days). Surgical removal of feline meningiomas is more successful, with median survival intervals of 22 to 27 months reported.

Traditional radiotherapy is often used as an adjunct to surgery of resectable tumors and as the sole therapy for nonresectable primary (nonmetastatic) brain tumors in dogs. Many dogs that are stable neurologically before therapy show some clinical improvement. Remissions in excess of 1 year are common in dogs with certain brain tumors (e.g., meningioma) treated with radiotherapy alone or with combined surgery and radiotherapy. Boron neutron capture therapy (BNCT) has been used to increase the radiation dose that can be administered to tumor cells while sparing normal brain cells. An important drawback of radiotherapy is that multiple anesthesias and access to a referral center are required.

Supportive chemotherapy can be administered even when definitive therapy is not an option. Corticosteroid administration (prednisone 0.5 to 1.0 mg/kg/day, taper to q48h) may decrease edema surrounding the tumor and improve CSF absorption. Chronic anticonvulsant therapy is administered if necessary. In the event of an acute exacerbation of tumor-related clinical signs, aggressive treatment to lower intracranial pressure is recommended, as outlined for head trauma. Specific chemotherapy for central nervous system lymphoma is possible, but most of the chemotherapeutic agents used for systemic therapy do not cross the blood-brain barrier. Cytosine arabinoside (Cytosar), lomustine (CCNU), and prednisone have some effect (see Chapter 80). Some non-lymphoid brain tumors, especially gliomas, respond to systemic chemotherapy with carmustine (BCNU) or CCNU.

### HYPERMETRIA

A hypermetric gait, with each limb raised excessively during protraction and then returned more forcefully than normal to weight bearing, suggests that there has been a loss of the normal cerebellar regulation of the rate, range, and force of movement. Animals with cerebellar disease are ataxic but strong, with normal postural reactions and spinal reflexes. Affected animals are unable to judge distances or control the range of movements and will make a series of jerking and bobbing movements (intention tremor) when attempting to perform precise movements. A fine tremor of the head and body may also be present at rest. Patients with cervical spinal cord damage to the very superficial spinocerebellar tracts will also exhibit a similar hypermetric gait in all four limbs, but postural reactions (especially knuckling) may be delayed and there will be no head tremor or other brain signs.

Most of the intracranial disorders that cause abnormal mentation or seizures can cause cerebellar dysfunction. Damage to the cerebellum usually occurs through trauma, hemorrhage, infarction, infectious inflammatory disease (see Chapter 69), granulomatous meningoencephalitis (dogs), or primary or metastatic neoplasia. In addition, there are several anomalous and degenerative conditions that specifically

result in cerebellar dysfunction. The diagnostic approach to patients with cerebellar dysfunction is identical to that outlined earlier for patients with abnormal mentation (see Box 65-1).

### CONGENITAL MALFORMATIONS

Malformations of the cerebellum have been described as a congenital anomaly in Chow Chows, Irish Setters, Wire Fox Terriers, and Siberian Huskies and sporadically in many breeds and in cats. Feline cerebellar hypoplasia is most often caused by naturally acquired in utero infection with panleukopenia virus (feline parvovirus) or when a pregnant queen is inoculated with modified-live panleukopenia virus vaccine. Clinical signs of cerebellar hypoplasia become noticeable when the animal first starts to walk, with hypermetria, ataxia, and tremor most apparent. Some cases are mild, and others are very severe, making walking and eating difficult. Because signs do not progress, mildly affected animals can function as pets.

### CEREBELLAR CORTICAL DEGENERATION (ABIOTROPHY)

Cerebellar abiotrophy is a syndrome of premature degeneration of cells within the cerebellum. Cells develop normally but later degenerate because of an intrinsic cellular defect. Rarely, the degeneration occurs in neonates, with signs evident at first ambulation and progressively worsening over weeks to months. In most breeds clinical signs begin between 3 and 12 months of age, but adult onset cerebellar abiotrophies (Brittany, Gordon Setter, Old English Sheepdog, American Staffordshire Terrier, and Scottish Terrier) occasionally are apparent between 2 years and 8 years of age. In addition to the abiotrophies, metabolic storage diseases occasionally cause progressively worsening cerebellar signs in juvenile or young adult dogs and cats. Diagnosis of all of these conditions is based on cerebellar biopsy or necropsy. No treatment is effective.

### **NEUROAXONAL DYSTROPHY**

Neuroaxonal dystrophy is a slowly progressive degenerative disorder affecting nerve cell bodies within gray matter throughout much of the central nervous system, with most severe lesions within the spinocerebellar tracts and the Purkinje cells. Young adult Rottweilers (1 to 2 years old) are initially presented for a hypermetric gait and ataxia, and signs progress slowly over 2 to 4 years. Affected dogs develop an intention tremor, a constant fine tremor, nystagmus, and menace deficits. Postural reactions (knuckling and hopping) remain normal. A similar disorder has been documented in young (2- to 4-month-old) Collies, Chihuahuas, Boxers, German Shepherd Dogs, and tricolor kittens (5 to 6 weeks old). Diagnosis requires biopsy or postmortem, and there is no effective treatment.

### **BRAIN CYSTS**

Epidermoid, dermoid, and arachnoid cysts occasionally compress the cerebellum, causing progressive neurologic signs, including hypermetria. The cysts can be identified on CT or MRI imaging and surgically drained or removed.

### **TREMORS**

A tremor is a rhythmic, oscillatory movement of a body part. Intention tremors of the head, usually associated with cerebellar disease, substantially worsen as the animal intends to initiate movement, as when the head nears a target during goal-oriented movement such as attempts to eat, drink, or sniff an object. Action tremors occur throughout movement and disappear with rest.

A toxic cause should be suspected in an animal with severe generalized tremors or tetany (increased muscle tone or rigidity) of acute onset (see Box 67-3). Strychnine, metaldehyde, chlorinated hydrocarbons, mycotoxins, and organophosphates are the most common toxic causes of tremors and tetany. Drug-induced tremor can be associated with metaclopramide, fentanyl/droperidol, or diphenhydramine administration. Metabolic disturbances such as hypoglycemia and hypocalcemia will also cause tremors, muscle fasciculations, and tetany.

Generalized head and body tremors unassociated with a metabolic or toxic disorder may arise acutely in young adult (5 months to 3 years of age) small-breed dogs. Historically, this disorder was first identified only in white dogs (Maltese, West Highland White Terrier), and the syndrome was called "little white shaker syndrome"; however, it is now known that dogs of any color can be affected. A fine tremor develops rapidly over 1 to 3 days. The tremor worsens with excitement and decreases during sleep. Neurologic findings are usually normal, although hypermetria, nystagmus, head tilt, or seizures have been observed in a few dogs. All clinicopathologic test results are normal. Occasionally, CSF analysis reveals a mild lymphocytosis and slightly increased protein content. Histological examination reveals a mild, nonsuppurative meningoencephalomyelitis with perivascular cuffing. In some dogs the tremors decrease and subside 1 to 3 months after onset, even without treatment, but they persist for life in other dogs. Diazepam (0.5 mg/kg, administered orally q8h) and corticosteroids (prednisone, 2 to 4 mg/kg/day, administered orally) administered early in the disease usually result in clinical improvement within 4 or 5 days. Treatment should be tapered gradually over 4 or 5 months, and drug doses titrated to control clinical signs. Relapse months to years later may require retreatment or lifelong low-dose therapy in a few dogs.

Tremor syndromes have also been reported in young dogs and cats with metabolic storage diseases or congenital spongy degeneration of the central nervous system. A congenital diffuse tremor syndrome associated with abnormal development of myelin in the central nervous system has been observed in puppies. Affected puppies stand with a widebased stance and show whole-body tremors that worsen with exercise or excitement. This syndrome is progressive and severe in male Welsh Springer Spaniels, usually resulting in death within 2 to 4 months. Less severe tremor syndromes have been recognized in the Weimaraner, Bernese Mountain Dog, Samoyed, Dalmatian, and Chow Chow as well as sporadically in other breeds, with signs apparent by 4 weeks of age. Diagnosis is based on the signalment and clinical findings in the absence of other neurologic deficits or clinicopathologic abnormalities. In the Chow Chow and in other mildly affected breeds, gradual clinical recovery may occur within 1 to 3 months without treatment.

Trembling of the pelvic limbs (senile tremors) may develop in old dogs that are weak but otherwise neurologically normal. The trembling disappears at rest but is apparent when the animals stand, and it worsens with exercise. Results of all tests are normal, and there is no effective treatment. Diagnostically, it is important to rule out electrolyte disturbances, hypothyroidism, hypoadrenocorticism, hip dysplasia, and lumbosacral disease.

### **DYSKINESIAS**

Dyskinesias are central nervous system disorders that result in involuntary movements in fully conscious individuals. These movement disorders have only occasionally been described in dogs and cats and may be difficult to distinguish from focal seizures or stereotypical behavior disorders. The abnormal electrical activity initiating these movements originates in the subcortical extrapyramidal basal nuclei of the multisynaptic corticospinal tract. The resulting extrapyramidal signs consist primarily of episodic, unpredictable, rhythmic, involuntary limb hyperextension or hyperflexion; head

bobbing; or the adoption of abnormal postures. Movement disorders thought to be dyskinesias have been reported in Norwich Terriers, Cavalier King Charles Spaniels, Malteses, and Soft Coated Wheaten Terriers. A syndrome of intermittent head-bobbing occasionally recognized in Boxers, English Bulldogs, and Doberman Pinschers may also be a dyskinesia.

# CHAPTER Loss of Vision and Pupillary Abnormalities

### CHAPTER OUTLINE

GENERAL CONSIDERATIONS
NEUROOPHTHALMOLOGICAL EVALUATION

Vision

Menace Response

Pupillary Light Reflex

Dazzle Reflex

Pupil Size and Symmetry

Disorders of Eyeball Position and Movement

Lacrimal Gland Function

LOSS OF VISION

Lesions of the Retina, Optic Disk, and Optic Nerve

Lesions of the Optic Chiasm

Lesions Caudal to the Optic Chiasm

HORNER'S SYNDROME

PROTRUSION OF THE THIRD EYELID

### **GENERAL CONSIDERATIONS**

Loss of vision or pupillary abnormalities may be detected during the physical examination of an animal examined because of neurologic dysfunction or may be the primary reason for presentation. Owners rarely recognize a visual deficit until it is bilateral and complete, at which time the animal is brought in because of an apparently sudden onset of blindness. When an animal is evaluated because of loss of vision, it is important first to determine whether or not the animal is actually blind and to perform a complete ocular and neuroophthalmological examination.

# NEUROOPHTHALMOLOGICAL EVALUATION

### VISION

Vision should initially be assessed by observing the animal's response to the environment, including its ability to negotiate doorways and stairs and the attention it pays to rolling

or falling silent objects such as cotton balls. If unilateral vision loss is suspected, the normal eye should be covered during testing. For vision to be present the entire visual pathway must be intact. This includes the retina; the optic nerve, which passes through the optic chiasm to the optic tract to synapse in the lateral geniculate nucleus (LGN) in the diencephalon; and axons projecting to the visual cortex in a band of fibers called the *optic radiation*. Most of the optic nerve axons cross in the optic chiasm (particularly those carrying information from the lateral visual field) and are continued in the contralateral optic tract, LGN, and optic radiations to the visual cortex (Fig. 66-1). The visual cortex must be functional for the animal to process and respond appropriately to visual cues.

### **MENACE RESPONSE**

The menace response is a cortically mediated blink produced by a threatening gesture (Fig. 66-2). The sensory part of this response involves each of the components of the visual pathway (see Fig. 66-1). Normally, the visual stimulus is directed at the nasal retina (i.e., the menacing gesture is in the lateral visual field coming from the side), and because almost all of the optic nerve axons that originate in the nasal retina cross in the optic chiasm, primarily the contralateral visual cortex is assessed. The information interpreted in the visual cortex is forwarded to the motor cortex to initiate a blink response, requiring a functional facial nerve (CN7). The menace response is also coordinated in the cerebellum, with unilateral cerebellar lesions causing ipsilateral loss of the menace response but no loss of vision. The absence of a menace response could therefore be a result of ocular, retinal, or optic nerve disease; damage to the contralateral forebrain; an altered mental state; cerebellar disease; or an inability to blink (CN7 deficit; Box 66-1). This learned response may not be present in puppies and kittens younger than 12 weeks of age.

### **PUPILLARY LIGHT REFLEX**

The pupillary light reflex (PLR) should always be assessed, whether or not an animal is able to see. A bright light is directed into the pupil, and the pupil is assessed for

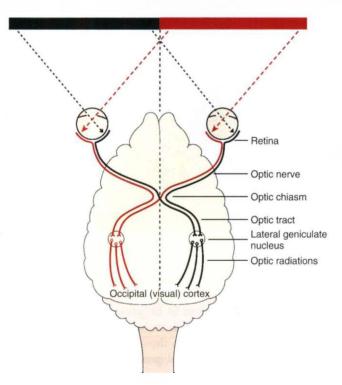

FIG 66-1 The visual pathways.

FIG 66-2

The menace response is performed by making a threatening movement toward each eye in turn. The expected response is a blink. The stimulus is primarily directed toward the nasal retina, assessing the contralateral visual cortex.

constriction (direct reflex). The opposite pupil should simultaneously constrict (consensual response). The sensory visual pathway is the same as that described for the menace response except that some optic tract axons synapse before the LGN in the pretectal nucleus located at the junction between the midbrain and the thalamus. Most of the axons arising from this nucleus cross midline again and synapse in the parasympathetic component of the oculomotor nucleus ipsilateral to the eye being stimulated. Stimulation of the parasympathetic axons of the oculomotor nerve (CN3)

BOX 66-

Lesions Causing Loss of the Menace Response in Dogs

### Loss Of Menace

Severe ocular disease Retinal disease Visual pathway lesion Ipsilateral optic nerve

Optic chiasm

Contralateral optic tract, lateral geniculate nucleus, optic radiation

Contralateral visual cortex (forebrain) lesion

Altered mental status

Metabolic encephalopathy

Severe systemic illness

Cerebellar disease

Inability to blink (CN7)

Immature reflex (<12 weeks of age)

results in pupil constriction. Because some of the axons leaving the pretectal nucleus do not cross, there is also stimulation of the contralateral oculomotor nucleus, resulting in a somewhat weaker consensual pupillary response. The pupillary response to light can be minimal if the light used is not bright enough, if the animal is nervous and has high resting sympathetic tone, or if there is ocular disease (iris atrophy or greatly increased intraocular pressure) preventing pupillary constriction. The pupillary light response requires fewer functional photoreceptors and optic nerve axons than vision, so partial lesions of the proximal visual pathways (retina, optic nerve, optic chiasm, optic tract) can sometimes cause loss of vision with normal PLRs, similar to lesions of the forebrain (Table 66-1).

### **DAZZLE REFLEX**

The dazzle response is the generation of a rapid blink when a very bright light is directed into the eye. The sensory visual pathway is as described for the PLR in that this is a subcortical ipsilateral reflex that does not require the visual cortex, but the motor pathway is mediated by the facial nerve (CN7) rather than the oculomotor nerve. A negative dazzle response in a blind eye suggests retinal or optic nerve disease. A positive dazzle response in a blind eye supports central (brain) disease.

### PUPIL SIZE AND SYMMETRY

Pupil size and symmetry should be assessed in room light as well as in darkness to evaluate the ability of the pupils to constrict (parasympathetic function) and to dilate (sympathetic function). Pupil abnormalities causing dilation (mydriasis) or constriction (miosis) of only one pupil will result in anisocoria. If the abnormal pupil is unable to constrict, the anisocoria caused by mydriasis in the affected

Retinal or eye lesions must be very severe to cause loss of pupillary light reflexes.

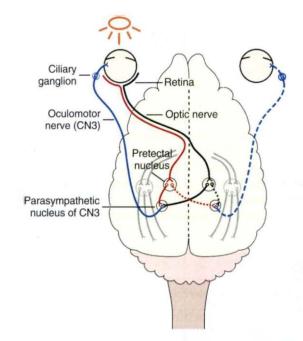

FIG 66-3
The pathway of the pupillary light reflex.

eye will be most apparent in bright light. Anisocoria caused by a single miotic pupil, such as is seen in animals with Horner's syndrome, will be most apparent in a darkened room as the normal pupil dilates. A complete ophthalmic examination should be performed to ascertain whether pupillary abnormalities can be explained by nonneurologic abnormalities of the eye. Iris atrophy, iris hypoplasia, and glaucoma will cause mydriasis, whereas uveitis and painful conditions of the cornea commonly cause miosis. Hippus, a condition in which there are exaggerated oscillations of

pupillary size in response to light, can be an indication of central nervous system disease.

# DISORDERS OF EYEBALL POSITION AND MOVEMENT

During the neurologic examination it is important to evaluate eye position and movement. The extraocular muscles are innervated by the oculomotor nerve (CN3), the trochlear nerve (CN4), and the abducent nerve (CN6), with lesions resulting in an abnormal eye position (strabismus) or failure of the eye to move appropriately when the head is moved during evaluation of the vestibulo-ocular reflex (see Chapter 63). Strabismus can occur with lesions of individual nerves, but most often paralysis of all of the extraocular muscles (external ophthalmoplegia) occurs with a mass in the region of the paired cavernous sinuses on the floor of the calvarium adjacent to the pituitary gland (cavernous sinus syndrome). Mass lesions in this area typically also damage the parasympathetic pupillary fibers in the oculomotor nerve (CN3), causing a fixed midrange or mydriatic pupil with normal vision (internal ophthalmoplegia). Ipsilateral damage to the ophthalmic and maxillary branches of the trigeminal nerve result in diminished corneal and medial palpebral sensation and occasionally atrophy of the ipsilateral masticatory muscles.

### LACRIMAL GLAND FUNCTION

The lacrimal gland and the lateral nasal gland are innervated by the parasympathetic portion of the facial nerve. Normal function is assessed by performing a Schirmer tear test and examining the ipsilateral nostril for dryness. Facial nerve lesions result in a loss of the palpebral reflex because of an inability to blink, decreased basal tear production, and a dry nose. Sensory innervation of the cornea is provided by the trigeminal nerve (CN5), and corneal stimulation by touch, cold, wind, or other irritants normally results in a blink

response and increased reflex tear production. Lesions of the ophthalmic branch of the trigeminal nerve (CN5) result in decreased reflex tear production and decreased blink frequency, which may lead to keratitis and corneal ulceration.

### LOSS OF VISION

# LESIONS OF THE RETINA, OPTIC DISK, AND OPTIC NERVE

Concurrent loss of vision and diminished or absent PLR indicate the presence of a lesion affecting both the visual and PLR pathways. Unilateral severe lesions of the retina, optic disk, or optic nerve before the optic chiasm result in impaired vision and loss of the direct PLR in the affected eye as well as a loss of the PLR in the opposite eye (the consensual response) when light is directed in the affected eye (see Table 66-1). The direct and consensual response to light directed in the unaffected eye should be normal. Ocular or optic nerve disease must be very severe to cause complete loss of PLRs. Whenever an animal is evaluated for blindness, the retina should be carefully examined to rule out disorders such as progressive retinal atrophy, retinal dysplasia, retinal detachment, retinal hemorrhage, and chorioretinitis. Optic nerve atrophy secondary to glaucoma or trauma must also be eliminated as a cause of blindness and PLR loss.

### **Sudden Acquired Retinal Degeneration**

Sudden acquired retinal degeneration syndrome (SARDS) is an idiopathic syndrome causing sudden bilateral degeneration of retinal photoreceptors in dogs. Middle-aged and old dogs of any breed can be affected, with females and obese individuals predisposed. The primary presenting complaint is loss of vision, with complete blindness occurring over a

period of hours to weeks and often overnight. Pupils are dilated and PLRs are sluggish in dogs examined shortly after vision loss and absent in dogs with advanced disease. Many affected dogs have concurrent polyuria, polydipsia, panting, weight gain, and lethargy. Clinical, serum biochemical, and urinalysis findings may be typical of hyperadrenocorticism, but endocrine tests and advanced imaging of the pituitary and adrenal glands rarely confirm that disorder. In the early stages of SARDS both fundi appear normal, but with time the retinal changes become indistinguishable from chronic retinal degeneration caused by other conditions. SARDS is differentiated from retrobulbar optic neuritis by its extinguished (flat-line) electroretinogram (ERG). The pathogenesis of the disorder appears to be localized production of antibodies directed against retinal neurons. No consistent response to treatment has been reported, but the administration of intravenous immunoglobulin infusions may be of some benefit early in the course of SARDS. Systemic signs are usually transient and resolve without treatment, but the blindness is permanent.

### Optic Neuritis

Inflammation of the optic nerves causes blindness and loss of PLRs (Fig. 66-4). Fundoscopic evaluation may reveal optic disk swelling and discoloration (red) with or without associated retinal detachment and hemorrhage. When optic neuritis occurs posterior to the globes (i.e., retrobulbar), the visible portion of the optic nerves will be normal. In dogs with blindness and loss of PLRs with a normal fundus, ERG is required to differentiate bilateral retrobulbar optic neuritis (normal ERG) from SARDS (flat-line ERG).

Optic neuritis is most commonly seen as an isolated idiopathic immune-mediated disorder affecting one or both optic nerves, but it may also be a manifestation of systemic

Systemic neoplasia Intracranial neoplasia

Idiopathic Immune-Mediated Optic Neuritis

disease (Box 66-2), especially canine distemper, ehrlichiosis, mycotic disease, and granulomatous meningoencephalitis (GME). Diagnosis of idiopathic (immune-mediated) optic neuritis is made only after infectious and neoplastic disorders are ruled out during a thorough workup for systemic and intracranial disease, including a complete blood count (CBC), serum chemistry profile, urinalysis, heartworm antigen test, serologic screening for infectious diseases, thoracic radiography, and cerebrospinal fluid (CSF) collection and analysis. Magnetic resonance imaging (MRI) can be used to eliminate mass lesions of the optic chiasm. If all test results are normal, primary immune-mediated optic neuritis is tentatively diagnosed.

Treatment of idiopathic optic neuritis should be initiated with orally administered corticosteroids (prednisone 1 to 2 mg/kg/day). If a favorable response is seen (i.e., improved vision and PLRs), then the dose of steroids should be gradually decreased over 2 to 3 weeks until alternate-day therapy is achieved. If there is no initial response to steroid therapy, then the prognosis for return of vision is poor. Untreated optic neuritis leads to irreversible optic nerve atrophy and permanent blindness. Even with appropriate therapy, many cases will progress or relapse.

### **Papilledema**

Edema of the optic disk usually indicates that there is increased intracranial pressure caused by a cerebral tumor or inflammatory mass lesion. This is seen as an enlarged optic disk with indistinct or fluffy margins and kinking of blood vessels as they pass over the disk. Papilledema may be difficult to distinguish on fundoscopic evaluation from

FIG 66-5
Neoplasm of the optic chiasm identified with magnetic resonance imaging in a 7-year-old Doberman Pinscher with an acute onset of bilateral blindness, loss of pupillary light reflexes, and no other neurologic deficits.

optic neuritis, although patients with a significant forebrain lesion causing papilledema should have clinical evidence of forebrain disease, including abnormal mentation, behavior change, and seizures. Despite reports that papilledema does not affect vision, most patients with papilledema caused by increased intracranial pressure are cortically blind.

### LESIONS OF THE OPTIC CHIASM

Lesions of the optic chiasm result in a failure of transmission of the visual image and the light stimulus, causing blindness, normal fundic examination, normal ERG, bilateral mydriasis, and loss of the direct and consensual PLRs in both eyes. Neoplasia and other space-occupying masses can occur at this location, especially lymphoma (cats), pituitary macroadenomas, meningiomas, and primary nasal tumors extending into the brain (Fig. 66-5; see also Fig. 66-4). Vascular lesions such as hemorrhage and infarction, infectious inflammatory granulomas, and granulomatous meningoencephalitis can also affect the optic chiasm. Evaluation should include a search for evidence of extraneural infectious or neoplastic disease followed by MRI, CSF collection and analysis, and endocrinologic testing as warranted.

# LESIONS CAUDAL TO THE OPTIC CHIASM

Lesions in the lateral geniculate nucleus, optic radiations, or visual cortex prevent interpretation of the image, resulting in a normal fundic examination, normal ERG, normal PLRs (direct and consensual), and blindness in the eye opposite the side of the lesion. With unilateral lesions of the optic tracts or optic radiations the visual deficits are most com-

plete in the lateral visual field of the contralateral eye and the medial visual field of the ipsilateral eye. Other clinical signs of forebrain disease, such as seizures, circling, and decreased consciousness, are expected with forebrain lesions severe enough to cause visual deficits. Causes of intracranial blindness (i.e., central or cortical blindness) include traumainduced hemorrhage and edema, vascular infarcts, GME, infectious encephalitis, central nervous system neoplasia, congenital disorders (e.g., hydrocephalus, lissencephaly), and degenerative disorders (lysosomal storage diseases). Animals with functional disturbances of the forebrain caused by metabolic encephalopathies, lead intoxication, hypoxia, or postictal depression may also present with cortical blindness. Diagnostic evaluation for intracranial blindness should follow guidelines outlined in Chapter 65 and should include thorough physical, ophthalmologic, and neurologic examinations; a laboratory database; screening thoracic and abdominal radiographs; CSF analysis; and CT or MRI evaluation.

### HORNER'S SYNDROME

Lesions affecting the sympathetic innervation to the eye result in Horner's syndrome. This condition causes miosis (constriction of the affected pupil), drooping of the upper eyelid (ptosis), and an inward sinking of the eyeball (enophthalmos). The third eyelid (nictitating membrane) is often partially protruded (Box 66-3; Fig. 66-6).

Horner's syndrome can result from injury to the sympathetic innervation to the eye anywhere along its pathway (Box 66-4; Fig. 66-7). Lesions are classified as first order (central), second order (preganglionic), or third order (postganglionic) according to the level of the lesion along the sympathetic pathway.

First order neurons originate in the hypothalamus and rostral midbrain and travel down the tectotegmental spinal tract, coursing through the brainstem and cervical spinal cord to terminate at the preganglionic cell bodies in the thoracic spinal cord. Upper motor neuron lesions in the brainstem or cervical spinal cord are a relatively rare cause of Horner's syndrome but may occur secondary to trauma, infarction, neoplasia, or inflammatory disease. Ipsilateral hemiplegia and other concurrent neurologic abnormalities are expected in these animals (see Box 66-4).

The preganglionic cell bodies of the second order neurons are located in the lateral horn of the spinal cord gray matter at the level of the first three thoracic spinal cord segments (T1-T3). The second order axons leave the spinal cord with

BOX 66-3

### Components of Horner's Syndrome

Miosis Enophthalmos **Ptosis** Prolapsed nictitans the T1 to T3 ventral nerve roots. The sympathetic axons then leave the spinal nerves to form the thoracic sympathetic trunk, which courses cranially within the thorax. The axons continue to course cranially within the vagosympathetic trunk in the cervical region and synapse in the cranial cervical ganglion, ventral and medial to the tympanic bulla at the base of the skull. Injury to second order neurons can occur when there is damage to the spinal cord at the cervical intumescence (C6-T2) caused by trauma, infarcts, neoplasia, or

Horner's syndrome in a domestic short-haired cat with otitis media/interna.

### Common Causes of Horner's Syndrome

### First Order (Central) Causes (Rare)

Intracranial neoplasia, trauma, infarct Cervical spinal cord lesion Intervertebral disk protrusion Neoplasm Fibrocartilaginous embolism Trauma

### Second Order (Preganglionic) Causes

Spinal cord lesion T1-T3 (trauma, neoplasia, fibrocartilaginous embolism)

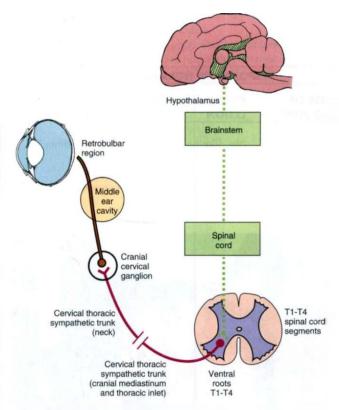

Brachial plexus avulsion Thoracic spinal nerve root tumor Cranial mediastinal mass Cervical soft-tissue neoplasia, trauma Skull base trauma

### Third Order (Postganglionic) Causes

Otitis media/interna Neoplasia in middle ear Retrobulbar injury, neoplasia

### **Unknown Causes**

Idiopathic

**FIG 66-7**Sympathetic innervation to the eye. An injury anywhere along this pathway will result in Horner's syndrome.

inflammatory disease. Affected animals will exhibit lower motor neuron signs in the affected forelimb, upper motor neuron signs in the ipsilateral rear limb, and Horner's syndrome. In animals with brachial plexus avulsion there will be complete lower motor neuron paralysis of the affected limb and an ipsilateral Horner's syndrome that may be partial (miosis only) because of sparing of the T3 (and sometimes T2) nerve roots (Fig. 66-8). Horner's syndrome can also occur when the second order neurons are damaged by thoracic surgery, mediastinal masses (lymphoma or thymoma), bite wounds to the neck, strangulation injuries, invasive thyroid carcinoma, or errors made during thyroid-ectomy or surgery for cervical intervertebral disk disease. Physical and neurologic findings are often useful in localizing preganglionic Horner's syndrome.

Most dogs and cats with Horner's syndrome have post-ganglionic lesions. The postganglionic (third order) axons for ocular sympathetic innervation course rostrally through the tympanooccipital fissure into the middle ear and enter the cranial cavity with the glossopharyngeal nerve (CN9), leaving the cranial cavity via the orbital fissure for distribution to the smooth muscle of the orbit, the upper and lower eyelids, the third eyelid, and the iris muscles. Third order Horner's syndrome is common in patients with otitis media or neoplasia within the middle ear, often accompanied by evidence of peripheral vestibular (CN8) disturbance and sometimes facial nerve (CN7) paralysis. Rarely, retrobulbar

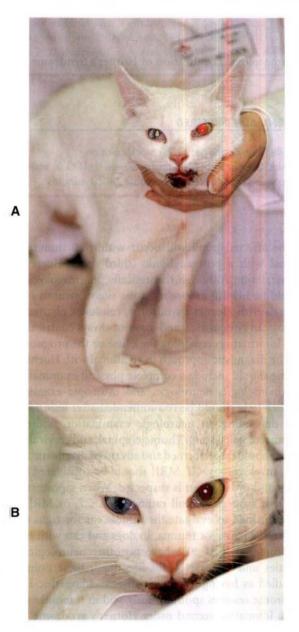

FIG 66-8
Horner's syndrome (A) in a domestic short-haired cat with traumatic right brachial plexus avulsion (B).

injury, neoplasia, or abscessation will result in a third order Horner's syndrome.

Pharmacologic testing has been recommended to help localize the cause of Horner's syndrome in dogs and cats (Table 66-2). This testing can be used to help determine the most likely site of the lesion. When the Horner's syndrome has been present for at least 2 weeks, denervation hypersensitivity will occur secondary to the loss of sympathetic innervation. A single drop of a very dilute concentration of a direct-acting sympathomimetic (0.1% phenylephrine: stock 10% solution diluted 1:100 with saline solution) is applied to both eyes, using the unaffected eye as a control. Because this dilute solution does not normally induce pupillary dilation, the pupil in the normal eye should not dilate. Dilation

### Pharmacologic Localization of Horner's Syndrome

	RI	ESPONSE OF NORMAL PUPIL		
AGENT ADMINISTERED	RESPONSE OF AFFECTED PUPIL	PREGANGLIONIC LESION	POSTGANGLIONIC LESION	
O.1% Phenylephrine: (10% stock solution Neo-Synephrine, Winthrop; diluted 1:100 in saline) Apply 2 drops topically; evaluate at 20 minutes	No dilation	No dilation	Dilation within 20 minutes	

of the affected pupil will occur within 20 minutes in an animal with a postganglionic (third order Horner's syndrome) lesion. Although, theoretically, pharmacologic testing should be helpful in localizing the site of neuron injury in animals with Horner's syndrome, results of pharmacologic testing can be equivocal and may not always contribute practical information regarding the cause or the prognosis.

The diagnostic approach in an animal with Horner's syndrome should include a complete physical examination and ophthalmologic, neurologic, and otoscopic examinations. Further tests should be recommended after lesion localization depending on neurologic examination findings and pharmacologic testing. Thoracic, spinal, and cervical radiography should be performed and advanced diagnostic imaging (e.g., myelography, CT, MRI) should be considered if a first or second order lesion is suspected. When a postganglionic lesion is suspected, skull radiographs, CT, or MRI should be performed to evaluate the middle ear for signs of otitis media, neoplasia, or trauma. In dogs and cats with Horner's syndrome, at least 50% have no other neurologic abnormalities and a cause is not identified; these animals are classified as having idiopathic disease. Idiopathic Horner's syndrome resolves spontaneously within 6 months in most dogs. Idiopathic second order Horner's syndrome is especially common in Golden Retrievers.

### PROTRUSION OF THE THIRD EYELID

In dogs and cats the third eyelid may protrude over the corneal surface in the presence of corneal or conjunctival irritation or space-occupying retroorbital disease. This may also occur if the animal experiences a decrease in periorbital mass as a result of dehydration, a loss of retrobulbar fat or muscle (Fig. 66-9), or a loss of volume within the eye (i.e., microphthalmos, phthisis bulbi).

Protrusion of the third eyelid is a conspicuous feature of Horner's syndrome (with miosis) and also of dysautonomia (with mydriasis). Systemic illness or tranquilization can also result in third eyelid protrusion in some dogs and cats. A peculiar syndrome (e.g., Haw's syndrome) has been observed in cats, and occasionally in dogs, in which a dramatic bilateral third eyelid protrusion of no obvious cause is observed.

### FIG 66-9

Dramatic muscle atrophy in a dog with masticatory muscle myositis has resulted in retraction of the globes into the orbits and protrusion of the third eyelid over most of the corneal surface.

Affected cats are usually younger than 2 years of age and in good health otherwise, although digestive disturbances or heavy intestinal parasite loads have occasionally been documented. The instillation of sympathomimetic drops (phenylephrine 10%) causes the membrane to rapidly retract. The condition resolves spontaneously within several weeks or months.

### **GENERAL CONSIDERATIONS**

A seizure is the clinical manifestation of excessive or hypersynchronous abnormal electrical activity in the cerebral cortex. The clinical features of seizures can be separated into four components: the prodrome, aura, ictal period, and postictal period. The prodrome is the period of time before the seizure begins, when the owner may report unusual behavior such as hiding, attention seeking, whining, or agitation. The prodrome may be barely noticeable in some animals and distinct enough to enable owners to accurately predict seizure onset in others. The aura is the initial manifestation of the seizure, when animals exhibit stereotypical sensory or motor activity (pacing, licking, swallowing), autonomic patterns (salivation, vomiting, urination) or abnormal behavior (barking, attention seeking) for seconds to minutes before seizure onset. The ictal period is the seizure itself, when the animal exhibits a variety of signs that may include loss or derangement of consciousness, altered muscle tone, jaw chomping, salivation, and involuntary urination and defecation. This phase usually lasts only seconds to minutes. The postictal period immediately follows the seizure and can last from a few seconds to several hours, during which time the animal may exhibit abnormal behavior, disorientation, altered thirst or appetite, somnolence, or blindness as well as defined sensory and motor neurological deficits. Epilepsy is a chronic neurologic condition characterized by recurrent seizures.

Dogs and cats are occasionally affected by nonepileptic paroxysmal disorders, during which they may experience altered behavior, collapse, abnormal movements, transient neurologic symptoms, or paralysis. Distinguishing these disorders from seizures is important for diagnosis and treatment. Cardiac arrhythmias causing syncope; weakness caused by hypoglycemia, hypocortisolemia, or electrolyte disturbances; acute vestibular "attacks"; narcoleptic or cataplexic events; and weakness caused by myasthenia gravis are all examples of such paroxysmal events. Descriptions of the event and the animal's activity and demeanor immediately preceding and following the event will help distinguish these events from seizures (Box 67-1). One helpful distinguishing feature is that only seizures should have an associated postictal period.

### SEIZURE DESCRIPTIONS

Most seizures in dogs and cats are tonic-clonic, generalized motor seizures in which the animal experiences a period of extremely increased extensor muscle tone (tonus), falls into lateral recumbency, and then has periods of tonus alternating with periods of relaxation (clonus), resulting in rhythmic

Idiopathic Epilepsy (Primary Epileptic Seizures)

contractions of muscles manifested as paddling or jerking of the limbs and chewing movements. Animals are usually unconscious during these seizures, although their eyes may remain open.

Less common than generalized, symmetric tonic-clonic seizures in dogs and cats are focal partial motor seizures. These seizures arise in part of one cerebral hemisphere, resulting in asymmetric signs that may include turning of the head away from the side of the lesion and focal twitching or tonic-clonic contractions of the contralateral facial or limb muscles. Some focal seizures are primarily manifested as altered consciousness and bizarre behaviors (psychomotor seizures), which may include aggression, howling, "fly biting," pacing, circling, restlessness, and staggering. It can sometimes be very difficult to distinguish psychomotor seizures from compulsive stereotypic behavior. Focal seizures may progress to generalized motor seizures in some animals. Although it is often stated that partial motor seizures are usually associated with structural brain disease, many dogs with idiopathic epilepsy experience focal seizures with secondary generalization.

### SEIZURE CLASSIFICATION AND LOCALIZATION

Seizure disorders are classified according to their cause as being idiopathic, intracranial, or extracranial in origin (Box 67-2). Idiopathic epilepsy is diagnosed in approximately 25% to 30% of dogs having seizures but is uncommon in cats. Animals with idiopathic epilepsy have no identifiable extracranial or intracranial cause for their seizures and no concurrent neurologic abnormalities, and their seizures are presumed to be genetically based. Approximately 35% of dogs with seizures and most cats with seizures have an identifiable structural intracranial lesion (e.g., anomaly, inflammation, neoplasia, trauma) that is causing seizures, and these animals are said to have symptomatic epilepsy. A very small number of patients have seizures believed to be secondary to a scar or residual brain damage following a previous insult, but this structural lesion is difficult to demonstrate; such animals are classified as having probable symptomatic epilepsy. Extracranial causes such as the ingestion of toxins or metabolic or endocrine derangements also result in seizures.

Seizure activity always indicates a functional or structural abnormality of the forebrain, particularly of the frontal or temporal lobes of the cerebrum. Metabolic and toxic disorders cause seizures through functional alterations of the balance between inhibitory and excitatory neurotransmitters. Defined, localizing neurologic deficits are unlikely to be detected interictally (between seizures) in patients with extracranial causes of seizures. Animals with an intracranial lesion causing symptomatic epilepsy may exhibit myriad signs leading to forebrain neurolocalization, including behavior change, circling toward the side of the lesion, contralateral hemiparesis and postural reaction deficits, and

BOX 67-3

Intoxications Resulting in Acute Neurologic Dysfunction

### Strychnine

Common use: rat, mole, gopher, and coyote poison Clinical findings: stiff extension of legs and body, erect ears, tetanic spasms induced by auditory stimuli

Diagnosis: history of access or ingestion, characteristic signs, chemical analysis of stomach contents

Treatment: vomiting (if no neurologic signs), gastric lavage, diazepam as needed, pentobarbital to effect; establish diuresis

### Metaldehyde

Common use: snail, slug, and rat poison

Clinical findings: anxiety, hyperesthesia, tachycardia, hypersalivation, muscle fasciculations, and tremors; not worsened by auditory stimuli; nystagmus in cats; may convulse; depression, respiratory failure

Diagnosis: history of access or ingestion, characteristic signs, acetaldehyde odor on breath, analysis of stomach contents

Treatment: gastric lavage, pentobarbital to effect, endotracheal tube and ventilation if necessary; establish diuresis

### Chlorinated Hydrocarbons

Common use: agricultural products and insecticides; lipidsoluble products are usually absorbed through skin

Clinical findings: apprehension, hypersensitivity, hypersalivation, exaggerated response to stimuli, muscle twitching of face and neck progressing to severe fasciculations and tremors; tonic-clonic seizures may occur

Diagnosis: history of access, characteristic signs, insecticide smell to haircoat, analysis of stomach contents

Treatment: wash with warm soapy water to prevent further exposure; if ingested (rare), gastric lavage and instill activated charcoal; pentobarbital to effect

### Organophosphates and Carbamates

Common use: insecticides

Clinical findings: excessive salivation, lacrimation, diarrhea, vomiting, and miosis; twitching of facial and tongue muscles, progressing to extreme depression and tonic-clonic seizures

Diagnosis: history of exposure, characteristic signs, analysis of stomach contents, low serum acetylcholinesterase activity

### Organophosphates and Carbamates—cont'd

Treatment: prevent further exposure; wash if topical exposure; gastric lavage and activated charcoal if ingested; atropine (0.2 mg/kg IV initially and 0.2 mg/kg SC as needed q6-8h); pralidoxime (20 mg/kg IM q12h) if within 48 hours of exposure or if was dermal exposure

### Lead

Common use: ubiquitous in environment in linoleum, rug padding, old lead-based paints (before 1950s), putty and caulking material, roofing materials, batteries, grease, used motor oil, golf balls, fishing sinkers, pellets, and lead shot

Clinical findings: gastrointestinal signs of anorexia, abdominal pain, vomiting and diarrhea, and megaesophagus; neurologic signs of hysteria, aggression, nervousness, barking, tremors, seizures, blindness, hypermetria and nystagmus (cats), and dementia

Diagnosis: history of exposure, characteristic signs, CBC changes (basophilic stippling of RBCs, increase in nucleated RBCs); blood lead level (heparinized tube: >0.5 ppm [50 mg/dl], diagnostic; >0.25 ppm, suggestive); radiographs may reveal radiopaque material in gastrointestinal system

Treatment: emetics, gastric lavage, activated charcoal, enemas; surgery or endoscopy if lead in stomach; specific: calcium ethylenediaminetetraacetic acid (Ca EDTA) to chelate lead and hasten excretion (25 mg/kg IV q6h as 10 mg Ca EDTA/ml in dextrose for 2-5 days); establish diuresis; alternative treatment: succimer (10 mg/kg PO for 10-14 days; Chemet; Sandofi Pharm, N.Y.)

### Ethylene Glycol

Common use: automobile antifreeze, color film processing solutions

Clinical findings: ataxia, severe depression, polyuria-polydipsia, vomiting; seizures are rare

Diagnosis: history of exposure, characteristic signs, severe metabolic acidosis, calcium oxalate crystalluria; eventually, decreased urine production and acute renal failure; diagnosis and treatment of this disorder are discussed in detail in Chapter 44

contralateral vision loss and facial hypalgesia. Some animals with small lesions will, however, be normal interictally, with no other defined neurologic deficits.

Idiopathic epilepsy is a condition wherein the seizure threshold is decreased. This can be caused by intrinsic neurotransmitter imbalances, genetic mutations affecting ion channels, or other functional abnormalities. Epileptic foci contain cells with an intrinsic pattern of high spontaneous firing, leading to seizure activity. Idiopathic epilepsy has been shown to be inherited in a few dog breeds, and a familial basis for the condition is suspected in others. Affected

animals are normal interictally, and extensive diagnostic evaluation, including histologic examination of the brain, is normal.

### DIFFERENTIAL DIAGNOSIS

The differential diagnosis for a patient with seizures includes idiopathic epilepsy, intracranial disease (symptomatic epilepsy), probable symptomatic epilepsy, and extracranial disease.

### **IDIOPATHIC EPILEPSY**

Idiopathic epilepsy is the most common cause of seizures in the dog and is characterized by repeated episodes of seizures with no demonstrable cause. Affected dogs are normal between seizures. Idiopathic epilepsy is uncommon in cats; most cats with seizures have an identifiable intracranial cause, such as neoplasia or encephalitis.

Idiopathic epilepsy is inherited in German Shepherd Dogs, Belgian Tervurens, Keeshonds, Beagles, and Dachshunds. On the basis of pedigree analysis, genetic factors are also strongly suspected in Labrador Retrievers, Golden Retrievers, and Collies. Epilepsy is also commonly seen in Saint Bernards, Cocker Spaniels, Irish Setters, Boxers, Siberian Huskies, English Springer Spaniels, Alaskan Malamutes, Border Collies, Shetland Sheepdogs, Miniature Poodles, and Wire Fox Terriers. It is seen sporadically in almost all breeds, mixed-breed dogs, and cats.

The initial onset of seizures usually occurs between 6 months and 3 years of age, although seizures are not observed until 5 years of age in some dogs. In most breeds it seems that the younger the age at the onset of a seizure disorder, the more difficult the disorder will be to control. A difficultto-control seizure disorder develops at a very young age in some purebred dogs (e.g., 8- to 12-week-old Cocker Spaniels), but such animals may then outgrow the problem by 4 to 6 months of age. This form of epilepsy is termed juvenile epilepsy.

The seizures in dogs and cats with idiopathic epilepsy are usually generalized, tonic-clonic, and associated with a loss of consciousness lasting from 1 to 2 minutes. Some dogs, especially Labrador Retrievers and Miniature Poodles, may instead experience a mild, generalized type of seizure in which they remain alert but anxious while they exhibit a crouched stance, uncontrollable trembling, muscular rigidity, or disequilibrium. Many of these dogs experience a postictal phase and develop more classical generalized tonic-clonic seizures later in life, confirming that these events are seizures. A similar syndrome identified in Chinooks (a Northern breed) may be a paroxysmal movement disorder (dyskinesia) rather than a seizure disorder.

Simple or complex focal seizures with or without secondary generalization may also occur in animals with idiopathic epilepsy. Seizures typically recur at regular intervals, with weeks or months intervening between the seizures. As the animal ages, the frequency and severity of seizures may increase, especially in large-breed dogs. In some dogs, particularly those of large breeds, seizures can eventually occur in clusters, in which multiple seizures occur during a 24hour period. Clusters of seizures are not usually seen in association with the first seizure in dogs with idiopathic epilepsy, except in Border Collies, Dalmatians, and German Shepherd Dogs. If more than two seizures occur during the first week of a seizure disorder, a progressive intracranial or extracranial cause should be suspected.

Idiopathic epilepsy is the most likely diagnosis in a young adult, neurologically normal animal with a long history (>1 year) of a nonprogressive intermittent seizure disorder and a lengthy interictal period (>4 weeks). Findings from a complete physical, neurologic, and ophthalmologic evaluation and results of routine clinicopathologic tests are normal. Intracranial evaluation, when performed, is normal (Fig. 67-1).

### INTRACRANIAL DISEASE

Symptomatic epilepsy is a direct result of intracranial disease localized in the forebrain. Congenital and infectious inflammatory conditions are most often seen in young animals, whereas neoplasia is the most common cause in dogs and cats older than 6 years of age. Most of the intracranial disorders discussed in Chapter 65 and the inflammatory disorders discussed in Chapter 69 can cause symptomatic epilepsy (see Box 67-2). Focal or multifocal neurological deficits identified interictally may suggest structural forebrain pathology, but not all patients with symptomatic epilepsy will have an abnormal neurologic examination. Diagnosis requires careful physical, neurological, and ophthalmologic examination; evaluation for concurrent systemic manifestations of infectious and neoplastic disorders; and often intracranial evaluation, including cerebrospinal fluid (CSF) analysis, and advanced diagnostic imaging (computed tomography [CT] or magnetic resonance imaging [MRI]).

### PROBABLE SYMPTOMATIC EPILEPSY

Scar tissue-related acquired epilepsy can occur after an inflammatory, traumatic, toxic, metabolic, or vascular insult. If a history of significant trauma or infection can be ascertained, the event usually precedes the onset of the seizure disorder by 6 months to 3 years. Findings from physical and neurologic examinations, clinicopathologic tests, and CSF analysis are normal. It is not usually possible to detect a structural abnormality using MRI, and even necropsy will not reliably demonstrate a lesion. The treatment is the same as for idiopathic epilepsy (i.e., anticonvulsant therapy), but the prognosis for seizure control in some large-breed dogs may be better for those with scar tissue-related acquired epilepsy than for those with idiopathic epilepsy.

### **EXTRACRANIAL DISEASE**

Hypoglycemia, hepatic encephalopathy, hypocalcemia, and primary hyperlipoproteinemia may cause seizures in dogs and cats. Other metabolic alterations, including hyperviscosity syndromes (e.g., multiple myeloma, polycythemia), severe electrolyte disturbances (e.g., hypernatremia), hyperosmolality (e.g., untreated diabetes mellitus), heatstroke, and prolonged severe uremia, also occasionally cause seizures (see Box 67-2). In many of these disorders intermittent nonneurologic clinical signs and physical examination findings point toward an extracranial cause of the seizures. Most metabolic encephalopathies also intermittently or permanently alter consciousness, manifesting as confusion, delirium, or depression at least intermittently. Results of a complete blood count (CBC), serum biochemistry panel, and urinalysis often help establish the diagnosis. Hepatic encephalopathy resulting from portosystemic shunting can

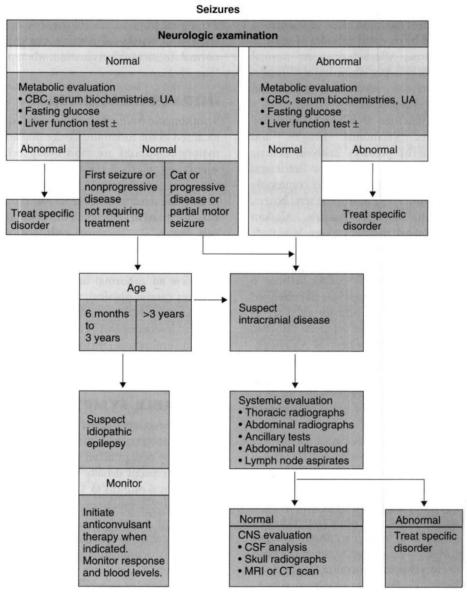

FIG 67-1
Diagnostic approach used in dogs or cats with seizures.

occasionally cause seizures in the absence of other clinical or clinicopathologic abnormalities, especially in cats, so evaluation of liver function is an important component of the initial evaluation for metabolic causes of seizures. More detailed information on the diagnosis and management of these metabolic disorders is contained elsewhere in this text. Common intoxications causing seizures are described in Box 67-3, and treatment of intoxications is outlined in Box 67-4.

### DIAGNOSTIC EVALUATION

A complete and accurate history must be obtained in every animal presenting for a seizure. The owner's description is critical to determine whether the observed paroxysmal event

was actually a seizure and to characterize any seizures as generalized, focal, or psychomotor. The relationship of seizures to daily activity (e.g., exercise, sleep, eating, excitement), seizure duration, and a description of any observed postictal abnormalities should be recorded. Owners should be asked whether they have noticed any changes in the animal's behavior, gait, vision, or sleep patterns in the weeks or months preceding the seizure, characteristics that might indicate a structural forebrain lesion. Recent systemic signs such as cough, vomiting, diarrhea, polyuria, polydipsia, and weight loss or weight gain should also be recorded. Vaccination status, diet, potential exposure to infectious causes of encephalitis, access to drugs or toxins, and history of serious head injury should also be determined. When seizures have occurred intermittently over a prolonged period of time (weeks to months), the seizure pattern and frequency should

BOX 67-4

### **Emergency Treatment of Intoxications**

### **Prevent Further Absorption of Intoxicant** Remove intoxicant from skin and haircoat

1. Toxin was cutaneously absorbed.

How: 1. Remove flea collar if that is source of toxin.

- 2. Wash animal in warm, soapy water; rinse and repeat.
- 3. Flush with warm water for 10 minutes.

### Induce emesis

If:

- 1. Ingestion of intoxicant occurred less than 3 hours before presentation.
- Product ingested was not a petroleum distillate, strong acid, or strong base.
- 3. Animal has a normal gag reflex and is not convulsing or very depressed (danger of aspiration).

- How: 1. At home can recommend syrup of ipecac, 6.6 ml/ kg. Use this in cats.
  - 2. Administer apomorphine subcutaneously (0.08 mg/kg) or in conjunctival sac (1 crushed tablet or 1 disk [6 mg]: rinse eye with saline solution after emesis).
  - 3. Administer xylazine (cats, 0.44 mg/kg IM).

Save vomitus for analysis.

### Gastric lavage

- 1. Ingestion of intoxicant occurred less than 3 hours before presentation.
- 2. Attempts to produce emesis were unsuccessful or emesis was not recommended.

- How: 1. Induce anesthesia and place cuffed endotracheal tube.
  - 2. Lower head relative to body.
  - 3. Pass a large-bore stomach tube to level of stomach.

### Prevent Further Absorption of Intoxicant-cont'd Gastric lavage-cont'd

- 4. Use water (5-10 ml/kg body weight) for each washing; aspirate with syringe.
- 5. Repeat 10 times.

Save stomach contents for analysis.

### Gastrointestinal adsorbents

- How: 1. If gastric lavage has been performed, administer activated charcoal slurry (10 ml/kg of 1 g of activated charcoal/5 ml of water) as last lavage. Let this sit for 20 minutes, then administer a cathartic.
  - 2. If gastric lavage was not performed, administer slurry (dose as above) via stomach tube or administer tablets of activated charcoal.

### Cathartics

How: 1. Sodium sulfate 40% solution should be administered (1 g/kg PO) 30 minutes after activated charcoal is administered.

### Diuresis

How: 1. Administer saline solution to effect diuresis.

2. Mannitol (20% solution, 1-2 g/kg IV) or furosemide (2-4 mg/kg IV) may be added to enhance diuresis if needed.

### Administer Specific Antidotes

See Table 69-3.

**Supportive and Symptomatic Care** 

BOX 67-5

### Indications for Initiating Chronic Anticonvulsant Therapy

- 1. Unresolvable intracranial disease causing seizures
- 2. Cluster seizures
- 3. At least one episode of status epilepticus
- 4. Interictal period less than 12 to 16 weeks
- 5. Increasing seizure frequency or severity

be assessed and the owner should be asked to record frequency and severity of all future seizures on a calendar to allow objective evaluation of disease progression or response to therapy. When idiopathic epilepsy is considered likely, owners should be encouraged to contact the breeder to ascertain whether litter mates or other related dogs are affected.

Physical, ophthalmologic, and neurologic examinations should be obtained in every animal presented for seizures. In the immediate postictal period transient symmetric neurologic abnormalities such as blindness, altered consciousness, and postural reaction deficits are common, so these should not be overinterpreted. Neurologic abnormalities that persist beyond the postictal period suggest an intracranial cause for seizures requiring further evaluation. Lymph node and abdominal palpation as well as mammary gland and prostate examination should be performed to evaluate for primary neoplasia that could have spread to the brain. Some animals with toxic or metabolic causes of seizures will also have specific abnormal findings on physical examination, which aid in diagnosis. Results of these examinations will be normal in dogs and cats with idiopathic epilepsy as well as in many patients with intracranial and extracranial causes of seizures.

Every animal evaluated for seizures should undergo routine screening laboratory tests, including a CBC, serum biochemistry panel, and urinalysis. Blood glucose should also be measured during observed neurologic signs or after a 12-hour fast. Liver function should be evaluated in dogs

and cats that are less than 1 year of age at the time of their first seizure and in all animals with initial laboratory results suggesting hepatic dysfunction (see Chapter 36).

The animal's signalment and history as well as the onset and progression of the seizure disorder allow ranking of likely differential diagnoses. Congenital structural disorders such as hydrocephalus and lissencephaly are the most likely causes of a seizure disorder in a very young animal. Infectious causes of encephalitis usually cause rapidly progressive neurologic dysfunction rather than seizures alone. In aging animals cerebral neoplasia, vascular accidents, and acquired metabolic disturbances are more likely causes of seizures. Animals with idiopathic epilepsy typically have their first observed seizure between 6 months and 3 years of age; thus it is not a likely diagnosis in a dog or cat with seizures that began late in life.

When the systemic, neurologic, and screening laboratory tests are all normal, recommendations for further testing are based on history and signalment. Dogs between 1 and 3 years of age when their first seizure is observed, presenting with a single generalized seizure or a history of a few generalized seizures weeks or months apart, most likely have idiopathic epilepsy; further evaluation may not be required. Typically, the frequency and severity of the seizures are monitored, and, when necessary, treatment is initiated with anticonvulsant therapy. Idiopathic epilepsy is uncommon in cats; therefore, even when all routine screening tests are normal, cats should be tested for feline leukemia virus and antibody against feline immunodeficiency virus, and intracranial evaluation should be recommended.

Further testing, including intracranial evaluation, should be recommended in all dogs with interictal neurologic abnormalities, in dogs older than 5 years of age when their first seizure is observed, and in dogs with focal seizures or multiple seizures that take place within a 1-month period. When neurologic or systemic signs are present that could be caused by infections diseases endemic to the region, noninvasive and relatively inexpensive serologic testing may be beneficial. Thoracic and abdominal radiographs and abdominal ultrasound should be performed to look for systemic manifestations of infectious causes of symptomatic epilepsy and for primary or metastatic neoplasia. If these tests are negative, advanced imaging of the brain with MRI or CT is performed, as well as CSF collection and analysis.

### ANTICONVULSANT THERAPY

Management of dogs and cats with seizures can be attempted using anticonvulsant therapy. Because this requires a large financial, emotional, and time commitment by owners, they should be involved in the decision to initiate treatment. Not every animal with seizures requires anticonvulsant therapy, but there is compelling evidence that dogs treated early in the course of their seizure disorder may have better long-term control of their seizures compared with dogs that are allowed to have many seizures before treatment is initiated.

### Guidelines for Anticonvulsant Therapy in Dogs

- 1. Initiate treatment with PB (2.0 mg/kg PO q12h).
- If the seizures continue to occur after 48 hours of treatment, double the dose.
- At least 10 days after initiating therapy, measure the trough (prepill) serum PB concentration. If the concentration is less than 25 μg/ml (107 μmol/L), increase the PB dose by 25% and reevaluate the serum concentration 2 weeks later. Repeat until the trough serum PB concentration is between 25 and 35 μg/ml (107 to 150 μmol/L).
- If seizures are adequately controlled, maintain dose and monitor serum PB concentration and liver enzymes/ function once twice a year.
- 5. If there is inadequate seizure control despite adequate trough serum PB concentration, measure serum PB peak (4 hours postpill) and trough (prepill) concentrations. If there is more than a 25% variation, increase PB administration to three times a day.
- If seizure control is still inadequate, add potassium bromide therapy (15 mg/kg PO q12h with food).
- 7. If necessary to control seizures, increase the dose of potassium bromide to 20 mg/kg PO q12h.
- Measure the trough potassium bromide concentration in 3 to 4 months. It should be 1.0 to 2.0 mg/ml (10-20 mmol/L).

PB, Phenobarbital; PO, by mouth.

Anticonvulsant therapy should be initiated in all dogs and cats with the following: (1) seizures caused by an intracranial lesion, (2) one or more episodes of cluster seizures or status epilepticus, (3) seizures that occur more often than once every 12 to 16 weeks, or (4) seizures that are becoming more frequent (Box 67-5).

Complete control of seizures in dogs and cats with idiopathic epilepsy is rarely possible, but a decrease in the frequency and severity of seizures is a realistic goal that can be accomplished in 70% to 80% of animals. Owners should keep a log detailing the frequency and severity of seizures so that the effects of the medication can be monitored. Adverse effects of the medication and plans for monitoring blood concentrations and dose adjustments should be discussed. Emergency situations, such as status epilepticus, should be described to owners and specific recommendations for treatment and veterinary assistance provided. A minimum database, including a CBC, serum biochemistry profile, and urinalysis, should always be obtained immediately before the start of anticonvulsant therapy, and if one was not recently performed, a liver function test is also recommended. Whenever possible, animals should be initially treated with a single anticonvulsant drug (monotherapy) to decrease the prevalence of adverse effects, optimize owner compliance, and decrease overall costs of drugs and monitoring. Clinical response and therapeutic drug concentrations should be monitored to determine the proper dose of anticonvulsant drug for the individual animal. If the initial drug administered is ineffective in spite of optimal serum drug concentrations, then another antiepileptic drug should be added or substituted (Box 67-6).

### ANTICONVULSANT DRUGS

### **PHENOBARBITAL**

Phenobarbital (PB) has been considered the drug of choice for the initial and ongoing treatment of seizures in dogs and cats for decades. PB is a relatively safe, effective, and inexpensive anticonvulsant drug. It has a high bioavailability and is rapidly absorbed, with peak plasma concentration 4 to 8 hours after oral administration. An appropriate starting dose is 2.5 mg/kg given orally twice a day.

After 2 weeks of therapy the animal should be examined and its morning prepill (trough) blood PB concentration determined. The trough serum PB concentration should be in the therapeutic range of 25 to 35  $\mu$ g/ml (107 to 150  $\mu$ mol/ L) in dogs and 10 to 30  $\mu$ g/ml (45 to 129  $\mu$ mol/L) in cats. If the serum concentration is too low, the dose of PB should be increased by approximately 25% (see Box 67-6) and the trough serum concentration determined again 2 weeks later. If the serum concentration is still inadequate, the dose of PB should be increased in 25% increments every 2 weeks while the blood concentration is monitored. Once the measured blood concentration of PB is adequate, the dog or cat should be observed through two or three cycles of seizures, and if control is determined to be acceptable, therapy is maintained at that dosage. Long-term dosing of PB can be complicated by the drug's induction of hepatic microsomal enzyme activity, increasing its own elimination and necessitating dosage increases. Blood PB concentrations should be reevaluated routinely every 6 months, 2 weeks after any change in dosage, and whenever two or more seizures occur between scheduled PB evaluations. Serum separator tubes should not be used to collect serum for this purpose because their use will underestimate the concentration of PB.

PB is well tolerated in most dogs at therapeutic serum concentrations. Sedation, depression, and ataxia may be pronounced for the first 7 to 10 days of therapy, but these adverse effects resolve with time (10 to 21 days) as the animal acquires a tolerance for the sedative effects of the drug. Transient (7 days) hyperexcitability can occur as an idiosyncratic effect in up to 40% of dogs and cats. The most common persistent adverse effects of PB include polyuria, polydipsia, and polyphagia. Owners should be advised to refrain from overfeeding animals receiving this anticonvulsant, even though their pet seems ravenous. Many animals acquire a dependence on the drug, and sudden withdrawal of the drug can precipitate seizures; therefore it is important for owners to administer the drug consistently once treatment is started.

Immune-mediated neutropenia or thrombocytopenia has been recognized in a few dogs within the first 6 months of starting PB, but these blood dyscrasias resolve when the PB is discontinued. PB administration may also be a risk factor for the development of superficial necrolytic derma-

titis in dogs. The most life-threatening potential complication of PB therapy is drug-induced hepatotoxicity. PB is a potent inducer of hepatic enzymes, and mild to moderate elevations in serum alkaline phosphatase (ALP) and alanine transaminase (ALT) activities are seen in virtually all dogs receiving the anticonvulsant. Significant hepatotoxicity is uncommon but is most likely to occur when peak serum PB concentrations are at the high end of the therapeutic range (>35 µg/ml; >150 µmol/L). Clinical features of significant hepatotoxicity include anorexia, sedation, ascites, and occasionally icterus. Laboratory testing typically reveals a large increase in ALT, decreased serum albumin, and abnormal bile acids. When hepatotoxicity is discovered, the patient should be rapidly switched to an alternative anticonvulsant and supportive measures initiated for liver failure. All animals receiving chronic PB therapy should be evaluated every 6 months to assess the effectiveness of the drug regimen, the serum concentration of PB, liver enzyme activities, and liver function.

PB increases the biotransformation of drugs metabolized by the liver, decreasing the systemic effects of many drugs administered concurrently. PB also increases the rate of thyroid hormone elimination, decreasing measured serum total and free T<sub>4</sub> and increasing serum thyroid-stimulating hormone concentrations, but this is rarely associated with clinical signs of hypothyroidism (see Chapter 51). Drugs that inhibit microsomal enzymes (e.g., chloramphenicol, tetracycline, cimetidine, ranitidine, enilconazole) may dramatically inhibit the hepatic metabolism of PB, resulting in increased serum concentrations of PB and potentially causing toxicity.

Seizures are controlled in 70% to 80% of dogs and most cats treated with PB monotherapy if serum PB concentrations are maintained within the target range. If seizures continue to occur at an unacceptable frequency or severity despite adequate serum concentrations, therapy with additional drugs must be considered.

### POTASSIUM BROMIDE

Control of refractory seizures can be improved through the addition of potassium bromide (KBr) to already established PB therapy in animals with poorly controlled seizures despite adequate serum concentrations of PB, decreasing seizure numbers by 50% or more in approximately 70% to 80% of dogs (see Box 67-6). KBr is also effective as a single agent and is considered by many to be the initial drug of choice in dogs with hepatic dysfunction and dogs that do not tolerate PB. KBr monotherapy is also commonly administered to large dogs with idiopathic epilepsy and a low frequency of seizures. The drug should not be administered to cats because of a high prevalence of drug-associated severe progressive bronchitis in that species. Bromide is excreted unchanged by the kidney. It is not metabolized by the liver and does not cause hepatotoxicity. Potassium bromide is typically administered as the inorganic salt dissolved in double distilled water to achieve a concentration of 200 to 250 mg/ml. Administration of the salt in gelatin capsules is also possible, but the concentrated drug in this form often causes gastric

irritation and vomiting. Dietary chloride should remain constant in dogs treated with KBr because high chloride intake (e.g., chips, rawhide bones) results in increased renal excretion of KBr and decreased serum concentrations. An appropriate starting dose of KBr is 20 mg/kg orally twice daily for monotherapy and 15 mg/kg orally twice daily when used as an add-on drug to PB. KBr serum concentrations should be measured 1 month after initiating therapy, 8 to 12 weeks later when a steady state is achieved, and then annually. The goal is to achieve a serum concentration of 2.5 to 3.0 mg/ml (25 to 30 mmol/L) of KBr when used as monotherapy and 1.0 to 2.0 mg/ml (10 to 20 mmol/L) when used together with PB. Serum PB concentrations should also be maintained in the midtherapeutic range in animals receiving KBr and PB.

When maintenance doses of KBr are administered, there is a long lag period between the initiation of treatment and achieving steady-state serum concentrations. KBr is therefore not recommended as monotherapy in dogs with frequent seizures in which rapid control is required. If KBr must be administered as the only anticonvulsant therapy in a dog with a severe or progressive seizure disorder or in a dog that must be switched from PB to KBr because of toxicity, it is possible to achieve therapeutic serum concentrations of KBr rapidly using a loading-dose protocol. Oral loading can be accomplished by administering 30 mg/kg of KBr orally four times a day for 5 days with food, followed by the administration of maintenance doses.

Adverse effects of KBr include polyuria, polydipsia, and polyphagia, but these may be less dramatic than the changes induced by PB therapy. Transient sedation, incoordination, anorexia, and constipation can also occur. Reversible limb stiffness, lameness, and muscle weakness will occur if serum bromide levels are excessive. Vomiting is a very common problem caused by gastric irritation from the hyperosmolality of the drug; this toxicity can be diminished by further splitting the daily dose (into four equal doses administered approximately every 6 hours) and by feeding a small amount of food with each dose. Pancreatitis occurs rarely. Dramatic sedation can occur in dogs being concurrently treated with PB; this is usually temporary but can be decreased by lowering the dose of PB administered by 25% or by administering intravenous saline to increase the renal excretion of KBr, keeping in mind that dramatically lowering the serum concentration of either drug may cause increased seizure activity. Biochemical abnormalities are not common in dogs treated with KBr monotherapy, but because some laboratory assays cannot distinguish bromide from chloride, there may be an artifactual increase in measured chloride.

### DIAZEPAM

Diazepam (Valium; Roche) is of limited use as a primary anticonvulsant in dogs because of its expense, its very short half-life, physical dependence, and the rapid development of tolerance to its anticonvulsant effects. Oral diazepam has been shown to be of some benefit for the long-term management of seizures in cats because tolerance to its anticonvul-

sant effect does not seem to occur in that species. Diazepam can be administered orally (0.3 to 0.8 mg/kg q8h) to achieve trough blood concentrations of 200 to 500 ng/ml. The drug is eliminated by hepatic metabolism, and the only common adverse effect is sedation, although idiosyncratic severe, lifethreatening hepatotoxicity has been documented in a few cats receiving daily diazepam for 5 to 11 days. This potentially fatal reaction warrants close owner observation of appetite and attitude and periodic monitoring of liver enzymes in all cats treated with diazepam. PB is a better choice for chronic anticonvulsant therapy in cats.

Diazepam also has a place in the emergency management of seizures and in the at-home treatment of dogs with idiopathic epilepsy experiencing cluster seizures. In dogs with a recognizable preictal phase or an aura preceding the seizure, an injectable preparation of diazepam (5 mg/ml) can be administered rectally (2 mg/kg) by the owner at the onset of these premonitory signs. Alternatively, this dose can be administered just after each observed seizure, with a maximum of three doses in 24 hours (each dose separated by at least 10 minutes). At-home rectal administration of diazepam decreases the occurrence of cluster seizures and the development of status epilepticus as well as dramatically decreasing the need for owners to seek expensive emergency treatment for their epileptic dogs. Diazepam dispensed for at-home rectal administration should be stored in a glass vial because plastic will adsorb the drug, decreasing its effectiveness. For administration the drug can be drawn into a syringe and injected through a 1-inch plastic teat cannula or rubber catheter directly into the rectum.

### **CLORAZEPATE**

Clorazepate (Traxene; Abbott Laboratories) is a benzodiazepine with a slightly more prolonged action than that of diazepam. This drug is effective as a sole anticonvulsant or when administered as an add-on drug. Chronic administration can result in tolerance to its antiseizure effects, potentially making all benzodiazepines ineffective for emergency use. The only recognized adverse effects are sedation, ataxia, and polyphagia, although acute hepatic necrosis might be a concern in cats because of shared metabolites with diazepam. There is also a potential for severe withdrawal seizure activity with this drug. The starting dose is 1 to 2 mg/kg, administered orally q12h, with desired therapeutic concentration of 300 to 500 ng/ml. Clorazepate administration to dogs being chronically treated with PB will increase serum PB concentrations, requiring monitoring and dosage adjustments.

### **FELBAMATE**

Felbamate (Felbatol; Wallace) is an effective anticonvulsant in dogs when used alone or as an add-on drug in dogs refractory to anticonvulsant therapy with PB and KBr. Following urinary excretion of 70% of the orally administered dose, Felbamate is metabolized by hepatic microsomal P450 enzymes. The recommended starting dose is 15 mg/kg q8h. Felbamate appears to have a wide margin of safety, and the daily dose can be increased in 15 mg/kg increments until the

seizures are adequately controlled, with reports of dosages as high as 70 mg/kg q8h without toxicity. Felbamate is an unusual anticonvulsant in that it does not cause sedation. Because approximately 30% of dogs treated with felbamate as an add-on drug with PB develop hepatotoxicity, monitoring of biochemistry panels and liver function tests is recommended. Aplastic anemia has been reported in humans receiving this drug but has not been documented in dogs. Serial monitoring of CBC and serum biochemistry panel is recommended at 1 month and every 3 months during treatment. Trough serum concentrations between 25 and 100 mg/L are reported to be therapeutic.

### **GABAPENTIN**

Gabapentin (Neurontin; Parke-Davis) is a structural analog of GABA, with a poorly understood mechanism of action. The drug is rapidly absorbed and renally excreted with some hepatic metabolism. The elimination half-life in dogs is very short (3 to 4 hours), requiring dosing every 6 to 8 hours. Moreover, the drug has a very high therapeutic index and very little potential for drug-drug interaction. Starting doses of 10 to 20 mg/kg q8h have been recommended. The dose should be increased gradually as needed (up to 80 mg/kg q6h) to avoid excessive sedation, which is the only reported adverse effect. Serum concentrations are rarely monitored, but the suspected therapeutic range for dogs is 4 to 16 mg/L. Preliminary clinical evaluation of gabapentin as an add-on drug in dogs with refractory epilepsy has recorded decreased seizure frequency in 50% of cases.

### **ZONISAMIDE**

Zonisamide (Zonegran; Elan) is a sulfonamide-based anticonvulsant that suppresses epileptic foci and blocks the propagation of epileptic discharges. This drug is well absorbed and hepatically metabolized, with a relatively long half-life (15 hours) in dogs not concurrently receiving PB or other drugs that induce microsomal enzymes. Zonisamide is effective as a sole agent or as an add-on drug. Mild adverse effects reported include sedation, ataxia, vomiting, and inappetence. The initial starting dose is 5 mg/kg twice daily in dogs not receiving PB and 10 mg/kg twice daily in dogs receiving concurrent PB. A serum concentration of 10 to 40 µg/ml is reported to be therapeutic.

### **LEVITIRACETAM**

Levitiracetam (Keppra) is a new anticonvulsant that is well tolerated and effective in human patients. The drug is well absorbed and rapidly metabolized, with a half-life of 3 to 4 hours in dogs. Most of the drug is excreted unchanged in the urine, and the remainder is metabolized by hydrolysis in multiple organs, with no significant hepatic metabolism. Limited information is available on its use in dogs and cats, but it reportedly decreases seizure frequency by over 50% in epileptic dogs when used as an add-on drug and has also been effective in cats with refractory seizures. A starting dose of 20 mg/kg q8h is recommended, with some reports of administration of much higher doses without toxicity.

Adverse effects include minimal sedation and salivation and vomiting in a few dogs.

### ALTERNATIVE THERAPIES

Approximately 20% to 25% of dogs treated for epilepsy using standard anticonvulsant therapy are never well controlled, despite attempts at therapeutic drug monitoring and appropriate dose adjustments. It is important to evaluate poorly controlled animals for underlying metabolic or intracranial disease that could be specifically treated. Alternative treatments should also be considered in these animals, including hypoallergenic diets, acupuncture, surgical division of the corpus callosum, and vagus nerve stimulation.

# EMERGENCY THERAPY FOR DOGS AND CATS IN STATUS EPILEPTICUS

Status epilepticus is a series of seizures or continuous seizure activity lasting for 5 minutes or longer without periods of intervening consciousness. Status epilepticus increases arterial blood pressure, body temperature, heart rate, cerebral blood flow, and cerebral oxygen consumption. It also decreases blood pH (because of lactic acidosis) and may decrease effective ventilation. As seizures continue, metabolic deterioration, increased intracranial pressure, acidosis, hyperthermia, and cardiac dysrhythmias are common, leading to progressive cerebral ischemia and neuronal death. Permanent neurologic damage and even death can result.

Status epilepticus is always a medical emergency. The most common reasons for a known idiopathic epileptic patient to present in status include poor chronic seizure control of cluster seizures and abrupt withdrawal of anticonvulsant medications (missed doses). Nonepileptics may present in status as a result of various metabolic (e.g., hypoglycemia, hypocalcemia, hepatic encephalopathy, hyperosmolality, renal failure, intoxications) and intracranial (e.g., neoplasia, trauma, infarct, malformation, heat stroke, granulomatous meningoencephalitis, infectious meningoencephalitis) disorders. History and physical examination findings help determine the cause of status epilepticus in an individual patient. Diagnostic testing for metabolic causes of seizures (especially hypoglycemia, hypocalcemia, electrolyte disturbances) should always be performed and specific treatment initiated when warranted. When intoxication is suspected, treatment should be directed at reducing further absorption of the toxin, increasing toxin excretion, and controlling the neurologic manifestation of seizures (see Box 67-4).

The goals of treatment are to stabilize the animal, stop the seizure activity, protect the brain from further damage, and allow recovery from the systemic effects of prolonged seizure activity. Oxygen is administered, as well as fluid therapy and supportive care, to minimize systemic effects. Diazepam is administered (intravenously or rectally) to stop the seizures; this is followed by phenobarbital to prevent seizure recur-

BOX 67-7

### Status Epilepticus Treatment in Dogs and Cats

- 1. If possible, insert an IV catheter.
- 2. Administer diazepam 2.0 mg/kg rectally if no IV access. If IV access is possible, administer 1.0 mg/kg intravenously. Repeat every 2 minutes if ineffective or if seizures recur. Administer maximum of four doses if necessary. If patient responds to diazepam administration but seizures recur, consider a diazepam CRI (1.0 mg/kg/h) in 0.9% saline or in D₅W. Continue the CRI for at least 6 hours; if no seizures occur, can then taper by 25%/h.
- Administer a loading dose of phenobarbital to prevent further seizures (5 mg/kg slow intravenously or intramuscularly twice, 10 minutes apart). This will take 20 to 30 minutes for maximum effect. Repeat 5 mg/kg dose q6h intramuscularly until oral dosing can be performed.
- 4. If seizures have not responded to diazepam or to the initial dose of phenobarbital, it will be necessary to stop the seizures using either:

- Sodium pentobarbital (3 to 15 mg/kg, intravenously slowly to effect)
- Repeat as needed (q4-8h) or maintain on CRI: (1.0-5.0 mg/kg/h to effect) in saline

or

Propofol (4 mg/kg, intravenously slowly over 2 minutes). Maintain on a CRI (0.10-0.25 mg/kg/minute). Maintain anesthesia for 6 to 12 hours, then taper CRI by 25% every 2 to 4 hours to recover.

- 5. Maintain a patent airway and monitor respirations.
- 6. Initiate IV fluids (maintenance rate).
- Assess body temperature. If >41.4°C (>105°F), cool with cool-water enemas.
- If hyperthermic or if seizure activity was prolonged (>15 minutes), administer:
   mannitol: 1.0 g/kg, intravenously over 15 minutes
   furosemide: 2 mg/kg, intravenously

IV, Intravenous; CRI, constant rate infusion.

rence. More aggressive treatment is required if seizures continue, usually involving a propofol or pentobarbital infusion to stop seizure activity. Mannitol and furosemide are also recommended (as for head trauma, Box 65-2) to decrease the brain edema secondary to prolonged seizure activity. Details regarding the treatment of status epilepticus are outlined in Box 67-7.

Disorders Causing Peripheral Vestibular Signs BILATERAL PERIPHERAL VESTIBULAR DISEASE CENTRAL VESTIBULAR DISEASE Metronidazole Toxicity

ACUTE VESTIBULAR ATTACKS

### **GENERAL CONSIDERATIONS**

Head tilt is a common neurologic abnormality in dogs and cats. It indicates a lesion of the vestibular system, which consists of central and peripheral parts.

The peripheral vestibular system includes sensory receptors for vestibular input located in the membranous labyrinth of the inner ear within the petrous temporal bone of the skull and the vestibular portion of the vestibulocochlear nerve (CN8), which carries information from these receptors to the brainstem. The central vestibular structures include the brainstem vestibular nuclei and pathways in the medulla oblongata and the flocculonodular lobe of the cerebellum (Fig. 68-1). Abnormalities involving the central or peripheral vestibular system typically cause head tilt, circling, ataxia, rolling, and nystagmus.

Nystagmus is defined as an involuntary rhythmic oscillation of the eyeballs. In the jerk nystagmus typical of vestibular disease the eye movements have a slow phase in one direction and a rapid recovery in the opposite direction. Jerk nystagmus direction is defined as the direction of the fast phase. Less common than jerk nystagmus is pendular nystagmus, a slight oscillatory movement of the eyeballs with no slow or fast phase; this condition is most often seen in

Siamese, Birman, and Himalyan cats because of a congenital abnormality of the visual pathway.

### LOCALIZATION OF THE LESION

Head tilt indicates vestibular dysfunction. The first step in a patient with a head tilt should always be an attempt to localize disease to either the central or the peripheral components of the vestibular system (Box 68-1). The clinician can usually accomplish this goal with a careful physical and neurological examination.

# PERIPHERAL AND CENTRAL VESTIBULAR DISEASE

Severe problems of balance resulting in ataxia, incoordination, falling, and rolling are prominent in animals with either central or peripheral vestibular disease. The head tilt (ear pointed toward the ground) is typically on the same side as the lesion, and tight circling toward that side is common. Ipsilateral strabismus may be seen when the nose is elevated. Vomiting, salivation, and other signs of motion sickness are often apparent.

Nystagmus observed when the head is held motionless is called *spontaneous nystagmus* or *resting nystagmus*. Nystagmus that develops only when the head is held in an unusual position is called *positional nystagmus*. Some animals with compensated vestibular disease (either central or peripheral) do not have detectable spontaneous nystagmus but develop positional nystagmus when they are rolled over on their back (see Fig. 63-23). Nystagmus in a patient with peripheral vestibular disease is always either horizontal or rotary, and although the intensity of nystagmus may change when the head is held in different positions, the direction will not. The nystagmus in animals with central vestibular diseases can be horizontal, rotary, or vertical and may change direction as the position of the head is changed.

### PERIPHERAL VESTIBULAR DISEASE

Animals with peripheral vestibular disease should have normal mentation and consciousness. They have normal

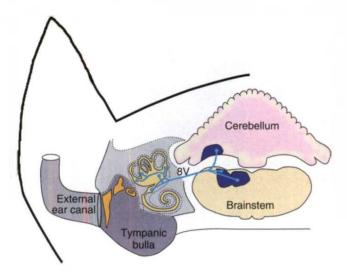

FIG 68.1

Anatomy of the central and peripheral vestibular system. Sensory receptors for vestibular input are located in the membranous labyrinth of the inner ear. Input from these receptors enters the brain via the vestibular portion of CN8 (8V), and fibers terminate in central vestibular nuclei in the brainstem and cerebellum.

strength and postural reactions, although these tests may be difficult to assess because affected animals have impaired balance and a tendency to fall and roll. Spontaneous and positional nystagmus is horizontal or rotary or alternates between the two and will not change fast-phase direction when the animal is held in multiple positions or examined repeatedly during the day. Damage to inner ear receptors or the axons of CN8 results in vestibular dysfunction and sometimes deafness. Disorders that affect both the middle and inner ear will sometimes damage the axons of the facial nerve (CN 7) and the sympathetic innervation to the eye, resulting in concurrent facial nerve paralysis, Horner's syndrome, and peripheral vestibular dysfunction (Fig. 68-2).

### CENTRAL VESTIBULAR DISEASE

Early in the course of disease, animals with central vestibular dysfunction may not have clinical features that readily distinguish them from animals with peripheral vestibular dysfunction. With time and progression, however, they usually develop additional signs indicating brainstem involvement. Mentation may be dull or depressed or behavior may be altered as the ascending reticular activating system is disrupted. Ipsilateral paresis and postural reaction deficits (abnormal knuckling, hopping) develop on the side of the lesion as the upper motor neuron pathways to the limbs are involved, and affected animals may lose the ability to walk. Although spontaneous nystagmus can be in any direction, a vertical nystagmus or a nystagmus that changes directions with different head positions indicates central vestibular disease. The presence of cranial nerve abnormalities other than facial nerve paralysis and Horner's syndrome in an animal with vestibular signs usually indicates central (i.e.,

FIG 68-2
Adult cat with peripheral vestibular disease and Horner's syndrome on the left side caused by otitis media-interna.

BOX 68-

Vestibular Disease Clinical Findings

### Central and Peripheral Vestibular Disease

Incoordination, loss of balance
Head tilt toward lesion
Circling/falling/rolling toward the side of the lesion
+/- ventral strabismus on side of lesion
Vomiting, salivation
Spontaneous nystagmus (fast phase away from lesion)
Nystagmus may be positional

### Peripheral Vestibular Disease

Nystagmus always horizontal or rotary
No change in nystagmus direction
Postural reactions and proprioception normal
With middle/inner ear disease, may see concurrent CN7
deficit and Horner's syndrome
No other cranial nerve deficits

### **Central Vestibular Disease**

Occasionally indistinguishable from peripheral disease Findings that confirm disease as central:

Vertical nystagmus
Nystagmus that changes direction with head position
Abnormal postural reactions on side of lesion

Multiple cranial nerve deficits

### Paradoxical Vestibular Syndrome (Cerebellar Lesion)

Head tilt and circling away from side of lesion
Fast phase nystagmus toward the lesion
May exhibit vertical nystagmus
Abnormal postural reactions on side of lesion
+/- Multiple cranial nerve deficits on side of lesion
+/- Hypermetria, truncal sway, and head tremor

brainstem) disease. Neoplasms or granulomas located at the cerebellomedullary angle often result in simultaneous dysfunction of the vestibular (CN8), facial (CN7), and trigeminal (CN5) nerves, so the trigeminal nerve (i.e., facial and nasal sensation) should always be assessed in animals with vestibular signs.

### PARADOXICAL VESTIBULAR SYNDROME

Vestibular signs can be seen with lesions affecting the caudal cerebellar peduncle or the flocculonodular lobe of the cerebellum. This syndrome is called paradoxical vestibular syndrome because affected animals have a head tilt and circling away from the lesion and a fast phase nystagmus directed toward the lesion. Postural reaction deficits, when present, are on the side of the lesion and are therefore the most reliable clinical feature allowing lesion localization. Other signs of cerebellar dysfunction, such as hypermetria, truncal sway, and head tremor, are often seen. Diagnostic evaluation is the same as that for central vestibular disease and other intracranial disorders (see Chapter 65).

### PERIPHERAL VESTIBULAR DISEASE

Peripheral vestibular disease is much more common in dogs and cats than central disease and generally carries a better prognosis. The most common disorders causing peripheral vestibular signs are infection, polyps, or neoplasia affecting the middle and inner ear and transient idiopathic vestibular syndromes. Peripheral vestibular disease can also occur as a congenital problem; as a result of trauma; and, rarely, as a result of aminoglycoside-induced receptor degeneration (Box 68-2). Peripheral vestibular signs with or without facial nerve paralysis have also been seen in hypothyroidassociated polyneuropathy in dogs.

Diagnostic evaluation of patients with peripheral vestibular signs should include a thorough otoscopic examination and external palpation of the bullae for asymmetry or pain. Ototoxic drugs or treatments should be discontinued and systemic evaluation for inflammatory or metabolic disease performed. Radiographs, computed tomography (CT), or magnetic resonance imaging (MRI) of the tympanic bullae (middle ear) should be evaluated with the patient under general anesthesia before ear flushing is performed. When warranted, a myringotomy can then be used to collect a sample from the middle ear for cytological analysis and culture.

### DISORDERS CAUSING PERIPHERAL **VESTIBULAR SIGNS** Otitis Media-Interna

Otitis media-interna (OM-OI) is one of the most common causes of peripheral vestibular signs in dogs and cats. Concurrent facial nerve paralysis or Horner's syndrome affecting the same side is sometimes apparent (Fig. 68-3; see also Fig. 68-2). All dogs and cats with peripheral vestibular disease should be evaluated for ear disease. Most animals with OM-

OI have obvious otitis externa, and many have a tympanic membrane that appears abnormal or ruptured. Occasionally, the otoscopic examination is normal.

Skull radiographs can be evaluated for changes in the tympanic bullae suggesting chronic inflammatory disease, trauma, or tumor. Ventrolateral, oblique, lateral, and openmouth radiographs of the skull should be performed with the patient under general anesthesia. Radiographic evidence of OM-OI includes increased thickness of the bones of the tympanic bullae and petrous temporal bone and increased fluid or soft-tissue density within the tympanic bullae (see Figs. 71-7 and 68-3). Because radiographs may be normal with acute infections, more sensitive advanced imaging techniques (CT and MRI) are recommended if radiographs are nondiagnostic.

While the animal is sedated or anesthetized, a culture should be obtained from the external ear canal and the ear canal and the tympanic membrane should be carefully examined using an otoscope or a small endoscope. If imaging suggests that fluid is present within the middle ear, a sample of that fluid should be collected for cytology and culture. If the tympanic membrane is ruptured, the sample can be obtained directly under visualization. If the tympanic membrane appears to be intact, the external ear canal can be cleaned by flushing with warm 0.9% saline until the fluid obtained is clear, and then a myringotomy may be performed. Using a 22-gauge, 3.5-inch spinal needle attached to a 6-ml syringe, the clinician punctures the tympanic membrane just caudal to the malleus at the 6 o'clock position and gently aspirates fluid from the middle car into the syringe. If fluid is not obtained, 0.5 to 1.0 ml of sterile saline can be instilled and then aspiration can be repeated. After the diag-

**FIG 68-3 A,** Adult Cocker Spaniel with left peripheral vestibular disease caused by otitis media-interna. **B,** Radiograph reveals thickening of the left bulla wall with an increase in density within the bulla. Osteotomy of the ventral bulla revealed bilateral otitis media-interna.

nostic sample is obtained, the middle ear should be flushed repeatedly with sterile saline to remove exudate from the bulla.

Medical treatment of dogs and cats with bacterial OM-OI consists of a 4- to 6-week course of systemic antibiotics, with the choice of antibiotic based on culture and sensitivity results. Pending culture results, antibiotic treatment can be initiated using a broad-spectrum antibiotic such as a first-generation cephalosporin (cephalexin, 22 mg/kg, administered orally q8h), a combination of amoxicillin and clavulanic acid (Clavamox, 12.5 to 25 mg/kg, administered orally q8h), or enrofloxacin (5 mg/kg, administered orally q12h). If conservative treatment does not resolve the infection or if there is radiographic evidence of chronic bone changes in the bulla, ventral bulla osteotomy should be performed, followed by a course of antibiotic therapy. Early recognition of OM-OI and prompt initiation of appropriate therapy result

**FIG 68-4 A** and **B**, A 12-year-old Golden Retriever with head and body tilt caused by geriatric canine vestibular disease.

in a good prognosis for recovery. The facial nerve paralysis may be permanent in spite of treatment. Failure to treat OM-OI aggressively can result in ascent of the infection up the nerves into the brainstem, resulting in neurologic deterioration, central vestibular signs, and often death.

### **Geriatric Canine Vestibular Disease**

Geriatric canine vestibular disease (i.e., old dog vestibular disease), an idiopathic syndrome, is the most common cause of acute unilateral peripheral vestibular dysfunction in old dogs, with a mean age of onset of 12.5 years. The disorder is characterized by the very sudden onset of head tilt, loss of balance, and ataxia with a horizontal or rotatory nystagmus (Fig. 68-4). Proprioception and postural reactions are normal, although they may be difficult to assess. Facial paresis and Horner's syndrome are not present, and no other neurologic abnormalities are observed. Approximately 30%

of affected dogs have transient nausea, vomiting, and anorexia.

Any older dog with a peracute onset of unilateral peripheral vestibular disease with no other neurologic abnormalities should be suspected to have geriatric canine vestibular disease. A careful physical examination, neurologic examination, and otoscopic examination should be performed. Further extensive diagnostic testing is often delayed for a few days while the dog is supported and monitored for improvement.

The diagnosis of geriatric canine vestibular disease is based on the signalment, neurologic findings, exclusion of other causes of peripheral vestibular dysfunction, and alleviation of clinical signs with time. The spontaneous nystagmus usually resolves within a few days and is replaced by a transient positional nystagmus in the same direction. The ataxia gradually abates during 1 to 2 weeks, as does the head tilt. Occasionally, the head tilt is permanent.

The prognosis for recovery is excellent; no therapy is recommended. When vomiting is severe, H1 histaminergic receptor antagonists (diphenhydramine, 2 to 4 mg/kg, administered subcutaneously 98h), M1 cholinergic receptor antagonists (chlorpromazine, 1 to 2 mg/kg, administered orally 98h), or vestibulosedative drugs (meclizine, 1 to 2 mg/ kg, administered orally q24h) can be administered for 2 to 3 days to alleviate the emesis associated with motion sickness. Recurrent attacks are unusual but may occur on the same side or on the opposite side.

### Feline Idiopathic Vestibular Syndrome

Feline idiopathic vestibular syndrome is an acute, nonprogressive disorder similar to the idiopathic geriatric vestibular syndrome that occurs in dogs. It is a common disorder affecting cats of any age. The disease may be more prevalent in the summer and early fall and in certain geographic locations, particularly the northeastern United States, suggesting a possible role for an infectious or parasitic cause. This syndrome is characterized by the peracute onset of peripheral vestibular signs, such as severe loss of balance, disorientation, falling and rolling, a head tilt, and spontaneous nystagmus, with no abnormalities of proprioception or in other cranial nerves. The diagnosis is based on the clinical signs and the absence of ear problems or other disease. If radiographs of the tympanic bullae and petrous temporal bone are obtained, the findings are normal, as are the results of cerebrospinal fluid (CSF) analysis. Spontaneous improvement is usually seen within 2 to 3 days, with a complete return to normal within 2 to 3 weeks.

### Neoplasia

Tumors involving the inner and middle ear may damage peripheral vestibular structures and result in peripheral vestibular dysfunction. Tumors can arise from regional soft tissues (e.g., squamous cell carcinoma, adenocarcinoma, lymphoma) or from the osseous bulla (e.g., fibrosarcoma, chondrosarcoma, osteosarcoma). Tumors originating within the external ear canal (e.g., squamous cell carcinoma, ceruminous gland adenocarcinoma) may also invade past the tympanic membrane to involve the middle and inner ear. Less commonly, tumors of CN8 (e.g., neurofibroma or neurofibrosarcoma) result in peripheral vestibular dysfunction.

When tumors are located in the middle and inner ear, facial nerve paralysis or Horner's syndrome commonly accompanies peripheral vestibular signs. Radiographic evidence of soft-tissue density within the bullae and associated bone lysis suggests tumor. Advanced imaging with CT or MRI provides additional detail and determines whether the tumor has invaded the cranial vault. Diagnosis can be confirmed by biopsy. The invasive nature of tumors in this location makes total resection difficult. Radiotherapy or chemotherapy may be beneficial in some animals (see Chapters 76 and 77).

### Nasopharyngeal Polyps

Nasopharyngeal inflammatory polyps originate at the base of the eustachian tube in kittens and young adult cats and grow passively into the nasopharynx, nose, or middle ear. Most affected cats exhibit stertorous breathing or nasal discharge as a result of respiratory obstruction by these polyps, but cats with polyps in the middle and inner ear are presented with peripheral vestibular signs and sometimes Horner's syndrome and facial nerve paralysis. Otoscopic examination is often normal, although bulging of the tympanic membrane or extension of a polyp into the external ear canal is possible. A diagnosis of nasopharyngeal polyps should be suspected when a young cat is presented with concurrent peripheral vestibular dysfunction and nasopharyngeal obstruction. Skull radiographs reveal soft tissue within the bullae and thickening of the bone but no bone lysis. Surgical removal requires ventral bulla osteotomy, and the prognosis is excellent for cure if all abnormal tissue is removed (see Chapter 15).

### Trauma

Trauma to the middle and inner ear will result in peripheral vestibular signs and commonly concurrent Horner's syndrome and facial nerve paralysis. Facial abrasions, bruises, and fractures may be evident on initial examination. Hemorrhage in the external ear canal may be evident on an otoscopic examination. Radiographs or advanced diagnostic imaging will reveal the extent of the problem. Supportive treatment for head trauma and possible posttraumatic infection should be initiated. Vestibular signs usually resolve with time, whereas facial paralysis and Horner's syndrome may persist.

### **Congenital Vestibular Syndromes**

Purebred dogs and cats that show peripheral vestibular signs before 3 months of age are likely to have a congenital vestibular disorder. Congenital unilateral peripheral vestibular syndromes have been recognized in the German Shepherd Dog, Doberman Pinscher, Akita, English Cocker Spaniel, Beagle, Smooth Fox Terrier, and Tibetan Terrier as well as in

Siamese, Burmese, and Tonkinese cats. Clinical signs may be present at birth or develop during the first few months of life. Head tilt, circling, and ataxia may initially be severe; however, with time, compensation is common, and many affected animals make acceptable pets. The diagnosis is based on the early onset of signs. If ancillary tests such as radiography and CSF analysis are performed, findings are normal. Deafness may accompany the vestibular signs, particularly in the Doberman Pinscher, the Akita, and the Siamese cat.

### **Aminoglycoside Ototoxicity**

Aminoglycoside antibiotics rarely cause degeneration within the vestibular and auditory systems of dogs and cats. This ototoxicity is usually associated with the systemic administration of high doses or the prolonged use of these antibiotics, particularly in animals with impaired renal function. Degeneration within the vestibular system may result in unilateral or bilateral peripheral vestibular signs and loss of hearing. In most cases the vestibular signs resolve if therapy is discontinued immediately, but deafness may persist.

### **Chemical Ototoxicity**

Many drugs and chemicals are potentially toxic to the inner ear. If the integrity of the tympanic membrane is in doubt, topical otic products containing chlorhexidine, dioctyl-sulfo succinate (DOSS), or aminoglycosides should never be used. Warm saline or 2.5% acetic acid solutions should be used for flushing ears. Whenever vestibular dysfunction becomes evident immediately after instilling a substance in an ear canal, the product should be removed and the ear canal flushed with copious quantities of saline. Vestibular signs will usually resolve within a few days or weeks, but deafness may persist.

### **Hypothyroidism**

Vestibular dysfunction has occasionally been reported in association with hypothyroidism in adult dogs. Concurrent facial nerve paralysis may be seen. Other systemic signs of hypothyroidism, such as weight gain, poor haircoat, and lethargy, may or may not be present. Clinicopathologic testing may show abnormalities suggestive of hypothyroidism (e.g., mild anemia, hypercholesterolemia). The diagnosis is established through thyroid function testing (see Chapter 51). The response to replacement thyroid hormone is variable.

# BILATERAL PERIPHERAL VESTIBULAR DISEASE

Most animals with bilateral peripheral vestibular disease have no discernible head tilt. Affected animals have a widebased stance and are ataxic, usually ambulating in a crouched position with a wide side-to-side swinging of the head. Their conscious proprioception (knuckling) is normal. Affected animals have a definite balance problem, and they fall or circle to either side. No spontaneous or positional nystagmus is observed; in most cases normal vestibular eye movements are also lost. Affected animals are deaf if the cochlear portion of CN8 is also involved. When the animal is held suspended by the pelvis and lowered toward the ground, an affected animal may curl its head and neck toward the sternum instead of raising its head and extending the thoracic limbs toward the floor for weight bearing. Differential diagnoses considered in animals with bilateral vestibular disease include an idiopathic or congenital syndrome, trauma, ototoxicity, inner ear infections, and hypothyroidism. The diagnostic workup is the same as that used in dogs and cats with unilateral peripheral vestibular disease.

### CENTRAL VESTIBULAR DISEASE

Central vestibular disease is much less common in dogs and cats than peripheral vestibular disease and generally carries a poor prognosis. Central vestibular disease can be caused by any inflammatory, neoplastic, vascular, or traumatic disorders affecting the brainstem (see Box 68-2). In particular, granulomatous meningoencephalitis (dogs), Rocky Mountain spotted fever (dogs), and feline infectious peritonitis (cats) seem to have a predilection for this region of the brain. Dogs and cats with cerebellar infarcts and tumors are commonly presented with paradoxical vestibular signs.

A standard workup for intracranial disease is performed in animals that have central vestibular signs. A complete physical, neurologic, and ophthalmologic examination is essential to look for evidence of disease elsewhere in the body. Clinicopathologic testing and thoracic and abdominal radiography are warranted to search for neoplastic or infectious inflammatory systemic disease. Finally, advanced diagnostic imaging, particularly using MRI, and CSF collection and analysis should be considered. (See Chapter 65 for a more thorough discussion of the diagnostic approach taken in animals with intracranial disease.)

### METRONIDAZOLE TOXICITY

Central vestibular signs have been reported in dogs after administration of metronidazole (Flagyl; Pharmacia and Searle). Signs of metronidazole toxicity are most likely to develop when the drug is administered orally at high doses (usually >60 mg/kg/day) for 3 to 14 days. Initial signs include anorexia and vomiting, with rapid progression to ataxia and vertical nystagmus. The ataxia may be very severe, making walking impossible and resulting in a "bucking" gait. Seizures and head tilt occasionally occur. Treatment consists of stopping the medication and providing supportive care. The prognosis is good for recovery, but complete recovery may take 2 weeks. The administration of diazepam (0.5 mg/kg once intravenously and then orally q8h for 3 days) has been shown to dramatically speed recovery. Metronidazole toxicity has also been reported in cats receiving lower doses of metronidazole. Forebrain and cerebellar signs predominate in this species.

### ACUTE VESTIBULAR ATTACKS

A peracute onset of loss of balance, nystagmus, and severe ataxia that lasts only minutes is occasionally seen in dogs. Head tilt may be mild or absent. Neurologic examination during an episode is usually most consistent with peripheral disease, with no postural reaction deficits or cranial nerve abnormalities, but a few dogs have had vertical nystagmus, localizing to central vestibular disease. Dogs completely recover within minutes with no residual neurologic abnormalities and no obvious postictal signs. Some affected dogs have gone on to develop brain (especially cerebellar) infarcts, which suggests that these events could be transient ischemic attacks, as reported in humans. Other affected dogs progress to have recognizable epileptic seizures, which suggests that these events could represent seizure activity in some dogs. Intracranial mass lesions have been identified in a few affected dogs. Rarely, dogs have been reported to have intermittent episodic peripheral vestibular dysfunction with early OM-OI. Dogs with a history of acute vestibular attacks should have a careful physical and neurologic examination performed as well as systemic screening tests for inflammatory or neoplastic disease, disorders of coagulation, and hypertension. An otoscopic examination should be performed. Advanced diagnostic imaging (CT, MRI) to evaluate the middle ear and the brain may be warranted.

Steroid-Responsive Meningitis-Arteritis Granulomatous Meningoencephalitis Necrotizing Meningoencephalitis Feline Polioencephalomyelitis

### INFECTIOUS INFLAMMATORY DISORDERS

Feline Immunodeficiency Virus Encephalopathy Bacterial Meningoencephalomyelitis

Canine Distemper Virus

Rabies

Feline Infectious Peritonitis

**Toxoplasmosis** 

Neosporosis

Lyme Disease

Mycotic Infections

Rickettsial Diseases

Parasitic Meningitis, Myelitis, and Encephalitis

### **GENERAL CONSIDERATIONS**

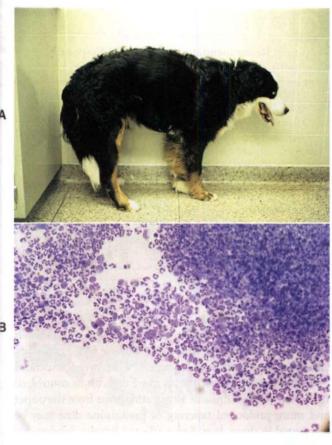

Bacterial, viral, protozoal, mycotic, rickettsial, and parasitic pathogens are all recognized as etiologic agents of inflammatory central nervous system (CNS) disease in dogs and cats. In addition, a variety of meningitis syndromes that have no identifiable etiology but are presumed to have an immunologic basis exist in dogs. These include a steroid-responsive meningitis-arteritis (SRMA) of young dogs, granulomatous meningoencephalomyelitis (GME), and necrotizing meningoencephalitis (NME).

The clinical signs of CNS inflammation vary and depend on both the anatomic location and the severity of inflammation. Individual syndromes may have characteristic constellations of clinical signs. Cervical pain and rigidity are common in dogs with meningitis of any etiology, causing a reluctance to walk, an arched spine, and resistance to passive manipulation of the head and neck (Fig. 69-1). Fever is common. Inflammation of the spinal cord (myelitis) will cause associated upper motor neuron (UMN) or lower motor neuron (LMN) deficits in the limbs, depending on the spinal cord region involved. Animals with inflammation in the brain (encephalitis) can experience vestibular dysfunction, seizures, hypermetria, or disorders of consciousness reflecting the distribution of intracranial lesions.

A thorough physical and ophthalmologic examination and search for systemic abnormalities should be performed. Dogs and cats with bacterial meningitis/meningoencephalitis usually have an infected site from which the infection has spread to the CNS. Animals with viral, protozoal, fungal, or rickettsial meningitis/meningoencephalitis may have involvement of other organs, such as the lung, liver, muscle, or eye, which may aid in diagnosis. Cerebrospinal fluid (CSF) analysis is necessary to confirm a suspected diagnosis of CNS inflammatory disease. Analysis of the cells found in the CSF, together with the clinical and neurologic findings, may aid in determining the etiology of the inflammation in an individual case (see Box 64-3). Analysis of CSF protein, CSF culture, measurement of serum and CSF antibody titers for likely infectious agents, and CSF polymerase chain reaction (PCR) analysis may also be of diagnostic value. These results, with the use of other appropriate ancillary diagnostic tests, allow diagnosis of a specific disorder and the initiation of prompt appropriate treatment (Table 69-1).

### **NECK PAIN**

Neck pain is a sign commonly associated with compressive or inflammatory diseases of the cervical spinal cord. Animals with neck pain typically have a guarded horizontal neck carriage and are unwilling to turn their neck to look to the side; they will instead pivot the entire body. As part of every routine neurologic examination, the presence or absence of cervical hyperesthesia should be assessed by deep palpation of the vertebrae and cervical spinal epaxial muscles and by resistance to flexion, hyperextension, and lateral flexion of the neck (Fig. 63-21). Anatomic structures that can cause

### FIG 69-1

(From Meric S et al: Necrotizing vasculitis of the spinal pachyleptomeningeal arteries in three Bernese Mountain Dog littermates, *J Am Anim Hosp Assoc* 22:463, 1986.)

neck pain include the meninges, nerve roots, intervertebral disks, joints, bones, and muscles. Neck pain has also been recognized as a clinical symptom of increased intracranial pressure, particularly as a result of forebrain mass lesions (Box 69-1).

# NON-INFECTIOUS INFLAMMATORY DISORDERS

# STEROID-RESPONSIVE MENINGITIS-ARTERITIS

SRMA is the most common form of meningitis diagnosed in most veterinary hospitals. An immunological cause is suspected, resulting in vasculitis/arteritis affecting the meningeal vessels throughout the entire length of the spinal cord and brainstem. This disorder has also been called *steroid-responsive suppurative meningitis*, necrotizing vasculitis, juvenile polyarteritis, pain syndrome, and aseptic meningitis. Affected dogs are usually juveniles or young adults (6 to 18

### Causes of Neck Pain in the Dog

MUSCLE: Myositis (immune, infectious), muscle injury BONE: Fracture/luxation, diskospondylitis, vertebral osteomyelitis, neoplasia

JOINT (facetal joints): Polyarthritis (immune, infectious), degenerative joint disease (osteoarthritis)

INTERVERTEBRAL DISK: Disk degeneration/prolapse

NERVE ROOT: Neoplasia, compression (by disk, tumor, fibrous tissue)

MENINGES: Neoplasia, inflammation (Immune, infectious)

BRAIN: Mass lesion (neoplasia, inflammatory)

months of age), but middle-aged and older dogs are occasionally affected. Large-breed dogs are most commonly affected. SRMA may be seen as a breed-associated syndrome in Beagles (Beagle pain syndrome), Bernese Mountain dogs, Boxers, German Shorthaired Pointers, and Nova Scotia Duck Tolling Retrievers. Clinical signs of SRMA include fever, cervical rigidity, and vertebral pain that may wax and wane early in the course of disease. Affected dogs are alert and systemically normal, with a common owner complaint being that the dog will not eat or drink unless the bowl is raised to head level. Neurologic deficits (e.g., paresis, paralysis, ataxia) are rare but can develop, particularly in chronically affected or inadequately treated dogs, as a result of concurrent myelitis, spinal cord hemorrhage, or infarction.

Laboratory changes typically include a neutrophilic leukocytosis with or without a left shift. Spinal fluid analysis shows an increased protein concentration and a neutrophilic pleocytosis (often >100 cells/µl; >75% neutrophils). Early in the course of the disease, when neck pain is intermittent, CSF may be normal or minimally inflammatory. Within 24 hours of administration of a single dose of prednisone, CSF may be normal or show a predominance of mononuclear cells; therefore CSF should always be collected for diagnosis when a dog is symptomatic before initiating therapy. High IgA concentrations are found in the CSF and serum of many dogs with SRMA, aiding diagnosis. Some dogs with SRMA have concurrent immune-mediated polyarthritis (IMPA). Bacterial cultures of the CSF and blood are negative. To date, no etiologic agent has been identified.

Treatment with corticosteroids consistently and rapidly alleviates the signs of fever and cervical pain. Dogs that are not treated early in the course of the disease occasionally develop neurologic deficits associated with spinal cord infarction and meningeal fibrosis; treatment may not resolve the resultant neurologic signs in these dogs. Corticosteroids should be administered initially at immunosuppressive dosages and then tapered to alternate-day therapy and decreasing dosages over a period of 4 to 6 months (Box 69-2). Dogs that do not respond completely to prednisone and dogs that relapse during prednisone tapering may benefit from the addition of azathioprine (Imuran; Burroughs Well-

### Treatment Recommendations for Steroid-Responsive Meningitis Arteritis

- 1. Prednisone 2 mg/kg q 12h orally for 2 days
- 2. Prednisone 2 mg/kg q 24h orally for 14 days
- 3. Assess clinical response

If clinical signs have resolved, the dose of prednisone is gradually tapered:

- 1 mg/kg q24h for 4 weeks
- 1 mg/kg q48h for 4 weeks
- 0.5 mg/kg q48h for 8 weeks

If clinical signs are present or if they recur during tapering, return to step 2 and add azathioprine (2 mg/kg/day) to treatment for 8 to 16 weeks. Continue prednisone, tapering after signs resolve.

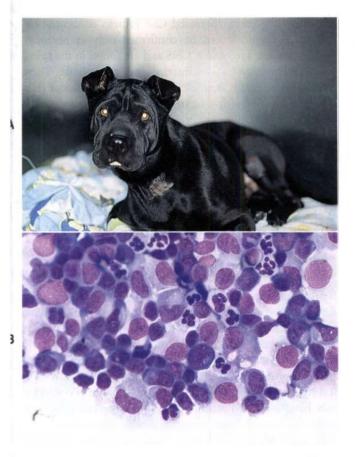

come; 2.2 mg/kg/PO q24h) to their treatment for 8 to 16 weeks. The prognosis for survival and complete resolution is excellent. Older dogs and Beagles, Bernese Mountain dogs, and German Shorthaired Pointers with breed-associated SRMA may have disease that is more difficult to control, so treatment with prednisone and azathioprine from the outset and more prolonged tapering of prednisone dose may be warranted in those dogs. Some affected Beagles develop systemic manifestations of vasculitis, thyroiditis, and amyloidosis of the spleen, liver, or kidneys.

# GRANULOMATOUS MENINGOENCEPHALITIS

GME is an idiopathic inflammatory disorder of the CNS that is believed to have an immunologic basis. GME occurs primarily in young adult dogs of small breeds, with Poodles, toy breeds, and Terriers most commonly affected. Large-breed dogs are occasionally affected. Most dogs with GME are 2 to 6 years of age, although the disease may affect older or younger dogs. Cats are not affected.

There are three distinct forms of GME. The ocular form is the least common and results in optic neuritis with an acute onset of blindness and dilated nonresponsive pupils (see Chapter 66). The focal form induces clinical signs suggestive of a single enlarging space-occupying mass with slowly progressive neurologic signs similar to a tumor. This form is most likely to affect the pontomedullary region, the forebrain, or the cervical spinal cord. The diffuse form of GME causes rapidly progressive signs of multifocal or disseminated disease affecting the brainstem, cerebrum, cerebellum, cervical spinal cord, or meninges.

Clinical signs reflect the location and nature of the lesion. Prominent features may include cervical pain, suggesting meningeal involvement, or brainstem signs such as nystagmus, head tilt, blindness, or facial and trigeminal paralysis. Ataxia, seizures, circling, and behavior change are also common. Many dogs with the diffuse form of GME have a fever and peripheral neutrophilia but no other evidence of

### FIG 69-2

**A**, A young Chinese Shar-Pei with incoordination, depression, vertical nystagmus, and a slight head tilt resulting from disseminated granulomatous meningoencephalomyelitis. **B**, Cerebrospinal fluid from this dog has increased cellularity—primarily lymphocytes, monocytes, plasma cells, and neutrophils.

systemic disease. The disseminated form of the disease has an acute to subacute progression over weeks to months, with 25% of the cases dead within 1 week. The focal form is more insidious, with progression over 3 to 6 months.

CSF analysis reveals an increase in protein concentration and a mild to marked mononuclear pleocytosis. Lymphocytes, monocytes, and occasional plasma cells predominate (Fig. 69-2). Anaplastic mononuclear cells with abundant lacy cytoplasm are sometimes present. Neutrophils are seen in two thirds of the samples, usually making up less than 20% of the cells. A single sample of CSF is sometimes normal. CSF electrophoresis typically shows evidence of blood-brain barrier disruption, and chronically affected dogs have dramatically increased intrathecal production of gamma globulins. Evaluation for infectious causes of meningoencephalomyelitis through culture and appropriate serum and CSF titers and a systemic search for neoplasia should precede a presumptive diagnosis of GME. Computed tomography (CT) or magnetic resonance imaging (MRI) usually shows a solitary contrast-enhancing mass in the brain or spinal cord with focal disease and may be normal or demonstrate patchy

### BOX 69-3

# Chemotherapy Options for Presumed Granulomatous Meningoencephalitis

### **Prednisone**

1 mg/kg PO q12h for 2 weeks, then 1 mg/kg PO q 24h for 4 weeks, then 1 mg/kg q 48h forever

### Cytosine arabinoside (Cytosar; Upjohn Pharma)

50 mg/m² body surface area SC q12h on 2 consecutive days every 21 days

### Procarbazine (Matulane, Sigma-Tau Pharmaceuticals)

25-50 mg/m² body surface area PO q 24h for 30 days, then q48h

### Cyclosporine (Neoral; Novartis)

6 mg/kg PO q12h (trough target 200-400 ng/ml)

### Leflunomide (Arava; Aventis Pharma)

4 mg/kg PO q24h, (trough target 20 µg/ml): maintenance dose of 0.5 mg/kg/day

PO, By mouth; SC, subcutaneous.

ill-defined regions of contrast enhancement with diffuse disease. Definitive diagnosis requires biopsy or necropsy for histologic examination.

Corticosteroids can occasionally halt or reverse the progression of clinical signs, particularly in animals with slowly progressive clinical signs associated with focal disease. The administration of prednisone (1 to 2 mg/kg/PO q24h) may cause a dramatic response, but clinical signs often recur quickly, with the median survival time highly variable depending on type and location of disease, ranging from longer than 12 months in dogs with focal forebrain GME to 8 days in dogs with diffuse GME. Improvement in clinical signs and survival can sometimes be seen when more aggressive chemotherapy protocols are used. Recommended drugs and protocols are outlined in Box 69-3. Radiation therapy may also greatly benefit some dogs with focal intracranial masses resulting from GME. With any protocol the best results are seen in patients with focal disease and those that receive treatment before neurologic signs are severe. Comparative efficacy between protocols is difficult to assess because of disease and patient variability and the failure to obtain a definitive pretreatment diagnosis in most patients. Most affected animals improve with treatment, but the prognosis for permanent recovery is poor.

### **NECROTIZING MENINGOENCEPHALITIS**

NME is a breed-specific idiopathic inflammatory condition affecting the brain of Pugs (pug encephalitis), Malteses, and Yorkshire Terriers (necrotizing leukoencephalitis). No infectious agent has been detected, and a genetic predisposition is likely. Necrosis and nonsuppurative necrotizing meningoencephalitis (NMG) and leptomeningitis occur, affecting

primarily the cerebral cortex in Pugs and Malteses and the cerebral cortex and brainstem in Yorkshire Terriers. Affected dogs first show clinical signs between 9 months and 7 years of age.

Dogs with rapidly progressive cerebral cortical disease caused by NME are presented with seizures and neurologic signs referable to the cerebrum and meninges. They may have difficulty walking or may be weak or lack coordination. Circling, head pressing, cortical blindness, and neck pain are common. Affected Yorkshire Terriers may have a head tilt and cranial nerve abnormalities. Neurologic deterioration is rapid, and within 5 to 7 days the dogs develop uncontrollable seizures or become recumbent, unable to walk, and comatose.

Dogs with a more slowly progressive form of NME are also commonly presented with a generalized or partial motor seizure, but these dogs are neurologically normal after the seizure. Seizures then recur at varying intervals from a few days to a few weeks, followed by the development of other neurologic signs referable to the cerebral cortex. Survival times are generally only a few weeks, with a maximum survival time of less than 6 months from the time of initial presentation.

A diagnosis of NME should be suspected on the basis of signalment and characteristic clinical and clinicopathologic features. Hematologic and serum biochemistry findings are unremarkable. Imaging studies are consistently abnormal, with focal hypodense areas within the brain parenchyma visible on CT and areas of high signal intensity seen on MRI. CSF analysis reveals a high protein concentration and an increased nucleated cell count, with the predominant cell type being the small lymphocyte. Definitive diagnosis requires autopsy or brain biopsy.

No specific treatment exists for this disease. Treatment with antiepileptic doses of phenobarbital may decrease the severity and frequency of the seizures for a short period of time. Corticosteroids are commonly administered (as for GME) but do not appear to alter the course of this disease. There are some anecdotal reports of improvement after the administration of mycophenolate mofetil (20 mg/kg, administered orally q12h for 30 days, then 10 mg/kg q12h for the remainder of the animal's life), but the prognosis for improvement and survival must be considered poor.

# FELINE POLIOENCEPHALOMYELITIS

A nonsuppurative encephalomyelitis with no etiologic agent identified occasionally causes progressive seizures or spinal cord signs in young adult cats. Affected cats range from 3 months to 6 years of age, with most cats being younger than 2 years old. Affected animals have a subacute to chronic progressive course of neurologic signs. Pelvic limb hyporeflexia may accompany ataxia and paresis of the pelvic limbs, and intention tremors of the head and seizures may occur. Seizures and behavior change may be the only signs observed in some cats.

Clinicopathologic findings are normal in most cats. CSF analysis reveals a mild increase in CSF mononuclear cells and

a normal or slightly increased CSF protein concentration. Definitive diagnosis can be confirmed only at necropsy. Lesions are confined to the CNS and are found in the spinal cord, cerebral cortex, brainstem, and cerebellum. These lesions include perivascular cuffing with mononuclear cells, lymphocytic meningitis, neuronophagia, and the formation of glial nodules. White matter degeneration and demyelination are also present. The prognosis is poor, although reports exist of spontaneous recovery from a clinically similar disorder in a few cats.

# INFECTIOUS INFLAMMATORY DISORDERS

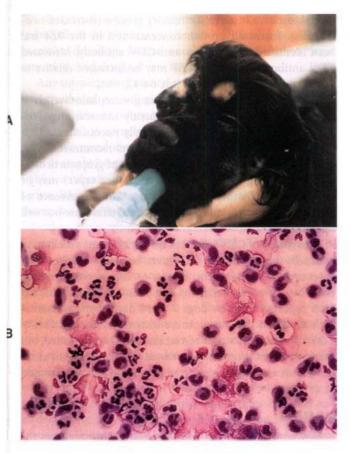

# FELINE IMMUNODEFICIENCY VIRUS ENCEPHALOPATHY

Neurologic abnormalities associated with feline immunodeficiency virus (FIV) encephalopathy in cats include behavioral and mood changes, depression, persistent staring, inappropriate elimination, seizures, twitching of the face and tongue, and occasionally paresis. A presumptive diagnosis of FIV encephalopathy is made on the basis of suggestive clinical signs and positive FIV serology, but because FIV-infected cats have increased susceptibility to numerous neoplastic and infectious causes of encephalitis, it is important to carefully exclude other neurologic diseases. CSF analysis reveals an increase in lymphocytes and normal or only slightly increased CSF protein concentration. FIV antibodies can be demonstrated in the CSF of most affected cats. Care must be taken to keep from contaminating the CSF with blood during collection because serum antibody titers are higher than those in the CSF. Culture of freshly collected CSF may yield the virus. Zidovudine (AZT: 5 mg/kg, administered orally q12h) administration may reduce the severity of neurologic impairment in some cats.

# BACTERIAL MENINGOENCEPHALOMYELITIS

Bacterial infection of the CNS is uncommon in dogs and cats. It may result from direct extension of infection from an extraneural site such as the middle ear, eye, sinus, or nose or because of a penetrating injury to the skull. Hematogenous dissemination from extracranial foci occurs rarely, except in neonates with omphalophlebitis and dogs and cats with severe immunodeficiency. In contrast to people, bacterial meningitis and meningoencephalomyelitis in dogs and cats is not caused by microorganisms having a specific predilection for the nervous system. Bacterial infections of the CNS are instead associated with the wide variety of organisms infecting primary sites.

Clinical signs of bacterial infection of the CNS commonly include pyrexia, neck pain, vomiting, and bradycardia. Neurologic abnormalities reflect the location of damaged parenchyma and may include seizures, coma, blindness, nystagmus, head tilt, paresis, or paralysis. The clinical course is usually rapidly progressive and frequently fatal. Affected animals are

A, A 4-year-old Cocker Spaniel with a chronic retrobulbar abscess developed fever and severe depression.

B, Cerebrospinal fluid from this dog reveals septic inflammation. Postmortem examination confirmed communication between the retrobulbar abscess and the central nervous system.

almost always systemically ill. Shock, hypotension, and disseminated intravascular coagulation are common. Routine laboratory tests often reflect the underlying inflamatory process.

CSF analysis reveals increased protein concentration and a predominantly neutrophilic pleocytosis, with cell counts often >500 cells/ul. Neutrophils in the CSF may appear degenerate, and occasionally intracellular bacteria are seen (Fig. 69-3). Treatment with antibiotics before CSF is collected may lower the CSF cell count and result in a predominance of mononuclear cells. The rate of organism recovery is improved by inoculation of CSF into broth enrichment media, but fewer than 50% will have positive CSF cultures. Whenever bacterial meningitis is suspected, diagnostic evaluation should include CSF cytologic analysis; CSF anaerobic and aerobic bacterial culture; blood and urine bacterial cultures; ophthalmologic and otic examination; screening radiographs of the spine, skull, and thorax; and abdominal ultrasound examination. MRI can be used to identify defects in the skull or infections or tumors extending into the cranial vault from the ear, eye, sinus, or nose. The presence of systemic bacterial illness or the identification of an extraneural focus of infection in a dog or cat with inflammatory CSF should prompt immediate treatment for suspected bacterial infection of the CNS. If the focus of underlying infection can be determined, that site should be cultured. Therapy usually is initiated before culture results are available.

Bacterial meningitis is a life-threatening infection and requires rapid and aggressive treatment. Appropriate therapy of CNS infections is based on identification of the causative organism and selection of an appropriate antimicrobial agent that will reach high concentrations in the CSF and CNS tissues. Enrofloxacin and third-generation cephalosporins (e.g., ceftriaxone, cefotaxime) are good choices for gram-negative infections, and metronidazole can be used for anaerobic infections. While inflammation persists, ampicillin and amoxicillin with clavulonic acid are also effective and may be the best choice for gram-positive infections. Initial treatment with a combination of ampicillin (22 mg/kg, administered intravenously q6h), cefotoxime (20-40 mg/kg, administered intravenously q6h), and metronidazole (15 mg/ kg administered once intravenously, then 7.5 mg/kg intravenously q8h or 10-15 mg/kg orally q8h) may be warranted if the infectious agent is unknown. Whenever possible, antibiotics should be administered intravenously for 3 to 5 days to achieve high CSF concentrations, and oral therapy should be continued for 4 weeks after recovery. Concurrent intravenous fluids and systemic support are important, and anticonvulsants should be administered to patients having seizures (see the discussion of status epilepticus in Chapter 67). Antiinflammatory drugs or corticosteroids (dexamethasone, 0.2 mg/kg IV q12h) are sometimes administered for the first 2 days of antibiotic treatment to minimize the inflammatory consequences of antibiotic-induced bacterial lysis.

The response to antibiotic therapy is variable, and relapses are common. The prognosis should be considered guarded because even with appropriate therapy many animals die. However, treatment should be attempted because some individual patients respond dramatically to therapy and have complete resolution of their neurologic defects.

#### **CANINE DISTEMPER VIRUS**

Canine distemper virus (CDV) is a paramyxovirus that commonly affects the CNS of dogs. Widespread vaccination has substantially decreased the incidence of clinically apparent CDV infections in many regions, but outbreaks still occur among unvaccinated dogs and sporadically in vaccinated dogs. Clinical signs vary, depending on virulence of the virus strain, environmental conditions, and host age and immune status. Most CDV infections are probably subclinical or are associated with mild signs of upper respiratory tract infection that resolve without therapy. Young, immunocompromised, and unvaccinated dogs are most likely to develop severe generalized distemper.

Progressive generalized infection with CDV most commonly affects unvaccinated puppies between 12 and 16 weeks of age. The first sign of infection is a mild serous to

mucopurulent ocular and nasal discharge followed by a dry cough and sometimes tonsillitis. The cough becomes moist and productive as pneumonia develops. Affected dogs are depressed, inappetent, and often febrile. Diarrhea develops and may be mild or severe. Hyperkeratosis of the footpads and nose may occur. Neurologic signs begin 1 to 3 weeks after dogs start to recover from systemic illness and may include dementia, disorientation, seizures, cerebellar or vestibular signs, tetraparesis, and ataxia. Neck pain is uncommon. Seizures can be of any type, depending on the region of the brain affected, but "chewing gum" seizures caused by polioencephalomalacia of the temporal lobes are commonly described. Myoclonus, a repetitive rhythmic contraction of a group of muscles resulting in repetitive flexion of a limb or contractions of the muscles of mastication, is often referred to as distemper chorea and is very common in dogs with distemper encephalomyelitis. Anterior uveitis, optic neuritis, or chorioretinitis occurs in some infected dogs. Dogs surviving mild CDV infection before eruption of their permanent teeth will often have irregular dental surfaces and brown discoloration of their teeth subsequent to virusinduced enamel hypoplasia. Older animals occasionally develop chronic encephalomyelitis months to years after prior CDV infection and recovery (old dog encephalitis), with neurologic abnormalities that include progressive tetraparesis or vestibular dysfunction in the absence of systemic signs.

CDV is diagnosed on the basis of history, physical examination, and laboratory findings. In many animals a history of mild to severe gastrointestinal and respiratory illness precedes the onset of neurologic signs. Results of a CBC may be normal or may reveal a persistent lymphopenia; distemper inclusions can sometimes be found in the circulating lymphocytes and erythrocytes. Optic neuritis, chorioretinitis, and retinal detachment may be detected during an ophthalmologic examination. Irregular, ill-defined, gray-to-pink densities in the tapetal or nontapetal region suggest acute or active choriorctinitis, whereas well-defined hyperreflective regions are more indicative of chronic infection with scarring.

Early in an infection, immunofluorescent techniques, using anti-CDV antibodies, may reveal CDV in cytologic smears prepared from conjunctival, tonsilar, or nasal epithelium. Virus may be detected past these initial stages in epithelial cells and macrophages obtained from the lower respiratory tract by tracheal wash. The virus persists for up to 60 days in the skin, footpads, and CNS; thus immunohistochemical techniques can be applied to biopsy or necropsy specimens for diagnosis. Biopsy of the haired skin of the dorsal neck can be used for antemortem immunohistochemical testing to confirm acute and subacute infection with CDV. Reverse-transcriptase polymerase chain reaction (RT-PCR) can also be used to detect CDV RNA in whole blood, buffy coat preparations, CSF, and tissues of affected dogs.

Distemper meningoencephalitis characteristically causes an increase in protein concentration and a mild lymphocytic pleocytosis in the CSF; occasionally, the CSF is normal or more indicative of an inflammatory process (increased neutrophils). Increased protein concentration in the CSF has been identified primarily as anti-CDV antibody. Measured CDV antibody titer in the CSF may be increased relative to the serum titer (C-value, see Box 64-4).

Treatment of acute CDV meningoencephalomyelitis is supportive, nonspecific, and frequently unrewarding. Progressive neurologic dysfunction usually necessitates euthanasia. Anticonvulsant therapy has been recommended to control seizures. Antiinflammatory doses of glucocorticosteroids (0.5 mg/kg q12h PO for 10 days, then taper) may be used to control other neurologic signs in the absence of systemic disease; however, their beneficial effects are not well documented.

Prevention of CDV infection through routine vaccination is usually very effective. CDV can, however, develop with exposure following stress, illness, or immunosuppression, even in a currently vaccinated dog. Meningoencephalitis has been reported in a few dogs 7 to 14 days after vaccination with modified live virus-canine distemper vaccines (MLV-CDV). Particular batches of vaccines may be implicated, but vaccination of immunosuppressed neonates, particularly those with a known or suspected parvoviral infection, should be avoided.

#### RABIES

Rabies virus infection in dogs and cats is almost always the result of a bite from an infected animal that has rabies virus in its saliva. Most dogs and cats are infected through contact with wildlife vectors (e.g., skunks, raccoons, foxes, bats). Although the prevalence of wildlife rabies has been increasing, cases of rabies in pet dogs and cats have been decreasing as a result of routine vaccination protocols. The incubation period from the time of the bite to the onset of clinical signs is extremely variable (1 week to 8 months), with average incubation 3 to 8 weeks. Once neurologic signs develop, the disease is rapidly progressive, with death occurring within 7 days in most animals.

Rabies can have a wide range of clinical signs, which makes it difficult to differentiate from other acute, progressive encephalomyelitis syndromes. Because of its public health significance, rabies should be on the list of differential diagnoses considered in every animal with rapidly progressing neurologic dysfunction and precautions should be taken to minimize human exposure. Rabies infection has classically been divided into two major types: furious and paralytic. Dogs and cats typically undergo an early prodromal phase lasting 2 to 3 days during which they may be apprehensive or nervous and may lick or chew at the site of inoculation. This can be followed by a furious or psychotic phase (1 to 7 days) in which animals are increasingly irritable and excitable, often snapping at imaginary objects and biting at their cage or surroundings. They become incoordinated and may exhibit generalized seizures, progressing to death. Animals with the paralytic or dumb type of rabies develop generalized LMN paralysis progressing from the site of inoculation to involve the entire CNS within a few (range 1 to 10) days. Cranial nerve paralysis may be the first sign seen (especially if the bite was on the face). Difficulty swallowing, excessive drooling, hoarse vocalization, diminished facial sensation, and dropped jaw may be seen.

Any unvaccinated animal with an acute, rapidly progressive course of neurologic disease should be suspected of having rabies. Ancillary testing should be performed with caution, minimizing exposure of personnel. CSF analysis reveals increased mononuclear cells and protein concentration, as might be expected with any viral encephalomyelitis. Rabies antibody may be increased in CSF compared with serum. Biopsies obtained from the dorsal skin at the nape of the neck or the maxillary sensory vibrissae may be positive for rabies virus antigen; however, although positive results are reliable, negative results are not. Definitive diagnosis of rabies encephalitis is through the demonstration of rabies virus antigen by immunohistochemical techniques in the brain tissue (thalamus, pons, and medulla) of an infected animal postmortem. Because of the risk associated with inadvertent human exposure, it is recommended that all unvaccinated animals with progressive neurologic dysfunction of unknown origin undergo postmortem evaluation for rabies.

Fortunately, vaccinations have been extremely effective in reducing the prevalence of rabies in pet dogs and cats and in decreasing the incidence of rabies infection in humans. Inactivated products and recombinant vaccines are available and are relatively safe and effective when used as directed. Dogs and cats should receive their first rabies vaccine after 12 weeks of age and then again at 1 year of age. Subsequent boosters are administered every 1 to 3 years, depending on the vaccine used and local public health regulations. Rarely, soft tissue sarcomas have developed in cats at the site of rabies virus prophylactic inoculation. Postvaccinal polyradiculoneuritis causing an ascending LMN tetraparesis has also been reported occasionally in dogs and

#### **FELINE INFECTIOUS PERITONITIS**

Progressive neurologic involvement is common in cats affected with the dry form of feline infectious peritonitis (FIP). Neurologic signs may include seizures, cerebellar signs, vestibular dysfunction, and paresis. Most affected cats have a fever and systemic signs such as anorexia and weight loss. Concurrent anterior uveitis, iritis, keratic precipitates, and chorioretinitis are common and should raise the suspicion of this disease. Careful abdominal palpation will occasionally reveal organ distortion caused by concurrent granulomas in the abdominal viscera.

Typically, the complete blood count is inflammatory and serum globulin concentrations may be very high. Serum tests for anticoronavirus antibodies are variable. MRI and CT may reveal multifocal granulomatous lesions and secondary hydrocephalus or may be normal. Typical findings on CSF analysis include a marked neutrophilic or pyogranulomatous pleocytosis (>100 cells/µl; >70% neutrophils) and an increase in CSF protein concentration (>200 mg/dl). In a few

cases, however, CSF will be normal or only slightly inflammatory. Coronavirus antibody will usually be positive in the CSF, and coronavirus can sometimes be detected in the CSF and affected tissue using RT-PCR. The prognosis for cats with CNS FIP is very poor. Some palliation may be achieved with immunosuppressive and antiinflammatory medications (see Chapter 97 for more information on FIP).

#### **TOXOPLASMOSIS**

Toxoplasma gondii infections can be acquired transplacentally, through ingestion of tissues containing encysted organisms, or through ingestion of food or water contaminated by cat feces containing oocysts. Most infections are asymptomatic. Transplacentally infected kittens may develop acute fulminating signs of liver, lung, CNS, and ocular involvement. Disease in older animals results from reactivation of a chronic encysted infection. Infection is evident in the lung, CNS, muscle, liver, pancreas, heart, and eye in cats. In dogs lung, CNS, and muscle infections predominate.

CNS toxoplasmosis can cause a variety of signs, including behavioral change, seizures, circling, tremors, ataxia, paresis, and paralysis. Muscle pain and weakness caused by *Toxoplasma* myositis is discussed in Chapter 72.

Routine labwork may be normal in dogs and cats with CNS toxoplasmosis, or a neutrophilic leukocytosis and eosinophilia may be seen. Serum globulins may be increased. Liver enzymes are increased when there is hepatic infection, and creatine kinase (CK) is increased in animals with myositis. Cats commonly have concurrent uveitis or chorioretinitis. CSF analysis typically reveals increased protein concentration and a mild to moderately increased nucleated cell count. Lymphocytes and monocytes usually predominate, but occasionally the pleocytosis is neutrophilic or eosinophilic. The CSF concentration of antibody directed against T. gondii may be increased relative to serum concentration, suggesting local production of specific antibody and an active infection. Rarely, cytologic examination of the CSF reveals T. gondii organisms within host cells, allowing a definitive diagnosis of toxoplasmosis.

Antemortem diagnosis of CNS toxoplasmosis may be difficult. If other organ systems are involved, finding organisms in samples from affected extraneural tissues allows definitive diagnosis. A fourfold rise in IgG titer in two serum samples taken 3 weeks apart or a single elevated IgM titer in a patient with neurologic signs supports a diagnosis of toxoplasmosis, but antibody titers are negative in some animals with severe disease (see Chapter 99). CSF titers should be interpreted in conjunction with evidence for blood-brain barrier disruption, calculating the antibody coefficient or c-value (see Box 64-4). PCR can sometimes be used to identify *Toxoplasma* in blood, aqueous humor, CSF, muscle, or nervous system tissue from affected dogs and cats.

Recommended treatment for meningoencephalomyelitis caused by toxoplasmosis in dogs and cats consists of clindamycin hydrochloride (10 mg/kg PO q8h for at least 4 weeks). This drug has been shown to cross the blood-brain barrier and has been used with success in a limited number of

animals. Trimethoprim-sulfadiazine (15 mg/kg, administered orally q12h) can be used as an alternate anti-Toxoplasma drug, especially in combination with pyrimethamine (1 mg/ kg/day), but if this is used for long-term treatment, folic acid supplementation should be considered. The prognosis for recovery is grave in animals with profound neurologic dysfunction. Affected cats should be routinely tested for concurrent feline leukemia virus (FeLV) and FIV infections. Neurologic, ocular, and muscular manifestations of toxoplasmosis are not usually associated with patent infection and oocyte shedding in cats, so isolation of affected animals is not necessary.

#### **NEOSPOROSIS**

Neospora caninum is a protozoan parasite that causes neuromuscular disease in dogs. Domestic dogs and coyotes are definitive hosts, shedding oocysts in their stool after ingestion of N. caninum cysts in muscle from intermediate hosts (primarily deer and cattle). The predominant route of transmission is transplacental, causing acute symptomatic infection in some puppies and subclinical infection leading to encystment in neural and muscle tissues in others. Young puppies 6 weeks to 6 months of age typically develop weakness, loss of patellar reflexes, and finally LMN paralysis of the rear limbs as a result of inflammation of the muscles and nerve roots (Fig. 69-4). Multiple puppies from a litter may be affected. If treatment is not initiated promptly, severe atrophy and contracture of affected muscles fixes the rear limbs in rigid extension (Fig. 69-5). Most affected puppies are bright and alert and otherwise normal. Disease in older animals usually results from reactivation of a chronic encysted infection acquired congenitally or through ingestion of tissue cysts. These dogs commonly have signs of multifocal CNS involvement. Paraparesis, tetraparesis, cerebellar signs, seizures, and cranial nerve abnormalities are reported. Some dogs have concurrent myositis. Rarely, a rapidly progressive diffuse LMN paralysis similar to acute

A 10-week-old Irish Wolfhound puppy with a crouched rear limb stance, quadriceps muscle weakness, and atrophy and patellar areflexia caused by Neospora caninum myositis and lumbar radiculoneuritis. This dog recovered after clindamycin treatment.

idiopathic polyradiculoneuritis has been reported. Most affected dogs are systemically normal, but occasionally systemic neosporosis will occur, causing fever, pneumonia, hepatitis, pancreatitis, esophagitis, or pyogranulomatous dermatitis.

Hematologic and biochemical findings vary and depend on the organ systems involved. With muscle disease, serum CK and aspartate aminotransferase (AST) activities are increased. Serology can be used to support the diagnosis, but there is no correlation between serum titer and severity of clinical signs. Puppies may have maternally derived antibodies without being infected; however, these should be gone by day 32 of life. CSF may be normal or may have mild increases in protein concentration (20 to 150 mg/dl) and leukocyte count (10 to 100 cells/ 1), with monocytes and lymphocytes predominating; some neutrophils and eosinophils may be present. Specific antibodies may occasionally be detected in the CSF. Immunocytochemical staining can be used to identify Neospora and differentiate it from Toxoplasma in muscle biopsies antemortem and in muscle and CNS tissues postmortem. Treatment with clindamycin hydrochloride (10 mg/ kg PO q8h for at least 4 weeks) is most effective in dogs without severe neurologic signs. Multifocal signs, rapid progression of signs, pelvic limb rigid hyperextension, and delayed treatment are all associated with a poor prognosis for recovery.

#### LYME DISEASE

Lyme neuroborreliosis, resulting from infection of the CNS by the spirochete Borrelia burgdorferi, has been well documented in people, but there are few reports of dogs with neurologic signs convincingly caused by Lyme disease. Most affected dogs have concurrent polyarthritis, lymphadenopathy, and fever. Reported signs of neurologic system involvement include aggression, other behavior changes, and seizures. CSF may be normal or only slightly inflammatory, and there may be an increase in anti-B. burgdorferi antibody in the CSF compared with serum. Although it is rare, Lyme

FIG 69-5 A young Labrador Retriever with rigid extension of the rear limbs caused by pediatric neosporosis.

neuroborreliosis should be considered in the differential diagnosis of disease involving the CNS in dogs from endemic regions. Early antibiotic treatment may be effective, but it is important to select an effective antibiotic that is capable of reaching high concentrations in the CSF. Ceftriaxone (25 mg/ kg, administered intravenously or subcutaneously q24h for 14-30 days), doxycycline (10 mg/kg, administered orally q12h for 30 days), and amoxicillin (20 mg/kg, administered orally 98h for 30 days) have all been recommended.

## MYCOTIC INFECTIONS

Disseminated systemic mycotic infections may occasionally involve the CNS and eyes. Clinical signs depend on the fungus involved and include gastrointestinal, respiratory, or skeletal problems in conjunction with neurologic and ocular signs. The most common neurologic signs are depressed mentation, behavior change, seizures, circling, and paresis. Ocular examination may reveal uveitis, chorioretinitis, retinal detachment, or optic neuritis. Typical abnormalities on CSF analysis include a neutrophilic pleocytosis and increased protein content. Diagnosis is usually by finding the organism in extraneural infected tissues. Therapy may be attempted; however, the prognosis is poor when the nervous system is involved.

It is uncommon for systemic mycoses to present with only neurologic signs. The exception is infection caused by the encapsulated yeasts Cryptococcus neoformans and Cryptococcus gatti. These organisms have a predilection for the CNS in the dog and cat. Infection occurs via extension from the nose through the cribiform plate and via hematogenous dissemination of severe disease in the dog or cat.

In cases of cryptococcal meningoencephalitis, CSF analysis reveals increased protein concentration and cell counts. A neutrophilic pleocytosis is most common, but eosinophils have been reported. Organisms can be visualized in the CSF in approximately 60% of cases. Fungal culture of the CSF should be considered in dogs with inflammatory CSF in which no organisms are visible. Detection of capsular antigen in the CSF or serum of affected animals using a latex agglutination test may also be a useful aid to diagnosis. Cytologic examination of nasal exudate, draining tracts, enlarged lymph nodes, and granulomas located extraneurally may yield the diagnosis. The organism is readily visible using Gram's stain, India ink, or Wright's stain. Treatment of CNS cryptococcus is usually attempted using amphotericin B or fluconazole, both of which penetrate the CNS. Itraconazole is sometimes effective (see Chapter 98 for more information).

#### RICKETTSIAL DISEASES

Rocky Mountain spotted fever (RMSF), caused by Rickettsia rickettsii, and ehrlichiosis, caused by Ehrlichia canis, commonly involve the CNS of dogs, causing meningoencephalomyelitis. Neurologic signs are seen in approximately 30% of dogs with both diseases, but the signs are most severe in dogs with RMSF. Neurologic abnormalities in dogs with RMSF tend to be more acute and progressive than those seen

with ehrlichiosis. Neurologic signs with either disease include neck pain, mental changes, ataxia, vestibular signs, stupor, and seizures. Neurologic abnormalities have not been recognized in dogs without concurrent systemic disease. Signs of systemic disease depend on the degree of involvement of other organ systems but may include fever, anorexia, depression, vomiting, oculonasal discharge, cough, dyspnea, and lymphadenopathy. Hematologic abnormalities including anemia, thrombocytopenia, leukocytosis, and hyperglobulinemia are common and should prompt consideration of tick-borne illness in dogs from endemic regions with neurologic signs. The organisms of granulocytic ehrlichiosis (Ehrlichia ewingii and Anaplasma phagocytophilia) also cause thrombocytopenia, polyarthritis, and meningitis in dogs.

Although the number of cases reported is small, neutrophils seem to predominate in the CSF of dogs with RMSF, whereas lymphocytes or neutrophils predominate in ehrlichiosis; the CSF is normal in some dogs with each disease. In some dogs with granulocytic ehrlichiosis, neutrophils in the blood or in the CSF may contain morulae. Serologic testing or PCR (blood or CSF) is essential to confirm the diagnosis of rickettsial infection and to differentiate between these diseases. Treatment with doxycycline (5 to 10 mg/kg, administered orally or intravenously q12h) is effective in most cases. Short-term treatment with corticosteroids may also be warranted. Dramatic clinical improvement should be expected within 24 to 48 hours of initiating treatment. The presence of neurologic signs may slow recovery, and in some cases the neurologic damage is irreversible (see Chapter 96 for more information on rickettsial diseases).

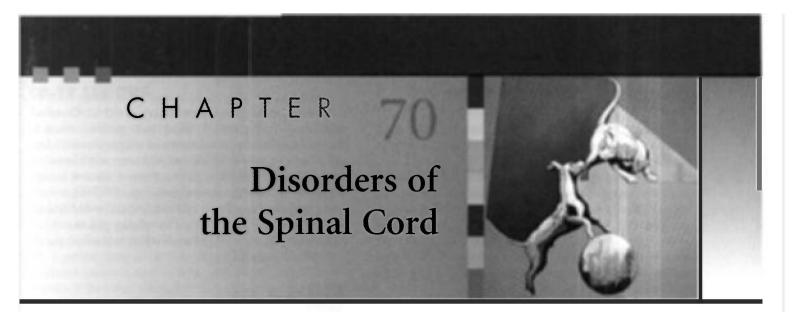

# PARASITIC MENINGITIS, MYELITIS, AND ENCEPHALITIS

Meningitis and meningoencephalitis caused by aberrant parasite migration have been reported in the dog and cat. In these diseases migration and growth of parasites can result in extensive damage to the neural parenchyma. An eosinophilic CSF pleocytosis should prompt consideration of parasitic migration through the CNS, although several more common neurologic disorders should also be considered, including intracranial neoplasia, toxoplasmosis, neosporosis, and GME. An apparently immune-mediated eosinophilic meningitis has also been described in young dogs, particularly Golden Retrievers. Diagnostic evaluation of animals with eosinophilic CSF should include a fundic examination, complete blood count, serum biochemistry profile, urinalysis, serum and CSF titers for Toxoplasma and Neospora, thoracic and abdominal radiographs, abdominal ultrasound, fecal flotation, and heartworm antigen testing. CT and MRI may document necrosis along the path of parasite migration within the CNS. Definitive diagnosis of parasitic CNS disease requires pathologic demonstration of the parasite in the CNS. Empirical treatment with ivermectin should be considered if parasite migration is likely (200 to 300 µg/kg, administered orally or subcutaneously every 2 weeks for three treatments). Antiinflammatory treatment with prednisone may also be indicated.

# **GENERAL CONSIDERATIONS**

Spinal cord disorders can be caused by anomalies, degeneration, neoplasia, inflammatory conditions, external trauma, internal trauma from disk extrusion, hemorrhage, or infarction (Box 70-1). Clinical signs depend on lesion location and severity and frequently include focal or generalized pain, paresis, paralysis, and occasionally an inability to urinate. Examination of the signalment, history, onset, and progression of the disease can provide valuable information necessary for establishing a likely cause. Congenital malformations are present at birth, do not progress, and are often breed-associated. External trauma, type 1 intervertebral disk extrusion, and vascular disorders (hemorrhage or infarction) are usually associated with acute, nonprogressive

signs. Infectious or noninfectious inflammatory disorders typically have a subacute and progressive course, whereas tumors and degenerative processes are most often slowly progressive.

# LOCALIZING SPINAL CORD LESIONS

Once a complete neurologic examination has been performed and postural reactions, proprioception, strength, muscle tone, and spinal reflexes have all been assessed, it is possible to identify the location of a spinal cord lesion. Functionally, the spinal cord can be divided into four regions: the cranial cervical spinal cord (C1-C5), the cervical intumescence (C6-T2), the thoracolumbar region (T3-L3), and the lumbar intumescence (L4-S3). Signs allowing localization of spinal cord lesion to each site and differential diagnoses considered for disease localizing to each site are listed in Table 70-1 and Box 70-2.

#### C1-C5 LESIONS

Lesions of the cranial cervical spinal cord cause upper motor neuron (UMN) paresis in all four limbs. Because the spinal cord pathways to the rear limbs are more superficial in the cord than those to the forelimbs, rear limb deficits are usually worse than forelimb deficits in patients with mild compressive C1-C5 spinal cord lesions. Central canal lesions (e.g., intramedullary neoplasia, infarcts, hydromyelia) in the C1-C5 region occasionally cause severe UMN deficits in the forelimbs with nearly normal rear limbs (central cord

syndrome) as the superficially located white matter tracts to the rear limbs are spared. Most lesions of the C1-C5 spinal cord cause a long-strided, ataxic gait; postural reaction deficits, including decreased conscious proprioception (slow knuckling); increased extensor muscle tone; and normal to increased spinal reflexes in all four limbs. Unilateral lesions of the cervical cord cause hemiparesis and UMN signs only in the ipsilateral rear limbs and forelimbs. Cervical lesions are rarely severe enough to cause loss of deep pain sensation; such a severe injury would cause complete respiratory paralysis and rapid death.

#### **C6-T2 LESIONS**

Lesions of the spinal cord between C6 and T2 result in paresis of all four limbs and ataxia that is most pronounced in the rear limbs. The spinal cord segments containing the cell bodies of the nerves of the brachial plexus are affected in this region, so lower motor neuron (LMN) signs of weakness, a short-strided "choppy" gait, muscle atrophy, and hyporeflexia predominate in the forelimbs. Disruption of ascending and descending spinal cord tracts in this region causes UMN deficits in the rear limbs, including ataxia, a long stride, loss of conscious proprioception, delayed postural reactions, increased extensor muscle tone, and normal to increased reflexes. If the lesion affects only the central cord, sparing the superficially located long tracts to the rear limbs, the forelimb LMN signs may be much more pronounced than the rear limb UMN signs. When C6-T2 lesions are unilateral, ipsilateral forelimbs and rear limbs will be affected. Horner's syndrome may be seen if the T1-T2 spinal cord segments or nerve roots are involved (see Chapter 66), and the ipsilateral cutaneous trunci reflex may be lost if the C8-T1 spinal cord segments or nerve roots are damaged. Because the phrenic nerve originates at C5 to C7, a severe lesion in this region could also cause diaphragmatic paralysis.

#### **T3-L3 LESIONS**

Lesions of the spinal cord between T3 and L3 cause UMN paresis and ataxia affecting the rear limbs (see Table 70-1), with normal forelimbs. Examination of the rear limbs reveals a long, incoordinated stride; loss of conscious proprioception; delayed postural reactions; increased extensor muscle tone; and normal to increased reflexes. As compressive lesions of the spinal cord in this region become more severe,

there is a predictable worsening of the neurologic deficits (Fig. 70-1). With severe focal lesions in this region there may be a loss of the cutaneous trunci reflex caudal to the site of the lesion.

#### **L4-S3 LESIONS**

Lesions affecting the lumbar intumescence cause LMN signs in the rear limbs. Severe weakness, muscle atrophy, and loss of reflexes are apparent in the rear limbs, and forelimbs are normal. Animals that can still walk exhibit a short-strided rear limb gait. Bladder dysfunction and paresis or paralysis of the anal sphincter and tail are common with severe lesions. Lesions that compress the lumbar, sacral, and caudal nerve roots as they extend caudally from the end of the spinal cord within the vertebral canal (the cauda equina) usually cause pain at the site and, when severe, cause LMN dysfunction as well.

## **DIAGNOSTIC APPROACH**

Lesions should be localized to a spinal cord region on the basis of the neurologic examination. It is important to recognize that spinal cord segments do not correlate directly with vertebral location in the dog and cat (Table 70-2; Fig. 70-2). The C6-T2 spinal cord segments of the cervical intumescence are located within vertebrae C4-T2. The L4-S3 spinal cord segments of the lumbar intumescence are located within vertebrae L3-L5 in dogs and L3-L6 in cats. The spinal cord is shorter than the vertebral canal, with the caudal segments ending at approximately the L6 vertebra in dogs and the L7 vertebra in cats. The nerve roots arising from the L7, sacral, and caudal spinal cord segments (the caudal equina) course caudally within the vertebral canal to their

site of exit immediately caudal to the vertebra of the same number and are susceptible to compressive damage in the lumbosacral region (see the discussion of cauda equina syndrome.

Once spinal cord lesions are localized to the proper regional spinal cord segments and vertebrae, further diagnostic testing will usually be necessary to establish an etiology. Radiographs should be taken of the vertebral bodies that house the affected spinal cord segments. Vertebral radiographs may identify vertebral malformations, subluxation caused by trauma, diskospondylitis, vertebral fractures, intervertebral disk disease, and lytic vertebral neoplasms. A

myelogram or other diagnostic imaging technique (e.g., computerized tomography [CT], magnetic resonance imaging [MRI]) may be performed to identify a compressive or expansive lesion in the spinal canal. Cerebrospinal fluid analysis can be performed to look for evidence of neoplasia or inflammation. When systemic infectious or neoplastic disorders are considered as differentials for a myelopathy, ancillary tests such as thoracic and abdominal radiographs, abdominal ultrasound, lymph node aspirates, complete ophthalmic examination, serology, and tissue biopsies may be helpful in determining the diagnosis. Rarely, surgical exploration of the spinal cord at the affected site will be required to achieve a diagnosis, gauge prognosis, and recommend treatment.

# **ACUTE SPINAL CORD DYSFUNCTION**

# TRAUMA

Traumatic injuries to the spinal canal are common, with fractures and luxations of the spine and traumatic disk extrusion being most frequent. Severe spinal cord bruising and edema can occur secondary to trauma, even without disruption of the bony spinal canal.

#### **Clinical Features**

The clinical signs associated with spinal trauma are acute and generally nonprogressive. Animals are usually in pain, and other evidence of trauma (e.g., shock, lacerations, abrasions, fractures) may be present. Neurologic findings depend on lesion location and severity. Neurologic examination should determine the location and extent of the spinal injury. Excessive manipulation or rotation of the animal should be avoided until the vertebral column is determined to be stable.

## **Diagnosis**

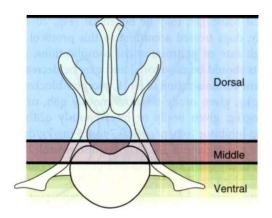

The diagnosis of trauma is readily made on the basis of the history and physical examination findings. A thorough and rapid physical examination is important to determine whether the animal has life-threatening, nonneurologic injuries that should be addressed immediately. Concurrent problems may include shock, pneumothorax, pulmonary contusions, diaphragmatic rupture, ruptured biliary system, ruptured bladder, orthopedic injuries, and head trauma. Concern that the animal may have vertebral column instability warrants the use of a stretcher or board to restrain, examine, and transport the dog or cat in lateral recumbency.

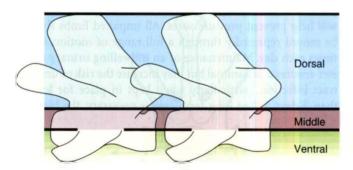

The neurologic examination can be performed with the animal in lateral recumbency but will be limited to evaluation of mental status, cranial nerves, posture, muscle tone, voluntary movement, spinal reflexes, the cutaneous trunci reflex, and pain perception. Dogs with severe thoracic spinal cord lesions may exhibit the Schiff-Sherrington posture (see Fig. 63-8). The most important prognostic indicator after spinal trauma is the presence or absence of nociception or deep pain sensation. If deep pain is absent caudal to a traumatic spinal cord lesion, the prognosis for return of neurologic function is poor.

The neurologic examination allows determination of the neuroanatomic site of the lesion. Survey radiographs can then be used to more specifically localize the lesion, assess the degree of vertebral damage and displacement, and aid in prognosis. Manipulation or twisting of unstable areas of the spine must be avoided during radiography. If the animal is recumbent or restrained on a board, then lateral and crosstable ventrodorsal views allow assessment for the presence or absence of fractures or an unstable vertebral column. CT is a more accurate means to assess vertebral damage.

The *entire* spine should be assessed radiographically. Most spinal fractures and luxations occur at the junction of mobile and immobile regions of the spine, such as the lumbosacral junction or the thoracolumbar, cervicothoracic, atlantoaxial, or atlantooccipital regions. LMN lesions at an intumescence can mask a UMN lesion located more cranially in the spinal cord; therefore radiographic and clinical evaluation are important. Myelography, CT, or MRI should be used to look for radiographically inapparent lesions when radiographic lesions do not correspond with neuroanatomic localization.

Various classification schemes exist to determine the stability of vertebral injuries and the need for surgery. The vertebral body can be divided into three compartments and each assessed using radiographs or CT for damage (Fig. 70-3). When two of the three compartments are damaged or displaced, the fracture is considered unstable. Unstable

#### FIG 70-3

Illustration of the three-compartment model for radiographic evaluation of spinal fractures. The dorsal compartment includes the articular facets, laminae, pedicles, spinous processes, and supporting ligaments. The middle compartment contains the dorsal longitudinal ligament, the dorsal annulus, and the floor of the spinal canal. The ventral compartment consists of the remainder of the vertebral body and the annulus, the nucleus pulposus, and the ventral longitudinal ligament. When two or three of the compartments are damaged or displaced, surgical stabilization is indicated.

fractures require surgical intervention or splinting, whereas stable fractures without significant ongoing spinal cord compression are managed conservatively. Splints are most effective when deep pain sensation is present, when ventral and middle compartments are intact, and when associated soft tissue injuries are minimal. Most dogs with cervical or lumbosacral injury are managed nonsurgically unless the patient deteriorates neurologically or remains in a great deal of pain 72 hours after injury, which suggests nerve root entrapment. Surgery is preferred for unstable thoracic and lumbar injuries.

#### **Treatment**

Primary treatment of animals with acute spinal injury involves evaluation for and treatment of other life-threatening injuries and maintenance of patient blood pressure, perfusion, and oxygenation. There is some evidence that the immediate IV administration of methylprednisolone sodium succinate (MPSS), a highly soluble corticosteroid with neuroprotective effects exerted primarily by its actions as a free

radical scavenger, may be beneficial (Fig. 70-4). Unfortunately, dogs treated according to this protocol suffer from a high rate of gastrointestinal complications, and adverse effects should be monitored and may be decreased by concurrent administration of an  $H_2$ -receptor blocker (ranitidine 2 mg/kg, given orally or intravenously q8h, or famotidine 0.5 mg/kg, given orally or intravenously q24h), a proton pump inhibitor (omeprazole 0.7 to 1.5 mg/kg/day) or a synthetic prostaglandin E1 analog (misoprostol 2 to 5  $\mu$ g/kg, given orally q8h), and a mucosal protectant (sucralfate 0.25 to 1 g, given orally q8h; see Chapter 30).

Intensive nursing care is critically important in dogs and cats managed conservatively or surgically. Narcotic analgesics may be administered as needed (Table 70-3). Thickly padded, clean, dry cages and frequent turning of the patient will help prevent pressure sores. All impaired limbs should be moved repeatedly through a full range of motion many times each day. Maintenance of an indwelling urinary catheter ensures a dry animal but may increase the risk of urinary tract infection, particularly when kept in place for longer than 3 days. When long-term care is necessary, the bladder

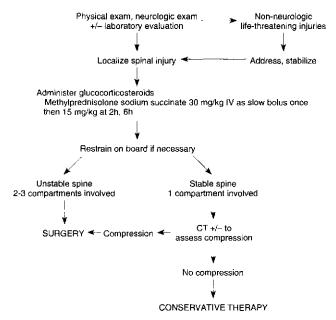

FIG 70-4

butorphanol	0.4-0.8 mg/kg SC
buprenorphine	0.02-0.06 mg/kg IM or SC

IM, Intramuscular; SC, subcutaneous.

should be gently expressed or catheterized and emptied four to six times daily and urinary tract infections treated as they occur. In animals with UMN bladders (see Chapter 63) or those with urethral spasm, medical therapy (phenoxybenzamine 1 mg/kg q8h and diazepam 1.25 to 2.5 mg/kg q8h) may help relax the urethral sphincter, making bladder expression easier and less traumatic. When an animal starts to regain voluntary motion in the limbs, physical therapy is increased; hydrotherapy or swimming stimulates voluntary movement, improves circulation to the limbs, and cleans the skin.

## **Prognosis**

Prognosis for recovery depends on the site and severity of injury. Unstable cervical vertebral fractures are associated with very high mortality at the time of trauma and also in the perioperative period. Prognosis for recovery is good if affected animals do not die acutely from respiratory dysfunction. Animals with thoracic and lumbar spinal cord injury and intact voluntary motion have a good prognosis for return of full function. Animals that are paralyzed but retain deep pain and normal bladder function have a fair prognosis for recovery, although they may have residual neurologic deficits. Animals presenting with no deep pain sensation rarely recover. Lesions of the white matter producing strictly UMN signs may have a better prognosis for full recovery than lesions affecting clinically important LMNs at the cervical or lumbar intumescence. In any animal with paralysis caused by a spinal cord injury, if no signs of improvement are evident by 21 days after injury, the prognosis for recovery is poor.

# **HEMORRHAGE/INFARCTION**

Nontraumatic hemorrhage into the spinal canal causing acute neurologic deficits and sometimes pain (i.e., hyperesthesia) has been recognized in young dogs with hemophilia A, dogs of any age with von Willebrand's disease, dogs and cats with acquired bleeding disorders (i.e., warfarin intoxication, thrombocytopenia), dogs with vascular anomalies (i.e., aneurysms, arteriovenous fistulas), and dogs and cats with primary or metastatic spinal neoplasia (i.e., lymphoma, hemangiosarcoma). Hemorrhage can be subdural or epidural. Signs occur acutely and are minimally progressive, with neurologic signs reflecting the site and severity of spinal cord damage. Antemortem diagnosis usually requires advanced diagnostic imaging (i.e., MRI), although identification of a systemic bleeding disorder or neoplasia can suggest the diagnosis. In addition to treatment to resolve the cause of bleeding, significant acute spinal cord compression caused by hemorrhage may require surgical decompression.

Spinal cord infarction by a blood clot is a rare cause of peracute neurologic dysfunction in dogs and cats. Signs are referable to the site and severity of the vascular compromise. Blood stasis, endothelial irregularity, hypercoagulability, and impaired fibrinolysis are all known predisposing factors for thromboembolism (see Chapter 12). Cardiomyopathy, hyperadrenocorticism, protein-losing nephropathy, immunemediated hemolytic anemia, heartworm disease, vasculitis,

and disseminated intravascular coagulation have all been associated with an increased risk of systemic thrombosis and can occasionally result in regional spinal cord infarction. Treatment consists of general supportive care and medications to decrease the risk of further infarction; however, antemortem definitive diagnosis is difficult.

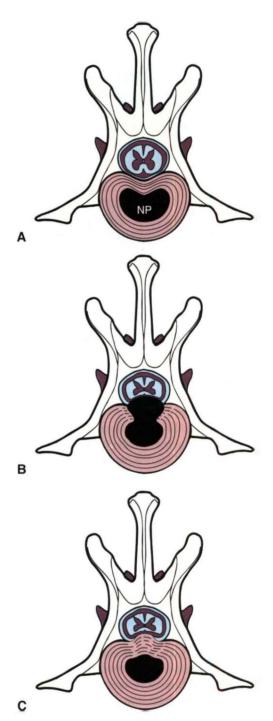

#### **ACUTE INTERVERTEBRAL DISK DISEASE**

The intervertebral disks are composed of an outer fibrous layer (the annulus fibrosus) and a gelatinous center (the nucleus pulposus). With normal aging the nucleus is gradually replaced by fibrocartilage. In some dogs, particularly the chondrodystrophoid breeds, the nucleus matrix degenerates and mineralizes, making these dogs prone to acute disk rupture. Acute extrusion of mineralized nucleus pulposus into the spinal canal through the dorsal annulus causing bruising or compression of the spinal cord is classified as a Hansen's type I disk (Fig. 70-5; for type II disk). This type of disk injury is most common in small breeds of dogs such as the Dachshund, Toy Poodle, Pekingese, Beagle, Welsh Corgi, Lhasa Apso, Shih Tzu, Chihuahua, and Cocker Spaniel, with a peak incidence between 3 and 6 years of age. Acute type I disk extrusions are also occasionally diagnosed in middle-aged large-breed dogs, particularly in Basset Hounds, Labrador Retrievers, Doberman Pinschers with caudal cervical vertebral instability, and German Shepherd Dogs. Intervertebral disk disease is a rare cause of clinically evident spinal cord compression in the cat, with predominantly acute type I disk prolapse occurring in older cats (mean age, 9.8 years) in the lower thoracic and lumbar regions (most commonly, L4/L5).

#### **Cervical Disk Disease**

#### **Clinical Features**

The predominant sign of cervical intervertebral disk disease (IVDD) is neck pain. The discomfort is often severe, and affected dogs may vocalize with the pain of movement. They may stand with their head and neck extended and may be reluctant to eat or drink from dishes placed on the floor. Some affected dogs lift one forelimb while standing to relieve the discomfort of nerve root irritation or cervical muscle spasm; this is called root signature (Fig. 70-6) and can be seen with cervical IVDD at any site. Compression of nerve roots and meninges causes neck pain. The vertebral canal in the cervical region has a very large diameter, such that even when large masses of disk material extrude into the spinal canal, significant spinal cord compression is unlikely. When significant spinal cord compression or concussion does occur, the result is usually UMN paresis or paralysis in all four legs, with rear limbs more severely affected than forelimbs. Caudal cervical disk extrusions (C6/7, C7/T1) can result in LMN forelimb weakness and scapular muscle atrophy together with UMN paresis in the rear limbs. Signs with spinal cord compression by type 1 disks are usually symmetric, although lateralized disk extrusions can result in asymmetry. The C2/3 intervertebral disk is most frequently

#### FIG 70-5

**A**, The normal relationship between the intervertebral disk and the spinal cord. *NP*, Nucleus pulposus. **B**, Hansen type I disk extrusion, wherein the NP herniated into the vertebral canal through a damaged *AF*, annulus fibrosus. **C**, Hansen type II disk protrusion, with bulging of the annulus into the vertebral canal.

involved, with the prevalence progressively decreasing from C3/4 to C7/T1. The C6/7 disk is more commonly affected in large-breed dogs as a component of cervical vertebral malformation malarticulation syndrome (also known as wobbler syndrome).

**FIG 70-6**Adult Beagle with neck and shoulder pain secondary to cervical intervertebral disk prolapse. Lifting of the limb has been referred to as *root signature*.

Cervical disk disease should be suspected on the basis of the signalment, history, physical examination, and neurologic findings. Most affected dogs show obvious signs of pain, but some stoic dogs do not exhibit discomfort during neck movement or manipulation. There should be no systemic signs of illness (e.g., fever, weight loss), and no specific neurologic abnormalities suggesting intracranial disease. Important differential diagnoses for dogs with neck pain include meningitis, diskospondylitis, vertebral neoplasia, polyarthritis, myositis, and trauma (see Box 69-1). Acute neurologic dysfunction caused by cervical disk disease must be distinguished through testing from cervical fracture/luxation, hemorrhage, or fibrocartilagenous embolism.

Spinal radiographs can be taken in an awake animal to look for evidence of disk disease and rule out other diseases (e.g., diskospondylitis, lytic vertebral tumor, fracture, atlantoaxial luxation). In animals with clinical features making surgery likely if disk extrusion is confirmed, radiographs are best obtained under general anesthesia to facilitate the optimal positioning and imaging necessary to detect subtle lesions.

Observation of calcified disk spaces confirms the presence of generalized intervertebral disk disease, but unless there is dorsal displacement of mineralized disk material into the spinal canal, this does not necessarily implicate the disk extrusion as the cause of neurologic dysfunction. Narrowing of the affected intervertebral space is commonly recognized (Fig. 70-7). Myelography or advanced diagnostic imaging (i.e., CT, MRI) are necessary to make a definitive diagnosis and determine which disk space is involved before surgical treatment. Myelography is the least expensive option, but it is also the most invasive and the least likely to provide later-

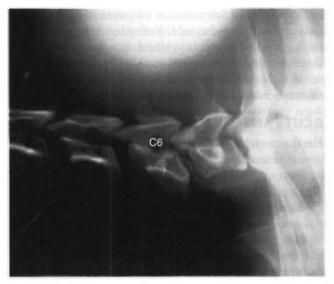

FIG 70-7
Lateral radiograph of the cervical vertebral column of an adult dog showing acute intervertebral disk prolapse at C6-C7 site. The intervertebral space is narrowed, and a calcified density can be seen in the spinal canal above the disk space.

TABLE 70-4

Classification of Dysfunction and Treatment Recommendations: Canine Cervical Disk Extrusion

GRADE	CLINICAL FINDINGS	TREATMENT
1	Single episode of pain	Cage rest
	Normal neurologic exam	+/- analgesics
2	Intractable pain or	Surgical
	Recurrent pain	Decompression
3	Neurologic deficits	Surgical
	+/- pain	Decompression

alizing information. Analysis of cerebrospinal fluid (CSF) should always precede myelography, to rule out inflammatory central nervous system (CNS) disease (see the discussion of myelography, Chapter 64). CSF changes associated with disk extrusion are usually minimal but may include very slight increases in protein concentration and cell count. CT and MRI may be used to further delineate a compressive disk lesion identified myelographically, or they may be used as the sole technique for detecting and characterizing a disk lesion, particularly in regions where myelographic interpretation can be difficult and precise anatomic localization is important (e.g., caudal cervical; Fig. 70-8).

#### **Treatment**

Treatment decisions in dogs with cervical disk disease are based on the severity of disease noted at the time of presentation (Table 70-4). Dogs with a single episode of acute neck

FIG 70-8
A 7-year-old Dachshund (A) with a 3-week history of severe neck pain and mild proprioceptive deficits in the left rear limb. Magnetic resonance imaging (MRI) revealed prolapse of the C3-C4 intervertebral disk, with significant spinal cord compression at that site (B).

pain and no neurologic deficits are usually managed conservatively with strict cage confinement and analgesics. Animals should be kept in a small kennel crate or in the owner's arms at all times except when walked outside with a harness to urinate and defecate. Nonsteroidal anti-inflammatory drugs or narcotic analgesics (see Table 70-3) can be administered for the first 3 to 5 days if strict confinement is likely to be enforced. Muscle relaxants (methocarbamol 15-20 mg/kg, administered orally q8h) will also decrease painful muscle spasms. After 3 to 4 weeks of strict crate confinement, 3 weeks of house confinement with no jumping or running and leash exercise should be recommended followed by a gradual increase in monitored exercise and (if necessary) a weight reduction program.

Most dogs with neck pain and no neurologic deficits respond initially to this conservative medical management, but a few will have intractable pain. Approximately 40% of responding dogs will experience recurrent episodes of pain in the future. Dogs with cervical pain that does not resolve

in 1 or 2 weeks, dogs with severe pain that cannot be controlled, dogs with recurrent episodes of neck pain, and dogs that develop paresis or paralysis indicating cervical spinal cord compression should be treated surgically. Even if cervical pain is the only clinical finding, most dogs with cervical intervertebral disk prolapse have a large amount of disk material within the spinal canal and these dogs will have a more complete and rapid recovery if surgery is performed. Myelography or MRI to locate the lesion and prompt surgical decompression using a ventral slot procedure are recommended. When the width of the ventral slot required to remove caudal cervical disk material is greater than 30% of the vertebral width, stabilization with a bone graft is recommended to prevent subluxation. Some surgeons recommend prophylactic fenestration of multiple cervical sites whenever a ventral slot surgery is performed to prevent further disk material prolapse and reduce the recurrence rate, but this is controversial. Most dogs are in a great deal less pain within 24 to 36 hours after decompressive surgery, and resolution of neurologic deficits occurs gradually over 2 to 4 weeks. Exercise is restricted for 2 weeks, followed by physiotherapy to enhance recovery. The prognosis for full recovery in dogs with neck pain alone or neck pain plus moderately severe tetraparesis is 80% to 90% at 4 weeks. Dogs with paralysis are more likely to have residual deficits, but approximately 80% of these dogs will become ambulatory. Rarely, vertebral subluxation occurs after ventral slot surgery, causing neck pain and worsening of neurologic deficits. Re-imaging (MRI preferred) followed by surgical distraction and stabilization is required in these dogs, which should result in a good prognosis for recovery.

# **Thoracolumbar Disk Disease**

#### **Clinical Features**

Most dogs with thoracolumbar disk disease are presented because of back pain and rear limb paresis or paralysis. The back pain in these dogs is usually less severe than that noted with cervical IVDD, but affected dogs may stand with an arched back and resent abdominal compression or palpation. The diameter of the vertebral canal is relatively small in the thoracolumbar region, so even small volumes of disk material extruded into the canal cause spinal cord compression and neurologic deficits. In addition to the compressive effect of the disk material, it is common to have impact injury to the spinal cord from explosive disk rupture. Most (>50 percent) of the disk extrusions in this region occur at the T12/13 or T13/L1 site, with 85% between T11/12 and L2/3. Disk extrusions at these sites cause UMN paresis or paralysis in the rear limbs. Only 10% to 15% of dogs will have a disk extrusion between the L3/4 and L6/7 disks, damaging the spinal cord at the lumbar intumescence and resulting in LMN signs.

The severity of the initial signs and the speed with which they progress are related not only to the volume of disk material extruded and the degree of resultant spinal cord compression but also to the force of the extrusion (see Fig. 70-1). In some dogs evidence of pain and subtle weakness resulting from partial disk rupture and mild spinal cord compression may be present for a few days or weeks before mild trauma or movement results in the extrusion of more disk material causing paralysis. The neurologic signs observed in dogs and cats with intervertebral disk disease are usually bilaterally symmetric. Affected animals usually exhibit pain on spinal palpation right over the affected disk because of meningeal and nerve root irritation at the site. When spinal cord damage is severe between T3 and L3, the cutaneous trunci reflex (see Fig. 63-17) can be used to further aid in lesion localization.

# **Diagnostic Approach**

Trauma, fibrocartilaginous embolism (FCE), and vertebral neoplasia are the major differential diagnoses considered in animals with acute thoracolumbar disk extrusions. The lesion should be localized as precisely as possible on the basis of neurologic examination findings and detection of a specific area of spinal pain. Spinal survey radiographs can be taken in an awake animal to look for evidence of disk disease and rule out other diseases. Careful positioning of the suspected disk space in the center of the beam, with the dog anesthetized, is necessary for radiographic identification of subtle lesions, but this testing is usually reserved for potential surgical candidates, when preparations have been made for further diagnostic imaging and decompressive surgery during the same anesthetic episode.

Observation of calcified disk spaces confirms the presence of generalized intervertebral disk disease, but radiographs are only between 60% and 70% accurate in identifying the location of thoracolumbar disk extrusion. Radiographic changes consistent with herniation of an intervertebral disk in the thoracolumbar region include a narrowed or wedged disk space, a small or cloudy intervertebral foramen (i.e., "horse's head"), narrowing of the facetal joints, and a calcified density within the spinal canal above the involved disk space (Figs. 70-9 and 70-10).

Myelography or advanced diagnostic imaging (i.e., CT, MRI) should be performed for definitive diagnosis before surgery. CSF is usually collected from the cerebellomedullary cistern before myelography. A cell count can be performed quickly to rule out meningitis/myelitis, and the sample can be saved for further diagnostic testing if the myelogram does not show a compressive lesion. A lumbar injection is preferred for myelography because the contrast medium must sometimes be injected under pressure to get past cord swelling in the area of the disk prolapse. CT is more accurate and faster than myelography; because it is much more reliable at determining what side the disk material is on, it is useful for surgical planning. MRI is superior to CT when extruded disk material is not mineralized and is best for spinal cord evaluation when the diagnosis of disk extrusion is uncertain (see Fig. 70-8). The increased sensitivity of CT and MRI can be problematic because clinically insignificant disk herniations not causing symptomatic spinal cord compression will also be identified.

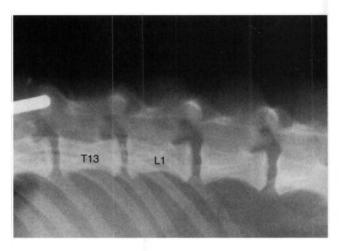

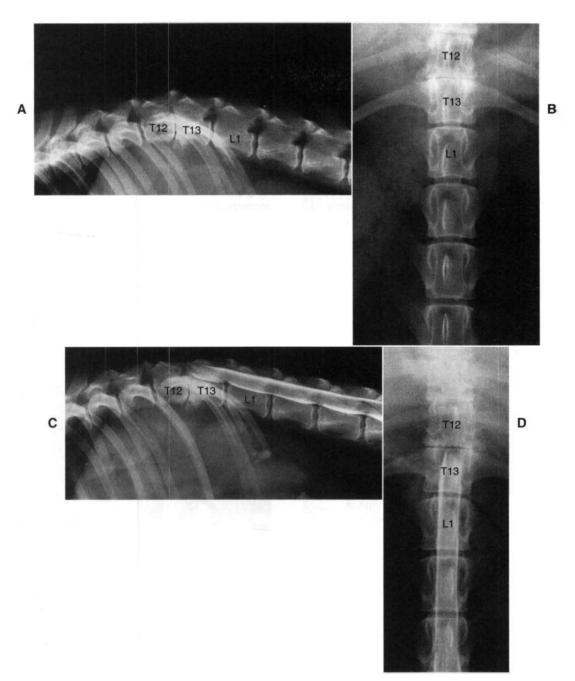

FIG 70-9

Lateral plain radiograph of vertebral column of a 4-year-old Pekingese with acute intervertebral disk prolapse. The intervertebral space between T13 and L1 is narrowed, the intervertebral foramen ("horse's head") is small, and a calcified density can be seen in the spinal canal above the T13-L1 disk space.

#### **Treatment**

Treatment of acute thoracolumbar intervertebral disk extrusion may be nonsurgical or surgical (Table 70-5). Nonsurgical treatment is usually recommended when there are minimal or inapparent neurologic deficits and the dog is still able to rise and walk unassisted. Strict cage rest is the most important aspect of nonsurgical treatment and must be maintained for a minimum of 6 weeks to allow the annulus to repair. Analgesics (see Table 70-3) and antiinflammatory drugs are often administered as for cervical IVDD. Animals being treated nonsurgically must be evaluated frequently for deterioration in neurologic status because these dogs often deteriorate within 6 to 24 hours. If neurologic symptoms do not improve within 5 to 7 days or if even minor deterioration in neurologic status is seen, then surgical therapy is indicated. Persistent or recurrent pain is also an indication for decompressive surgery.

Surgical treatment is recommended for all patients unable to walk at the time of presentation and for all dogs with signs suggesting less severe spinal cord compression (e.g., paresis, pain) if neurologic signs do not rapidly resolve with medical therapy. The rate of recovery is faster after decompression than after nonsurgical treatment, and the likelihood of residual neurologic deficits is decreased. Decompression is usually accomplished through a hemilaminectomy, and disk material is removed from the spinal canal. Preoperative imaging is essential to identify the affected interspace and to determine which side to decompress to gain access to disk material. Because clinical signs and myelography are not always reliable indicators of lateralized disk material, CT or MRI should be performed whenever possible. In addition to surgical decompression, many surgeons recommend concurrent fenestration at adjacent high-risk sites (T11 to L3) to

#### FIG 70-10

Lateral **(A)** and ventrodorsal **(B)** plain radiographs of the vertebral column of an 8-year-old Miniature Schnauzer with acute paralysis after a chronic history of intermittent back pain. Marked collapse of the intervertebral space at T12-T13, a small intervertebral foramen, and clouding of the foramen is evident. The T13-L1 space is also slightly narrowed. **C** and **D**, Myelography confirms the presence of a significant extradural mass at T12-T13, located ventrally and on the right, causing considerable cord compression and displacement. A minimal extradural mass effect exists as well at T13-L1 without significant compression. Surgery confirmed spinal cord compression by the disk material at T12-T13.

help decrease the likelihood of subsequent herniations in dogs with generalized thoracolumbar disk disease.

Postsurgically, animals must be kept clean and confined. Pressure sores should be prevented in paralyzed patients through the use of padded bedding and frequent turning. Complete bladder emptying at least four times daily by

manual expression, an indwelling catheter, or intermittent aseptic catheterization is necessary in dogs that have lost bladder function. In dogs with UMN bladders medical treatment with phenoxybenzamine and diazepam can lower sphincter pressure, facilitating manual expression and attempts by the animal to void. Massage of the limbs and

passive physiotherapy, including limb abduction, may help prevent neurogenic atrophy and muscle fibrosis in the paraplegic animal. Towel walking of paraparetic dogs can improve attitude and promote early use of the affected limbs. Once the skin incision has healed, swimming may be instituted to encourage movement. In dogs with a prolonged anticipated recovery period, use of a paraplegic cart can provide a stimulus for recovery (Fig. 70-11). Improvement in neurologic function usually occurs within 1 week of surgery. No improvement after 21 days signals that the prognosis for recovery is poor.

More than 90% of dogs with deep pain perception at the time of evaluation recover fully after effective decompression (Table 70-6). The best surgical results are obtained when decompression can be accomplished within 48 hours of the onset of neurologic signs. Dogs with very rapid progression to paralysis (grade 4 or grade 5) over less than 4 to 6 hours should be treated as a surgical emergency and decompressed

without delay. There may be some benefit to preoperative treatment of this group of patients with methylprednisolone sodium succinate, as described for spinal trauma patients if they are presented within 8 hours of the onset of paralysis. This treatment is controversial insofar as the benefits are not well established and adverse effects are common. Dogs with loss of deep pain perception (grade 5) are very unlikely to recover without surgical intervention, but with rapid decompression (within 72 hours) 60% of small-breed dogs and 25% of large-breed dogs will make a functional recovery. If deep pain does not return within 4 weeks, the prognosis for recovery is very poor.

Acute, forceful, intervertebral disk extrusions sometimes cause considerable intramedullary hemorrhage and edema. In approximately 10% of dogs presenting for a rapid onset of complete paralysis and loss of deep pain perception, focal spinal cord damage and edema result in spinal cord ischemia and progressive myelomalacia of the cord cranial and caudal

The use of a paraplegic cart can provide a stimulus for recovery and improve mobility and attitude in paralyzed dogs recovering from thoracolumbar disk surgery.

# **TABLE 70-6**

Results of Treatment for Thoracolumbar Disk Disease

NEUROLOGICAL GRADE	CONSERVATIVE % SUCCESS	CONSERVATIVE RECOVERY TIME (WEEKS)	DECOMPRESSION % SUCCESS	DECOMPRESSION RECOVERY TIME (WEEKS)
1 no deficits	>95%	3	>95%	<2
2 paresis (walking)	84%	6	95%	<2
paresis (not walking)	84%	6	93%	<2
4 paraplegia	81%	9-12	95%	1-4
5 no deep pain	<10%		64%	5-10

to the original lesion (i.e., ascending descending myelomalacia). This condition usually develops within 5 days of the original disk extrusion. This disorder should be suspected when the line demarcating the loss of the cutaneous trunci reflex moves cranially or the patellar and withdrawal reflexes are lost (LMN signs) in the rear limbs of a dog that previously had UMN paralysis in the rear limbs after disk extrusion. Most affected dogs are also very anxious and experience a great deal of pain. When ascending descending myelomalacia is recognized, euthanasia should be recommended because no chance for recovery exists and most affected dogs will die within a few days of respiratory paralysis.

#### FIBROCARTILAGINOUS EMBOLISM

Acute infarction and ischemic necrosis of the spinal cord parenchyma occur when fibrocartilage identical to that in the nucleus pulposus of the intervertebral disks is embolized into the very small arteries and veins supplying the spinal cord parenchyma and leptomeninges. This very acute, nonprogressive phenomenon can affect any region of the spinal cord and result in paresis or paralysis. The cause of this disorder is unknown. It is most common in medium-sized and large-breed dogs. It has also been described in smallbreed dogs (especially the Miniature Schnauzer) and a few cats. Most affected dogs are middle aged, with the majority of cases between 3 and 7 years of age. A few dogs younger than 1 year of age have been recognized with FCE, especially Irish Wolfhounds. No gender predilection exists.

#### **Clinical Features**

The onset of neurologic signs is very sudden, and signs may worsen for 2 to 6 hours. In approximately half of all cases, FCE occurs immediately after minor trauma or during exertion. Neurologic examination reflects a focal spinal cord lesion, and the deficits observed depend on the region of spinal cord affected and the severity of cord involvement. The thoracolumbar cord (causing UMN signs in the rear limbs) and the lumbosacral intumescence (causing LMN signs in the rear limbs) are most often affected. The cervical cord is affected less frequently, but it is the site most often affected in small-breed dogs. Neurologic dysfunction may be mild or severe. Asymmetry is common, with the right and left sides affected to different degrees. Dogs commonly cry out as though in pain at the onset of signs, and dogs evaluated within 2 to 6 hours of onset sometimes exhibit focal spinal hyperpathia (i.e., painfulness); however, this resolves quickly, and most affected dogs do not exhibit pain by the time they are brought to a veterinarian, even on manipulation of their spine. The lack of pain and the asymmetry are very helpful in differentiating FCE from other disorders that cause acute nonprogressive neurologic dysfunction, such as acute intervertebral disk extrusion and fracture/luxation.

# **Diagnosis**

FCE is suspected on the basis of the signalment, history, and recognition of acute, nonprogressive, nonpainful spinal cord dysfunction. Radiographs are normal in dogs and cats with

FIG 70-12

This adult Border Collie had an acute onset of lameness, decreased conscious proprioception, and hyporeflexia in the left rear limb while retrieving a Frisbee. The limb was not painful, and radiographs, cerebrospinal fluid (CSF) analysis, and myelogram were all normal. A presumptive diagnosis of fibrocartilaginous embolism (FCE) involving the lumbar and sacral spinal cord segments on the left side was made. This dog recovered uneventfully within a 3-week period.

FCE but assist in ruling out diskospondylitis, fractures, lytic vertebral neoplasia, and IVDD. CSF is usually normal, although an increase in protein (especially albumin) concentration may be observed in some (50%) cases. In the first 24 hours after the onset of clinical signs, a few dogs have a mild increase in neutrophil numbers within the CSF. Myelography is usually normal, although some animals exhibit focal intramedullary cord swelling. Myelography is most useful to rule out compressive lesions of the spinal cord for which surgery might be indicated, such as fractures, disk extrusion, and neoplasia.

CT is not useful in the diagnosis of FCE beyond excluding a compressive myelopathy. MRI may reveal focal cord density changes in severely affected dogs, but mild lesions will not be evident. The diagnosis of FCE be made only on the basis of clinical findings and exclusion of compressive and inflammatory acute spinal cord disorders (Fig. 70-12).

#### **Treatment**

Treatment for FCE consists of nonspecific supportive measures and nursing care, as described for paralyzed dogs. Most affected dogs are large breeds, making this type of management difficult. In animals brought to the clinician during the first 6 hours of paralysis, it may be reasonable to treat aggressively with one dose of methylprednisolone sodium succinate, as recommended for the initial treatment of acute spinal cord trauma (see Figure 70-4). Most clinical improvement takes place within the first 7 to 10 days after the onset of neurologic signs, although it may take 6 to 8 weeks for a complete return to function. If no improvement is seen within 21 days, it is unlikely that the dog or cat will improve.

## **Prognosis**

Recovery depends on the extent and location of spinal cord injury. The prognosis is best for recovery in dogs and cats with intact deep pain sensation and strictly UMN signs, including increased muscle tone and hyperactive reflexes. When the spinal cord is damaged at the brachial or lumbosacral intumescence (C6 to T2 or L4 to S3), causing LMN signs, a full recovery is less likely.

#### ATLANTOAXIAL INSTABILITY

Because many dogs with congenital atlantoaxial instability have slowly progressive waxing and waning tetraparesis, this condition will be discussed with chronic progressive spinal cord disease. Traumatic fracture of the dens leading to subluxation can occur in any dog or cat and will result in acute UMN dysfunction in all limbs.

## **NEOPLASIA**

Neoplasms usually cause neurologic signs by compressing or infiltrating the spinal cord parenchyma. Neoplastic conditions will be discussed in this chapter with chronic progressive spinal cord diseases. Occasionally, neoplasia will cause acute nonprogressive neurologic signs as a result of tumoror metastasis-associated intraparenchymal hemorrhage or lysis of vertebral bones, leading to fracture.

# PROGRESSIVE SPINAL CORD DYSFUNCTION

Damage to the spinal cord that progresses over a few days to weeks (subacute) is most often caused by inflammatory (infectious or immune) processes or some type of neoplasia. Degenerative disorders and most cancers generally cause more slowly progressive spinal cord dysfunction. In all patients with progressive spinal cord dysfunction complete patient evaluation, including systemic evaluation for extraneural disease, should be recommended. The lesion should be localized and ancillary tests performed to reach a diagnosis and determine appropriate treatment.

# **SUBACUTE PROGRESSIVE DISORDERS**Infectious Inflammatory Disease

Most of the infectious inflammatory diseases discussed in Chapter 69 can result in myelitis (i.e., spinal cord inflammation), leading to progressive neurologic signs suggesting multifocal or focal spinal cord damage. CSF analysis is necessary to confirm that inflammatory disease is present. Additional diagnostic tests may be necessary to identify an etiology (see Chapter 69).

# **Noninfectious Inflammatory Disease**

Noninfectious inflammatory diseases, specifically granulomatous meningoencephalitis (GME), steroid-responsive meningitis arteritis (SRMA), and feline polioencephalomyelitis, can affect the spinal cord. Cervical pain is a constant feature of SRMA, but neurologic deficits suggesting spinal cord parenchyma damage with this disorder are rare. Neurologic deficits are common, however, with focal or disseminated GME affecting the spinal cord. CSF analysis is necessary to confirm inflammatory myelitis, and additional tests are required to rule out infectious etiologies. See Chapter 69 for more information on these syndromes.

# **Diskospondylitis**

Diskospondylitis is an infection of the intervertebral disks and adjacent vertebral endplates by bacterial or fungal organisms. Hematogenous spread of infection from infected foci in the body, extension from an infected local site, and migration of inhaled plant material (grass awns) have all been implicated. Numerous causative organisms have been isolated, with the most common being *Staphylococcus intermedius*, *Streptococcus* spp., and *Escherichia coli*. *Brucella canis* is less common but should be tested for because of human health implications. The fungal organisms *Aspergillus terreus* (in German Shepherd Dogs) and *Paecilomyces varioti* have been isolated from diskospondylitis lesions in a few dogs. *Actinomyces* spp. are commonly implicated in L2-L4 diskospondylitis caused by migration of inhaled grass awns.

Diskospondylitis occurs most often in young and middleaged medium- to large-breed dogs. German Shepherd Dogs and Labrador Retrievers may have an increased prevalence of this disorder. Diskospondylitis is very rarely diagnosed in cats. Males are affected more often than females in both species.

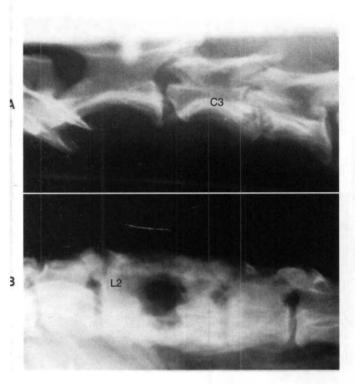

# **Clinical Features**

Spinal pain is the most common initial clinical sign of diskospondylitis. Palpation of the affected region of the spine usually allows lesion localization. Systemic signs such as fever, anorexia, depression, and weight loss occur in 30% of affected dogs, but hematologic inflammatory changes are rarely observed unless there is concurrent endocarditis or some other systemic infection. Secondary (i.e., reactive) polyarthritis may occur (see Chapter 74), resulting in a generally stiff, stilted gait in some dogs.

Neurologic deficits in dogs and cats with diskospondylitis are extremely uncommon. In chronic or untreated cases neurologic dysfunction can result from spinal cord compression by proliferating inflammatory tissue or from pathological fracture of lytic vertebrae. Occasionally, severe inflammation in the bone will cause functional abnormalities in the overlying spinal cord without any cord compression.

#### Diagnosis

The diagnosis of diskospondylitis is suspected after physical examination and confirmed by radiographic examination of the affected vertebrae. Radiographic changes of diskospondylitis characteristically include narrowing of the disk space, irregularity or lysis of one or both vertebral end plates (especially ventrally), sclerosis at the margins of bone loss, and osseous proliferation of adjacent vertebral bone (Fig. 70-13). The most commonly affected sites are the midthoracic,

#### FIG 70-13

**A**, Lateral radiograph of cervical vertebral column of adult dog showing diskospondylitis between the third and fourth cervical vertebrae (C3 and C4). **B**, Lateral radiograph of lumbar vertebral column of an adult Pointer showing severe chronic diskospondylitis between the second and third lumbar vertebrae (L2 and L3).

caudal cervical, thoracolumbar, and lumbosacral spine. It is common for diskospondylitis to affect more than one disk space (Fig. 70-14), so survey radiographs of the entire spine are recommended. Radiographic signs of diskospondylitis may not be apparent for several weeks after the onset of clinical signs. MRI or CT can identify subtle endplate erosion before radiographically apparent lesions are visible.

Blood culture is the most rewarding noninvasive method of isolating the organism responsible for the vertebral infection, yielding the organism in approximately half of the cases. Echocardiography and urine culture should be performed to evaluate the cardiac and urogenital systems as potential sources of infection. Percutaneous needle aspiration of the infected disk during general anesthesia using fluoroscopy has been effective in yielding positive cultures in some cases with negative blood and urine cultures, but this technique is usually reserved for cases in which other culture techniques have yielded negative results and the response to an empirically selected antibiotic is inadequate. A spinal needle is guided into the disk space using fluoroscopy or CT, and a small amount of sterile saline (0.3 to 0.5 ml) is injected and then aspirated for culture. Brucella serology or polymerase chain reaction (PCR) should be considered in all affected dogs because of the public health significance of brucellosis (see Chapter 58), despite its very low prevalence (<10%) in the United States and Canada.

#### **Treatment**

Initial treatment of diskospondylitis consists of antibiotics, cage rest, and analgesics. If an organism is isolated, susceptibility testing should guide antibiotic therapy. If an organism is not found, initial treatment attempts should be directed against Staphylococcus spp. Bactericidal antibiotics with a spectrum against gram-positive organisms and the ability to concentrate in bone are recommended. Firstgeneration cephalosporins (cefazolin 25 mg/kg, given intravenously q8h, cephalexin 22 mg/kg, given orally q8h) and amoxicillin with clavulanate (Clavamox 12.5 to 25 mg/kg, given orally q8h) have been effective. Quinolones can be added if gram-negative organisms are suspected. Ampicillin is the antibiotic of choice for Actinomyces infections associated with grass awn migration. Antibiotics are administered parenterally for the first 3 days whenever neurologic deficits are present, and then oral administration is continued for at least 8 weeks and up to 6 months, if necessary.

In addition to antibiotic therapy, the patient's activity should be restricted to minimize discomfort and decrease the chance of pathologic fracture and luxation. Analgesics may be administered for 3 to 5 days, but their use will make it difficult to assess the efficacy of antibiotic therapy and may make it more difficult to enforce strict cage rest. Most dogs show very rapid clinical improvement within the first week of treatment. Dogs treated medically should be reevaluated clinically and radiographically every 3 weeks. With time, the lytic process should resolve and the affected vertebrae should fuse. Antibiotics should be administered for a minimum of 8 weeks. Antibiotics may then be discontinued if the spine is no longer painful over the affected sites and there is no radiographically visible lysis. Most treated animals do not relapse, unless the diskospondylitis is caused by a grass awn foreign body.

# CHRONIC PROGRESSIVE DISORDERS Neoplasia

Tumors that grow and compress or infiltrate spinal cord parenchyma frequently cause chronic, progressively worsening signs of spinal cord dysfunction. Spinal tumors can be primary or metastatic. The most common tumors affecting the spinal cord in the dog are extradural tumors arising from the vertebral body (e.g., osteosarcoma, chondrosarcoma, fibrosarcoma, myeloma) and extradural soft tissue tumors, including metastatic hemangiosarcoma, carcinoma, liposarcoma, and lymphoma. Intradural extramedullary tumors such as meningiomas, neuroepithelioma, and peripheral nerve sheath tumors are also common, comprising 35% of all spinal tumors. Intramedullary tumors (i.e., astrocytomas, ependymomas, metastatic tumors) are relatively rare in the dog, with the exception of metastatic hemangiosarcoma. Lymphoma can be extradural, intradural/extramedullary, or intramedullary in the dog and is usually a manifestation of multicentric disease. Extradural lymphoma is the only common spinal tumor in the cat.

Spinal tumors occur with equal frequency in males and females and can occur in any breed of dog or cat, although

**A,** A 5-month-old Boxer puppy with back pain resulting from diskospondylitis. **B** and **C,** Lateral spinal radiographs reveal lesions at T8-T9 and L2-L3, with destruction of adjacent vertebral body end plates, collapse of the intervertebral disk spaces, shortening of the vertebral bodies, and new bone production around the ends of the affected vertebral bodies.

large-breed dogs are most often affected. Most spinal cord tumors are found in middle-aged and older dogs, with the mean age at the time of diagnosis being 5 to 6 years. Two noteworthy exceptions are lymphoma, which can affect dogs of any age, and neuroepithelioma, a primary intradural extramedullary tumor that has a predilection for T10 to L1 in young dogs, particularly German Shepherd Dogs and Golden Retrievers. In addition, vertebral osteomas may occur in young dogs and result in spinal cord compression, as can cartilaginous exostoses, benign proliferative lesions of the bone indistinguishable from neoplasia except by biopsy (Fig. 70-15; see also see Fig. 64-7). Spinal lymphoma is most common in young (mean age, 4 years) adult feline leukemia (FeLV)-positive cats. Certainly, spinal neoplasia cannot be eliminated as a differential diagnosis strictly on the basis of signalment.

#### **Clinical Features**

Clinical signs are usually insidious and related to the location of the tumor. Early diagnosis is difficult because neurologic abnormalities are not clinically apparent until there has been significant compression or destruction of the spinal cord. Many animals have months of slowly progressive clinical signs before a diagnosis is made. Pain may be a prominent feature in dogs and cats with nerve root tumors encroaching on the spinal cord, tumors involving the meninges, and aggressive tumors involving vertebral bone. Progressively worsening lameness and pain on limb manipulation (i.e., radicular pain, root signature) without initial neurologic deficits are common in dogs with peripheral nerve sheath tumors involving nerve roots in the cervical or lumbar intumescence. An ipsilateral Horner's syndrome and/or loss of the panniculus reflex may be seen if the thoracic nerve roots are involved. Pain is not a common feature of intramedullary spinal cord primary tumors or metastases. Although animals with compressive lesions of the T3-L3 spinal cord typically maintain urinary and fecal continence until after the limbs are paralyzed, some animals with intramedullary neoplasms will become incontinent while still able to walk.

Differential diagnoses must include other disorders that cause slowly progressive neurologic dysfunction, including type II disk protrusion and degenerative myelopathy (DM). Rapidly growing extradural tumors such as lymphoma and primary or metastatic intramedullary tumors sometimes

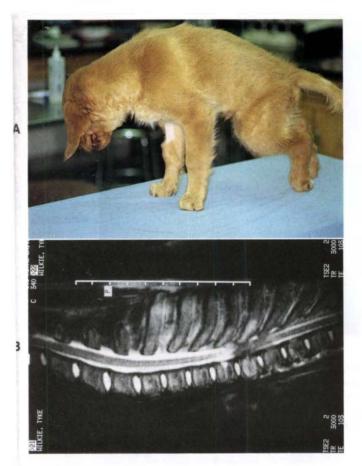

FIG 70-15

**A,** A 3-month old Golden Retriever puppy with spinal pain and progressive upper motor neuron (UMN) signs in both rear limbs resulting from a vertebral osteoma. **B,** Magnetic resonance imaging (MRI) showing severe compressive spinal cord damage from the caudal aspect of the T4 vertebral body extending caudally through the T6 vertebral body.

cause rapidly progressive neurologic signs more typical of inflammatory myelitis. Acute paresis/paralysis may be seen in dogs or cats with tumor-associated hemorrhage or vertebral pathologic fractures.

#### **Diagnosis**

Whenever a neoplasm is considered as a differential diagnosis for spinal cord dysfunction, a thorough physical examination and clinicopathologic evaluation are necessary to look for sites of primary tumor and evidence of associated systemic disease. Fundic examination, palpation of lymph nodes, and rectal examination should be performed, as well as thoracic and abdominal radiographs, to identify a primary tumor site or metastasic lesions. Ultrasonographic examination of the spleen, liver, and heart should be performed in dogs whenever metastatic hemangiosarcoma is possible. Aspiration of the lymph nodes, spleen, and/or liver and examination of peripheral blood or bone marrow smears may yield the diagnosis in dogs with lymphoma. Patients with multiple myeloma often secrete paraproteins, causing a hyperproteinemia and a monoclonal gammopathy. Most

cats with spinal lymphoma are FeLV-positive (>80%), and many have obvious systemic disease and hematologic evidence of bone marrow involvement.

Survey radiographs of the affected region of the spine are recommended. Bony changes will be seen primarily with vertebral tumors, in which obvious osteolysis or bone proliferation is common (Fig. 70-16). When a region of lysis is identified, fine needle aspiration of the lesion sometimes yields a diagnosis. The entire axial and appendicular skeleton should be surveyed for lytic lesions if clinical findings make multiple myeloma likely. Soft tissue tumors of the spinal cord are almost never visible using survey radiographs. Myelography is a fairly reliable method to identify, localize, and characterize spinal cord tumors, but it is relatively invasive and provides less useful diagnostic information than advanced imaging techniques such as CT and MRI. CSF analysis should always precede myelography. With tumors compressing the spinal cord, CSF analysis typically reveals nonspecific changes, including slight increases in protein concentration and a mild mononuclear pleocytosis. Neoplastic cells are rarely identified, except in cats and dogs with lymphoma (Fig. 70-17).

Myelography allows most spinal cord tumors to be characterized as intramedullary, extramedullary-intradural, or extradural (see Fig. 64-6). When available, advanced imaging techniques (i.e., CT, MRI) add valuable information regarding precise tumor location and degree of spinal cord involvement, which may be important when considering surgical treatment and/or radiation therapy.

# **Treatment**

Surgical decompression and attempts at complete tumor excision are usually limited to well-encapsulated intradural extramedullary tumors as a referral procedure. Feline menigiomas may have a good prognosis following surgical excision. Intramedullary tumors cannot usually be treated successfully with surgery because of their intimate involvement with neural tissue.

Chemotherapy and radiation therapy as primary or postoperative adjuvant therapies have met with limited success in the treatment of spinal tumors in dogs and cats. Radiation therapy may be of some benefit in dogs and cats with spinal lymphoma, plasma cell tumors, meningiomas, and some nerve sheath tumors. Corticosteroids, although they have little effect on most tumors, can decrease tumor-associated edema and inflammation and result in remarkable temporary improvement. Lymphoreticular tumors such as lymphoma and myeloma can also be treated with traditional chemotherapy protocols, although only a few of the drugs used cross the blood-brain barrier and the long-term prognosis is poor.

## **Intraspinal Articular Cysts**

Cysts arising from the joint capsule of spinal facetal joints can, through enlargement, cause chronic progressive focal compression of the spinal cord or nerve roots. These cysts can result from an outpouching of the synovium (i.e., syno-

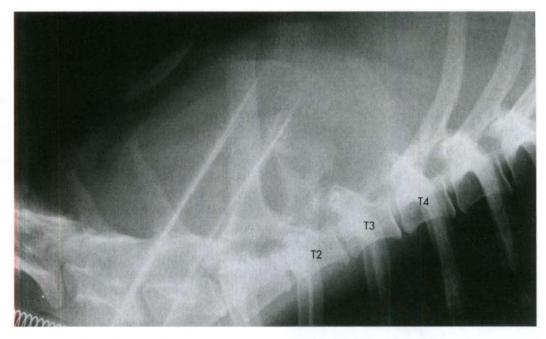

FIG 70-16

Lateral spinal radiograph from a 2-year-old Irish Setter with a 1-week history of progressive ataxia and a 12-hour history of upper motor neuron (UMN) paralysis of the rear limbs and Schiff-Sherrington syndrome. The entire spinous process of T3, the roof of T3, and most of the spinous process of T2 are destroyed, most consistent with a neoplastic process. An undifferentiated sarcoma at this site was identified on postmortem examination.

FIG 70-17

**A,** A 2-year-old cat with a 5-day course of progressive rear limb ataxia and upper motor neuron (UMN) paresis. **B,** Cerebrospinal fluid (CSF) analysis revealed an increased cell count consisting predominantly of neoplastic lymphoid cells.

vial cysts), or they may arise from mucinous degeneration of periarticular connective tissue (i.e., ganglion cysts). Synovial cysts and ganglion cysts are clinically indistinguishable, and both arise secondary to degenerative changes in the facetal joints. Degenerative changes occur because of congenital malformations, vertebral instability, or trauma. Signs are referable to the site and degree of resulting spinal cord or nerve root compression. Young giant breeds of dogs such as Mastiffs and Great Danes most commonly develop single or multiple cysts in the cervical region, which cause a UMN

myelopathy and occasionally cervical pain. Older dogs, particularly German Shepherd Dogs, have been identified with thoracolumbar or lumbosacral articular cysts that cause spinal cord or cauda equina compression. Radiographs reveal degenerative changes of the articular facets. CSF analysis reveals normal cytology and slightly increased protein consistent with a noninflammatory chronic compressive myelopathy. Myelography reveals focal extradural dorsolateral compression of the spinal cord. MRI is necessary to identify the facetal joints as the origin of the cysts and to

precisely localize the cysts before surgical therapy. Treatment consists of spinal cord decompression, cyst drainage, and arthrodesis of the facetal joint and usually produces excellent results. A similar syndrome with degeneration and bony proliferation of multiple thoracolumbar articular facets causing spinal cord compression has been reported as a hereditary condition in 4- to 10-month-old Shiloh Shepherds.

# **Arachnoid Cysts**

Focal accumulations of CSF within cystlike structures within the subarachnoid space can lead to slowly progressive, non-painful spinal cord compression in young dogs (Fig. 70-18). The cystlike structures containing CSF may represent a congenital diverticulum or a pocket caused by adhesions in the subarachnoid space secondary to trauma or disk extrusion. The cervical region and the caudal thoracic region are most often affected, and as CSF fills the arachnoid cyst, compression of the spinal cord occurs. Young large-breed dogs are most likely to be affected, with Rottweilers overrepresented. Cats are rarely affected. Myelography or MRI reveals the accumulation of CSF at the site. Exploration and marsupialization of the cyst is associated with a good prognosis for recovery if performed within 4 months of development of clinical signs and if neurologic deficits are not severe.

# Type II Intervertebral Disk Disease

Fibroid degeneration of the intervertebral disk occurs in some dogs as part of the aging process, and this can lead to prolapse of a small amount of disk nucleus into the annulus fibrosus. A fibrotic reaction ensues, resulting in a round, domelike dorsal bulging of the annulus so that it protrudes into the spinal canal and causes slowly progressive spinal cord compression (see Fig. 70-5). This type of disk pro-

trusion (i.e., Hansen's type II) is seen most commonly in aging large-breed nonchondrodystrophoid dogs, particularly German Shepherd Dogs, Labrador Retrievers, and Doberman Pinschers; however, it has also been recognized occasionally in small-breed dogs.

#### **Clinical Features**

Clinical signs result primarily from slowly progressive spinal cord compression, although spinal discomfort is apparent in a few dogs. Thoracolumbar type II disk protrusion results in UMN signs to the rear limbs, with normal forelimbs. Cervical type II disk disease may be seen in Doberman Pinschers, particularly in association with the cervical vertebral malformation-malarticulation syndrome (i.e., wobbler syndrome). In these dogs thoracic and pelvic limbs are affected, with UMN neurologic signs most prominent in the pelvic limbs.

# **Diagnosis**

Slowly progressive signs of spinal cord dysfunction in an older dog should prompt consideration of type II disk protrusion, degenerative myelopathy (DM), and neoplasia. Neurologic examination localizes the lesion to a spinal cord region, but because the site is not usually painful, spinal palpation rarely results in more precise localization. Survey radiographs of the spine are normal in most affected dogs. Disk space narrowing, osteophyte production, and end-plate sclerosis may be seen at the site of type II disk protrusion in some dogs, but these abnormalities are common at multiple sites in older large-breed dogs; thus they are not very helpful in further localizing the lesion. Myelography or advanced imaging technique (i.e., CT, MRI) is necessary to determine the extent and location of the lesion and to distinguish type II disk protrusion from spinal neoplasia and DM.

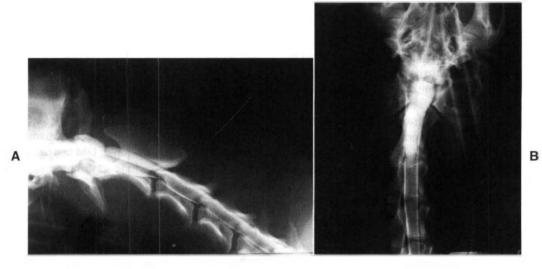

FIG 70-18

Lateral (A) and ventrodorsal (B) views of a myelogram from a 10-month-old Akita with progressive hypermetria of all four limbs and mild paraparesis. A well-defined, bulbous dilation of the dorsal subarachnoid space communicating with the rest of the subarachnoid space was present at C2-C3, suggesting an arachnoid cyst. Surgical exploration and marsupialization resulted in rapid and persistent (>6 years) return to normal gait.

#### **Treatment**

Medical therapy with antiinflammatory drugs (nonsteroidal antiinflammatory drugs or low-dose prednisone) and muscle relaxants will provide relief in dogs that are uncomfortable when the affected site is palpated or manipulated. Neurologic signs will progress, however, and surgery is recommended as the definitive treatment. Ventral decompression is performed if the cervical vertebrae are affected, whereas hemilaminectomy for decompression at the site is usually attempted for type II disks in the thoracolumbar spine. Effective surgical decompression is often difficult to achieve because of the chronic nature of the lesion and the difficulty encountered in removal of the dorsal annulus. The goal of therapy is to stabilize the animal's neurologic status. The spinal cord has usually undergone considerable chronic compression before clinical signs appear; thus full recovery is rare. A few dogs experience temporary or permanent worsening of clinical signs postoperatively.

# **Degenerative Myelopathy**

A degenerative disorder of the spinal cord white matter characterized by widespread myelin and axon loss occurs most often in aging German Shepherd Dogs and the Pembroke Welsh Corgi. DM has been recognized in dogs from 5 to 14 years of age and has rarely been seen in old dogs of other large breeds, in young German Shepherd Dogs, and in cats. A DM-like disorder has also been identified in the Pembroke Welsh Corgi. The thoracic and thoracolumbar spinal cord segments are most severely affected in all affected breeds; thus the neurologic findings suggest a lesion between T3 and L3.

#### Etiology

The cause of DM is uncertain. Some have speculated that deficiencies of nutrients or vitamins are responsible for the widespread demyelination and degeneration of axons observed histologically. An inherited cause has also been proposed in the German Shepherd Dog and the Pembroke Welsh Corgi. Whatever the initiating event, DM is generally considered to be an immune-mediated neurodegenerative disease similar to multiple sclerosis in humans. Depressed cell-mediated immunity and an increase in circulating immune complexes are consistent findings in dogs with DM, and spinal cord deposition of immunoglobulin and complement has been documented in association with histologic lesions of the disease.

# **Clinical Features**

Clinically, DM results in a slowly progressive (e.g., 6 months to 2 years) UMN paraparesis and ataxia of the rear limbs. A loss of conscious proprioception results in knuckling of the toes, wearing of the dorsal nail surfaces of the digits of the rear limbs, and severe posterior ataxia.

Increased muscle tone and hyperactivity of the rear limb tendon reflexes result in clinical localization of the problem to the spinal cord between the T3 and L3 spinal cord segments. Thoracic limbs are normal, and urinary and fecal continence are maintained until very late in the course of the disease. Neurologic deficits may be asymmetric. In a very small number of cases (<10%) a decrease or loss of pelvic limb reflexes is observed late in the course of the disease as a result of involvement of the dorsal spinal nerve roots important for the afferent arm of the reflexes.

# **Diagnosis**

A diagnosis of DM is suspected in any large-breed dog with slowly progressive UMN paresis in the rear limbs. Rear limb ataxia, a long-strided gait, toe scuffing, abnormal postural reactions (especially knuckling), and normal to increased rear limb reflexes are the most common findings. Affected dogs are systemically normal, with no site of localizable spinal pain. Neurologic findings distinguish DM from lumbosacral disease and from orthopedic disorders such as hip dysplasia and bilateral anterior cruciate ligament rupture. The primary differential diagnoses for chronic UMN paresis in the rear limbs include DM, spinal cord neoplasia, and type II disk disease.

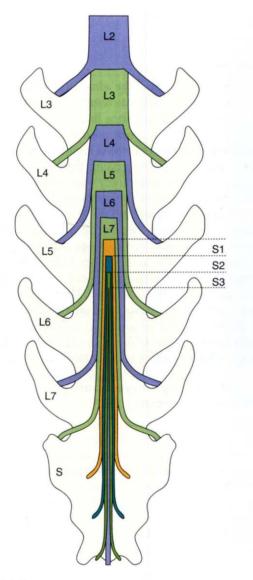

The antemortem diagnosis of DM is one of exclusion. Radiographs of the spine are normal, as is CSF analysis, although a slight increase in CSF protein concentration is occasionally found. Myelography or MRI must be performed to rule out the presence of spinal cord compression or focal spinal cord neoplasia. Normal spinal radiographs, a cytologically normal CSF, and normal spinal cord imaging in an older dog with slowly progressive UMN signs to the pelvic limbs warrant a diagnosis of DM.

# **Treatment**

No treatment has been proven effective in dogs with DM. Corticosteroids should not be administered because they cause muscle wasting and exacerbation of muscle weakness. Other immunosuppressive agents have not been shown to be beneficial. Some investigators have advocated vitamin (i.e., vitamin E, vitamin B complex, vitamin C) and omega-3 fatty acid supplementation, but conclusive evidence of their benefit is lacking. Exercise may be helpful in slowing the progression of the disease. Walking, running, and swimming for 30 minutes every other day is recommended. Some clinicians report success after long-term administration of aminocaproic acid (EACA; Amicar; Lederle Laboratories, American Cyanamide), 500 mg orally q8h. This drug blocks the final common pathway of tissue inflammation and may slow or halt the progression of DM in a few cases. Drawbacks of EACA therapy include gastrointestinal irritation, high cost, and a need to treat for 2 to 3 months before response to treatment is detectable. Administration of EACA in combination with the potent antioxidant acetylcysteine (25 mg/kg administered as a 5% solution orally q8h for 14 days, then every other day) has also been recommended. In the absence of other effective treatments for DM, these unproven treatments should be considered.

#### Cauda Equina Syndrome

In dogs the last three lumbar spinal cord segments (L5, L6, L7) are within the fourth lumbar vertebra, the sacral seg-

# FIG 70-19

The anatomy of the cauda equina region in the dog. L5-L7 spinal cord segments sit within the L4 vertebra. S1-S3 spinal cord segments are within the L5 vertebra, and the coccygeal segments are within L6. Nerve roots from all of the lumbar, sacral, and coccygeal spinal cord segments leave the canal through the intervertebral foramen just caudal to the vertebra with the same number so that these nerve roots course a considerable distance within the vertebral canal.

ments (S1, S2, S3) are within the body of the fifth lumbar vertebra, and the coccygeal segments are within the sixth lumbar vertebra. Nerve roots from these lumbar, sacral, and coccygeal segments of the spinal cord exit the spinal canal through the intervertebral foramina caudal to the vertebrae with the same number; thus they must course a considerable distance within the vertebral canal caudal to the point of termination of the spinal cord (Fig. 70-19). This collection of nerve roots descending in the vertebral canal is termed the *cauda equina*. The spinal nerves from the sacral and caudal segments overlie the lumbosacral junction, so com-

pressive diseases of this region are likely to involve the L7, sacral, and caudal nerves.

Compression of the nerves of the cauda equina (cauda equina syndrome) is usually the result of acquired type II disk protrusion at the L7/S1 intervertebral space together with progressive proliferation of joint capsules and ligaments at that site, perhaps caused by excessive motion or instability. This disorder is most common in large-breed dogs, including German Shepherd Dogs, Labrador Retrievers, and Belgian Malinoises, and particularly affects male working dogs over the age of 5 years. Rarely, compression of the cauda equina may be caused by tumor, diskospondylitis, vertebral or sacral osteochondrosis, or congenital bony malformations.

Genetic predisposition, conformation, and physical activity are all factors proposed to cause increased mechanical stress on the intervertebral disk at the lumbosacral junction, promoting type II disk prolapse at this site. Loss of the structural strength of the disk worsens instability at the site, resulting in proliferative changes in the articular facets, joint capsules, and the interarcuate ligament (i.e., ligamentum flavum). Proliferative changes result in further narrowing of the vertebral canal, compression of the cauda equina, and compression of the nerve roots as they exit the foramina (degenerative lumbosacral stenosis).

#### **Clinical Features**

Compression of the cauda equina results in a very characteristic constellation of clinical signs. Affected dogs are slow to rise from a prone position and reluctant to run, sit up, jump, or climb stairs. Rear limb lameness worsens with exercise as the blood vessels accompanying the spinal nerve roots within the already crowded intervertebral foramen dilate and further compress the nerve roots (i.e., neurogenic claudication). Affected dogs may be reluctant to raise or wag their tails.

The most consistent physical examination finding is pain elicited by deep palpation of the dorsal sacrum or by dorsiflexion of the tail or hyperextension of the lumbosacral region (Fig. 70-20). Most dogs have no neurologic deficits at the time of initial evaluation, making it difficult to distinguish affected dogs from those with pain and lameness caused by diskospondylitis, prostatic disease, or degenerative joint disease. When lumbosacral spinal canal and foraminal narrowing progress to cause compression of the L7, sacral, and caudal spinal nerves, rear limb weakness, atrophy of the muscles of the caudal thigh and distal limb, and reduced or absent hock flexion during the withdrawal reflex will become apparent. The patellar reflex may appear increased in some dogs because there is a loss of tone in the opposing caudal thigh muscles (pseudohyperreflexia). In severely affected dogs decreased anal tone and fecal and urinary incontinence will occur. Hyperesthesia or paresthesia of the perineum may develop, with self-inflicted moist dermatitis of the perineum and tail base.

# Diagnosis

Historical, physical, and neurologic examination findings are the primary basis for reaching a tentative diagnosis of cauda

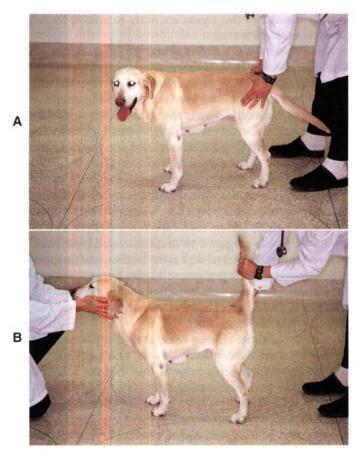

FIG 70-20
Dogs affected by cauda equina syndrome will often experience pain upon (A) deep palpation of the dorsal sacrum and (B) dorsiflexion of the tail.

equina syndrome in affected dogs. Spinal survey radiographs are useful to rule out unusual causes of lumbosacral pain (e.g., diskospondylitis, lytic vertebral neoplasia, fracture/luxation). Radiographs of this region in dogs with cauda equina syndrome may be normal or may reveal end plate sclerosis and spondylosis of the L7 and S1 vertebral end plates and narrowing or collapse of the L7-S1 intervertebral disk space. These same abnormalities are common in clinically normal dogs.

Diagnosis is based on documentation of nerve compression using imaging. Myelography (cervical injection) can document cauda equina compression, but it will not be diagnostic in those dogs (20%) in which the dural sac ends cranial to the lumbosacral junction or in dogs in which the primary lesion is lateral compression of the spinal nerves at the intervertebral foramen. When available, MRI with the spine in extension provides the most sensitive, accurate, and noninvasive means of evaluating the lumbosacral region, allowing visualization of all components potentially involved in cauda equina compression (see Fig. 70-21). There is some concern that routine use of MRI for diagnosis may lead to overinterpretation of incidental minor compressive lesions of the cauda equina; therefore clinical findings must support the MRI diagnosis. When available, electrophysiological

studies can be useful to confirm LMN disease and nerve root dysfunction of the rear limbs and tail.

#### **Treatment**

Restriction of exercise and the administration of analgesics or antiinflammatory drugs may result in temporary improvement in dogs with clinical signs limited to pain and lameness. Signs usually recur when normal activity is resumed. More definitive treatment involves lumbosacral dorsal laminectomy, excision of compressing tissues, and foraminal decompression by foraminotomy when necessary. Decompressive surgery together with lumbosacral distraction and stabilization have been recommended for dogs with marked neurologic deficits or severe pain. Descriptions of the surgical procedures are provided in Suggested Readings. Rapid relief from pain occurs in most dogs. Strict confinement is important for 4 to 8 weeks postoperatively, followed by a gradual return to exercise and work. The prognosis is excellent for resolution of lameness and mild neurologic deficits. Most dogs with mild to moderate deficits will return to working function. Dogs with severe LMN deficits or incontinence are likely to have permanent deficits.

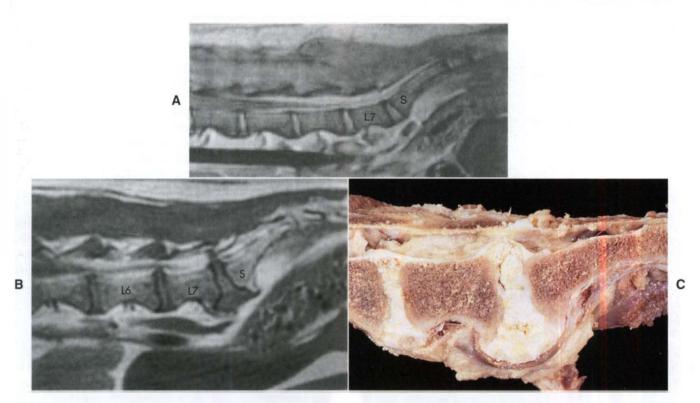

# Cervical Spondylomyelopathy (Wobbler Syndrome)

Cervical spondylomyelopathy (CSM), or canine wobbler syndrome, is a term used to describe caudal cervical spinal cord and nerve root compression in large-breed dogs that occurs secondary to developmental malformations, instability, or instability-associated changes in the spinal canal. Vertebral canal narrowing can be the result of malformed vertebral laminae, hypertrophy of the ligamentum flavum, articular facet enlargement, periarticular soft tissue hypertrophy, or a combination of these. In addition, changes in the vertebral body and end plates can result in instability that leads to intervertebral disk failure and the development of type II disk protrusions or occasionally type I disk herniation.

Typically, Great Danes and Doberman Pinschers are affected, but the condition has been reported in many large breeds of dogs. Males may be affected more often than females. Age at presentation varies from 7 weeks to 10 years. Stenosis of the cranial aspect of the cervical vertebrae (usually C4, C5, or C6) and articular facet deformities are the most common abnormalities in young Great Danes. Vertebral column instability with spinal cord compression by secondary soft tissue hypertrophy or disk, with or without congenital cervical vertebral malformation and canal stenosis (usually C5, C6, or C7), is more commonly recognized in middle-aged and older Doberman Pinschers. Genetic predisposition, overnutrition, and conformation have all been implicated in the development of this disorder.

#### **Clinical Features**

A slowly progressive course of paresis and an incoordinated or wobbling gait, particularly in the pelvic limbs, is characteristic of CSM. Affected dogs have a broad-based rear limb

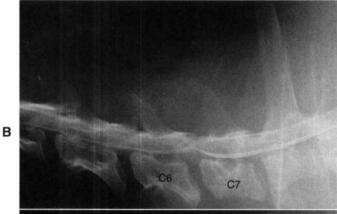

A, Normal midline sagittal T1 on a magnetic resonance image (MRI) scan of the lumbar spine of a dog. (The image reveals the high signal intensity [white] of the nucleus pulposus and the epidural fat, in contrast to the lesser signal density of the spinal cord and the nerve roots of the cauda equina [darker].) **B,** MRI from a dog with lumbosacral pain showing T1-weighted midline sagittal, displacement of epidural fat, and ventral and dorsal compression of the nerve roots at the L7-S1 disk space. Spondylosis deformans ventral to the L7-S1 intervertebral disk space and disk protrusion at the L6-L7 space can also be seen. C, Postmortem dissection of the lumbosacral region of a German Shepherd Dog with acquired degenerative lumbosacral stenosis and type II disk protrusion. The vertebral canal is compromised at the lumbosacral junction, resulting in compression of the nerves of the cauda equina. (A and B, Courtesy Dr. Greg Daniel, University of Tennessee.)

stance, ataxia, and abnormal postural reactions in the rear limbs (which are invariably more severely affected than the forelimbs). Neurologic findings in the forelimbs vary depending on whether spinal cord compression is centered in the cranial cervical region or in the caudal cervical region. Dogs with C1-C5 compression often have a floating or hypermetric front limb gait. Dogs with caudal cervical lesions may have a short-strided, weak front limb gait with a weak withdrawal reflex and pronounced atrophy of the supraspinatus and infraspinatus muscles over the scapula. Lameness and muscle atrophy in one thoracic limb or pain when traction is applied to a limb (i.e., root signature; see Fig. 70-6) suggests that nerve root compression is present. Slowly progressive deterioration in neurologic status is common, but occasionally a traumatic episode or an acute disk extrusion results in sudden tetraplegia. At the time of examination, neurologic deficits can be localized to the cervical spinal cord. Resistance to dorsal extension of the cervical spine is common, but overt cervical pain is rare unless secondary disk prolapse has occurred.

# Diagnosis

The diagnosis is suspected on the basis of signalment, history, and clinical findings. Survey radiographs are useful to rule out other disorders associated with cervical spinal cord compression but are not definitive for CSM. Severe articular facet changes or vertebral body malformations should, however, raise the index of suspicion for CSM in a largebreed dog (Fig. 70-22A). Myelography is the standard means of confirming a diagnosis of CSM and has the advantage that the spinal cord compression can be observed with the spine in multiple positions, allowing differentiation between static, dynamic, and positional lesions. CSF should be evaluated before injection of contrast. Once contrast is injected, it should be concentrated in the cervical region through patient positioning and routine lateral, ventrodorsal, dorsoventral, and then lateral flexion and traction views should be taken. Compressive lesions that improve with traction (traction-responsive or dynamic lesions), include type II disks and ligamentous hypertrophy. Spinal cord compression by bone proliferation or by extruded nucleus pulposus

#### FIG 70-22

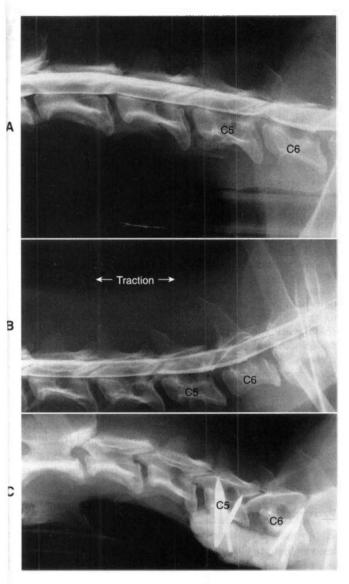

**A,** Radiographs of the cervical region in a 6-year-old Doberman Pinscher "wobbler" with a sudden onset of ataxia, paraparesis, proprioceptive deficits and hyperreflexia in the rear limbs, and mild cervical pain. A slight narrowing of the C6-C7 disk space can be seen; the vertebral canal is stenotic within the cranial aspect of C6 and C7. **B,** Myelography shows spinal cord compression by a ventral extradural mass at C6-C7 that is not altered significantly with traction, **(C).** Surgery revealed a large amount of disk material within the vertebral canal at this **site**.

(type 1 disk) will not resolve with traction (traction nonresponsive or static lesions; Fig. 70-22, B and C). Some dogs have spinal cord compression that is not evident in neutral or traction views but that becomes apparent with flexion or extension (positional lesions). Ideally, all conventional myelograms for CSM should be followed by a CT scan or MRI to improve surgical planning. Rational decisions regarding therapy and prognosis can be made after determining whether compression is at one site or many, is primarily dorsal or ventral, and is static or dynamic. Because a temporary worsening of neurologic status may occur after imaging dogs with CSM under general anesthesia, if surgery is planned, it should be scheduled 48 to 72 hours after imaging to allow recovery and neurologic stabilization. All affected animals should be evaluated for systemic disease before surgery, particularly Doberman Pinschers that may have concurrent hypothyroidism, von Willebrand's disease, or cardiomyopathy.

#### **Treatment**

The clinical course of untreated wobbler syndrome is chronically progressive. Medical or surgical therapy can be used to attempt to relieve clinical signs. Severe exercise restriction, use of a harness, and administration of antiinflammatory doses of prednisone may result in temporary improvement in neurologic function. Sometimes, long-term management of dogs with minimal or mild signs of neurologic dysfunction is satisfactory with exercise restriction and corticosteroid therapy alone (prednisone 0.5 mg/kg orally q12h for 2 days; then 0.5 mg/kg once every day for 2 days; then 0.5 mg/kg once every other day for 14 days; then 0.25 mg/kg once every other day for 2 months).

Although initial improvement is common after medical therapy, the underlying compression and instability persist and generally progress without more definitive treatment. Surgical treatment is recommended in all dogs with persistent neurologic deficits. The main factor determining the specific surgical procedure to be recommended is the appearance of the cord myelographically, especially on the traction view. If the only lesion identified is static (traction nonresponsive) ventral spinal cord compression resulting from type 1 disk herniation, then ventral decompression is performed. If a single dynamic lesion is causing compression, such as a bulging annulus (ventrally) or a hypertrophied ligamentum flavum (dorsally), then a distraction/fusion technique is used to pull the vertebral bodies apart and maintain the separation, decreasing spinal cord compression and relieving pressure on the nerve roots (Fig. 70-23). The method used depends on the number of sites involved and surgeon preference. If the imaging studies indicate static dorsal compression of the spinal cord resulting from vertebral malformation or articular process osteophytes, then a dorsal decompressive technique must be attempted. Details of the surgical procedures and potential complications are discussed in Suggested Readings.

#### FIG 70-23

A, Cervical myelogram of an 11-year-old Doberman/
Weimaraner cross with a chronic history of nonpainful
ataxia and hypermetria of all four limbs. Narrowing of the
C5-C6 disk space and thinning of the dorsal contrast
column over this site (in association with dorsal deviation
and thinning of the ventral contrast column) can be seen.
B, The dramatic resolution of this spinal cord compression
in the traction view suggests a dynamic compression by a
bulging annulus fibrosus or ligamentum flavum. C, Surgery
was performed to maintain traction on the spine at this site.

# **Prognosis**

Dogs with wobbler syndrome have extremely variable prognoses, depending on their neurologic status, the temporal course of their disease, and the specific abnormalities that are present. Surgical results in ambulatory animals with a short history and only one lesion can be good, with up to 80% success reported. Multiple lesions, chronic disease, and an inability to walk are all associated with a poor prognosis.

# PROGRESSIVE DISORDERS IN YOUNG ANIMALS Breed-Associated Neuronal Abiotrophies and Degenerations

Neuronal abiotrophies and degenerative disorders have been recognized in many breeds of dogs. Progressive neurologic dysfunction usually begins early in life. In disorders affecting the entire spinal cord, clinical signs involving the rear limbs are often noted early in the course of disease with progression to tetraparesis. Disorders that primarily affect white matter and result in UMN signs are most often seen in Rottweilers, Afghan Hounds, Dalmatians, and Jack Russell Terriers. Disorders primarily affecting gray matter and causing LMN signs are seen in Alaskan Malamutes, Boxers, Brittany Spaniels, German Shepherd Dogs, English Pointers, and Maine Coon Cats. The disorders are diagnosed on the basis of the typical clinical course, the signalment, and the lack of any definable etiology on screening blood tests, spinal radiographs, CSF analysis, myelography, and other diagnostic testing. Diagnosis is confirmed by necropsy examination in most cases. No treatment is available.

# **Metabolic Storage Diseases**

A large group of rare disorders, characterized pathologically by the accumulation of metabolic products in cells caused by a genetically based enzyme deficiency, may result in signs of spinal cord dysfunction. The enzyme deficiency itself or the accumulation of the metabolic intermediates within cells causes a gradual progression of neurologic signs. Spinal signs are usually UMN in nature, although peripheral nerve dysfunction may occur. Cortical signs (e.g., seizures) and cerebellar signs (e.g., hypermetria) are more common. Signs are gradually progressive and usually obvious within the first year or two of life. Metabolic storage diseases are diagnosed on the basis of the typical clinical course and signalment; the lack of any other identifiable etiology; and, in some cases, organomegaly, abnormal appearance, blindness, and other readily identifiable clinical abnormalities resulting from the accumulation of metabolic product in extraneural sites.

# **Atlantoaxial Instability and Luxation**

Normally, the atlas (C1) and the axis (C2) are bound together by ligaments. The dens, a bony projection from the cranial aspect of the body of the axis, is held firmly against the floor of the atlas by the transverse ligament, maintaining alignment of these two vertebrae and integrity of the spinal canal. Malformation or absence of the dens leading to instability can be seen as a congenital defect in many small breeds of dogs, including the Yorkshire Terrier, Miniature or Toy Poodle, Chihuahua, Pomeranian, and Pekingese; it occurs rarely in large-breed dogs and in cats. The malformation and resultant atlantoaxial instability lead to repeated spinal cord trauma and slowly progressive signs of cranial cervical spinal cord compression. Alternatively, in young dogs with congenital atlantoaxial instability, mild trauma may cause C1/C2 luxation, precipitating a sudden onset of cervical pain,

tetraparesis, or paralysis. Of course, in any normal dog severe trauma could result in traumatic luxation or fracture in this region with similar clinical findings.

#### **Clinical Features**

Dogs with congenital atlantoaxial instability typically develop UMN signs indicating cervical spinal cord compression before 2 years of age. Clinical signs include neck pain (30% to 60%), low head carriage, ataxia, tetraparesis and postural reaction and conscious proprioceptive deficits in all limbs. Manipulation of the spine should be avoided because it can exacerbate motor dysfunction. Paralysis is rare, but if it does occur, it may be accompanied by hypoventilation. Some dogs have a persistent head tilt or turn. Atlantoaxial luxation secondary to malformation should be suspected in any young (i.e., 6- to 18-month-old) toy-breed dog with a history of cervical pain, tetraparesis, or tetraplegia. Atlantoaxial luxation should also be considered as a possible differential diagnosis in any dog with evidence for high cervical spinal cord disease (UMN tetraplegia) after trauma.

## Diagnosis

Radiographic examination should be performed initially without anesthesia when atlantoaxial luxation is suspected to prevent inadvertent overflexion or twisting of an unstable cervical spine. Lateral and oblique lateral views may aid in demonstrating absence or deformity of the dens. Accurate positioning with the region of interest located in the center of the film is important. Instability with significant luxation can be recognized on a lateral view as widening of the space between the dorsal arch of the atlas and the dorsal spinous process of the axis on the lateral view and dorsal displacement of the body of the axis (Fig. 70-24). In cases of congenital luxation the dens may be recognized as abnormal, and fracture of the dens may be apparent in traumatic luxations. If preliminary radiographs are not diagnostic, the animal should be anesthetized and the radiographs repeated with the head gently flexed. This may allow demonstration of the instability. Extreme care is critical when manipulating an animal suspected of having atlantoaxial instability under anesthesia because rotation or excessive flexion of the neck may result in further spinal cord compression, respiratory paralysis, and death. Splinting the animal's head and neck in extension before anesthesia is recommended to prevent excessive flexion during induction of anesthesia and intubation.

#### **Treatment**

Treatment for acute severe tetraparesis caused by atlantoaxial luxation should include medical treatment as for acute spinal cord trauma (see Fig. 70-4). Nonsurgical treatment should include cage rest, application of a neck brace, and administration of analgesics. The purpose of the splint is to immobilize the atlantoaxial junction, so the splint must extend from over the head cranial to the ears and go back to the chest. Nonsurgical treatment is recommended in small dogs that fracture a normal atlantoaxial articulation. It is

FIG 70-24

Atlantoaxial subluxation in a 7-month-old Bichon Frise. The dens rises well above its normal position, consistent with rupture of its ligament and compression of the cervical spinal cord. The space between the arch of the atlas and the spinous process of the axis is increased. This dog had a chronic history of intermittent cervical pain and severe upper motor neuron (UMN) tetraparesis.

also very effective short term in dogs with congenital lesions, but the long-term results are unknown. Surgical treatment is effective but may be associated with high perioperative morbidity and mortality. Dorsal and ventral techniques are described in Suggested Readings.

#### **Prognosis**

The prognosis for recovery is good in dogs with congenital lesions that survive the perioperative period. Outcome is most likely to be positive if the onset of signs occurs before the patient is 2 years of age, when signs have been present for less than 10 months, and if surgical reduction is good.

# NONPROGRESSIVE DISORDERS IN YOUNG ANIMALS Spina Bifida

Spina bifida results from embryonic failure of fusion of the two halves of the dorsal spinous processes of the vertebral arch. Although spina bifida may occur anywhere along the spinal canal, the caudal lumbar and lumbosacral region is most often affected. This malformation is most common in English Bulldogs and Manx cats. In the Manx cat the condition is an autosomal recessive trait and may be associated with caudal agenesis. Clinical signs are nonprogressive and present from birth, including rear limb LMN paresis, fecal and urinary incontinence, loss of perineal sensation, and decreased tone of the anal sphincter. No therapy is available.

# Caudal Agenesis of Manx Cats

Congenital malformations of the sacrococcygeal spinal cord and vertebrae are common in tailless Manx cats. Clinical signs result from agenesis or dysgenesis of the caudal vertebrae and sacral spinal cord. Signs are typically present from birth and include hopping or crouched pelvic limb gait, fecal and urinary incontinence, and chronic constipation.

## Spinal Dysraphism

Spinal dysraphism is an inherited congenital malformation of the spinal cord. It results from the abnormal development of the structures of the spinal cord along the central plane. The malformation includes a dilated or absent central canal, cavitation in the white matter, and the abnormal presence of ventral gray column cells across the median plane between the central canal and the ventral median fissure. Spinal dysraphism is recognized most commonly in Weimaraners, although other breeds are occasionally affected.

Clinical signs are present at birth. Affected dogs have a symmetric, bunny-hopping pelvic limb gait; a wide-based stance; and depressed proprioception. The patellar reflex is normal. The pelvic limb flexor reflex stimulated in one limb usually elicits simultaneous flexion of both pelvic limbs. Clinical signs caused by spinal dysraphism do not progress, and mildly affected dogs can live a normal life.

# Syringomyelia/Hydromyelia

Cystic accumulations of fluid within the spinal cord causing compression of adjacent parenchyma are being recognized with increasing frequency as advanced diagnostic imaging techniques (i.e., CT, MRI) are used for neurologic diagnosis. Syringomyelia is the development of a CSF-filled cavity anywhere within the cord, and hydromyelia is the accumulation of excessive CSF within a dilated central canal. These disorders can develop as a result of altered CSF pressures within the spinal canal, a loss of spinal cord parenchyma, or secondarily to obstructed CSF flow caused by congenital malformations or inflammatory or neoplastic disorders.

Clinical signs reflect the site and degree of spinal cord parenchymal destruction. Ataxia and paresis are common. With cervical lesions UMN signs are more pronounced in the rear limbs if the dorsal and lateral portions of the cord are affected. When the spinal cord damage is more centrally located, ataxia and paresis will often be more significant in the forelimbs than in the rear limbs (i.e., central cord syndrome). Spinal pain may be seen because of stretching of nerve roots or meninges. Scoliosis occasionally develops as LMN cell body damage within the cord causes asymmetric denervation of the paraspinal muscles, resulting in vertebral deviation. Syringohydromyelia has been reported in numerous Cavalier King Charles Spaniels with occipital bone malformations leading to overcrowding at the foramen magnum.

The onset of clinical signs in this breed is usually in young adult dogs, with most dogs presenting because of scratching at the shoulder region; intolerance to touching of the ear, limb, or neck of the affected side; and cervical pain. Muscle atrophy and LMN weakness of the associated thoracic limb and ataxia and UMN deficits of the rear limbs may also be seen. Diagnosis is most reliably made with MRI. Treatment with antiinflammatory doses of prednisone to decrease CSF production may result in clinical improvement. Decompression of the caudal fossa with an occipital craniectomy to reestablish normal CSF flow can be effective.

#### GENERAL CONSIDERATIONS

The clinically important peripheral nerves are the peripheral nerves arising from the spinal nerves in the cervical and lumbar intumescences to innervate the muscles of the limbs and the 12 pairs of cranial nerves originating in the brainstem. Spinal nerve or peripheral nerve lesions result in lower motor neuron (LMN) motor signs of weakness, decreased tone, and decreased reflexes in affected muscles and limbs. When sensory components of the peripheral nerves are involved, there may also be decreased, absent, or altered sensation in the skin supplied by that nerve.

At the neuromuscular junction (NMJ) a nerve impulse reaching the nerve terminal initiates the release of acetylcholine (ACh) into the synaptic cleft. ACh binds to ACh receptors on the postsynaptic (muscle) membrane, inducing a conformational change and ion flux that results in muscular contraction. Presynaptic NMJ disorders that interfere with the release of ACh from the nerve terminal result in general-

ized LMN signs of weakness and hyporeflexia similar to disorders affecting peripheral nerves. Myasthenia gravis is a postsynaptic disorder that causes partial failure of neuromuscular transmission, resulting in weakness with normal spinal reflexes, similar to the muscle disorders discussed in Chapter 72.

## **FOCAL NEUROPATHIES**

# TRAUMATIC NEUROPATHIES

Traumatic neuropathies are common. They result from mechanical blows, fractures, pressure, stretching, laceration, and the injection of agents into or adjacent to the nerve. Diagnosis is usually straightforward and is based on the history and clinical findings. Individual nerves or a group of adjacent nerves may be damaged. Traumatic radial nerve paralysis, complete avulsion of the entire brachial plexus, and sciatic nerve injury are most common in the dog and cat (Table 71-1; Fig. 71-1).

Electrodiagnostic testing, when available, can be used to evaluate the extent of nerve damage. In 5 to 7 days after denervation of a muscle, electromyography detects denervation action potentials (i.e., increased insertional activity and spontaneous action potentials) in the muscles normally supplied by the damaged nerve (see Table 71-1). Nerve conduction studies proximal and distal to the site of injury are also useful in assessing nerve integrity.

When an animal is presented with a peripheral nerve injury, careful mapping and assessment of cutaneous sensation and motor function help determine the precise location of the injury, and sequential mapping can be used to monitor progress (Fig. 71-2). The regenerative ability of a nerve is proportional to the continuity of connective tissue structures remaining around the damaged portion of the nerve. If adequate connective tissue scaffolding is left, axonal regeneration can occur at a rate of 1 to 4 mm/day. Severed nerve ends should be surgically brought into apposition and anastomosed to increase the likelihood of regeneration. The closer a nerve injury is to the innervated muscle, the better the chances are of recovery.

TABLE 71-1

Traumatic Neuropathies

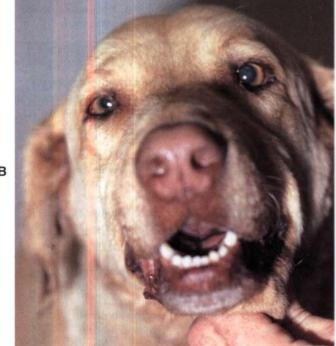

PERIPHERAL NERVES DAMAGED	MOTOR DYSFUNCTION	SKIN REGION OF SENSATION LOSS	MUSCLES AFFECTED
Lesions of Nerves of the B	rachial Plexus		
Peripheral radial nerve damage (at level of elbow)	Loss of carpus and digit extension; may walk on dorsal paw or carry limb	Cranial and lateral forearm and dorsal forepaw	Extensor carpi radialis, ulnaris lateralis, extensors
Brachial plexus avulsion (j	proximal damage)		
Suprascapular nerve ([C5]),C6,C7	Loss of shoulder extension; muscle atrophy over scapular spine	None	Supraspinatus, infraspinatus
Axillary nerve ([C6],C7,C8)	Reduced shoulder flexion. Deltoid muscle atrophy	Lateral brachium over humerus and scapula	Deltoideus, teres major, teres minor, subscapularis
Musculocutaneous (C6,C7,C8)	Reduced elbow flexion	Medial forearm	Biceps brachii, brachialis, nerve coracobrachialis
Radial nerve (C7,C8,T1,[T2])	Reduced extension of elbow, carpus, and digits; cannot support weight	Cranial and lateral forearm and foot (except digit 5)	Triceps brachii, extensor carpi radialis, ulnaris lateralis, digital extensors
Median nerve (C8T1[T2])	Reduced flexion of carpus and digits	None	Flexor carpi radialis, digital flexors
Ulnar nerve (C8T1[T2])	Reduced flexion of carpus and digits	Caudal forearm distal to elbow, 5 <sup>th</sup> digit	Flexor carpi ulnaris, deep and digital flexors
Lesions of Nerves of the L	umbosacrai Plexus		
Femoral nerve damage L4,L5,L6	Inability to extend stifle. Cannot support weight. Atrophy of quadriceps Loss of patellar reflex	Medial limb (toes to thigh)	lliopsoas, quadriceps, sartorius
Obturator nerve ([L4],L5,L6)	Abduction of limb at hip	None	External obturator, pectineus gracilis, adductor
Sciatic nerve paralysis (L6,L7,S1,[S2])	Reduced flexion and extension of hip; loss of stifle flexion; loss of hock flexion and extension; hock dropped; paw is knuckled but weight bearing does occur; absent withdrawal reflex; atrophy of cranial, tibial, semimembranosus, and semitendinosus muscles	All regions below stifle except medial surface	Biceps femoris, semimembranosus, semitendinosus
Tibial branch (L7, S1,[S2])	Dropped hock	Plantar paw and limb distal to stifle	Gastrocnemius, popliteus, digital flexors
Peroneal branch (L6,L7,S1,S2) Cranial and caudal gluteal (L7,S1,S2)	Stands knuckled; no cranial tibial reflex; weak hock flexion Reduced hip flexion; stifle rotates laterally during weight bearing	Cranial and lateral limb (distal to stifle)) None	Peroneus longus, digital extensors, cranial tibial Superficial, middle, and deep gluteals, tensor fascia lata

Physical therapy such as swimming, limb manipulation, heat therapy, and massage help delay muscle atrophy and tendon contracture and speed return of function in animals with incomplete lesions. Self-mutilation may become a problem 2 to 3 weeks after injury because regeneration of sensory nerves can result in abnormal sensation lasting 7 to 10 days. Lack of improvement in motor function after 1 month warrants consideration of amputation of the affected limb or, when feasible, arthrodesis for limb salvage.

#### PERIPHERAL NERVE SHEATH TUMORS

Tumors of nerve sheath origin arise from cells surrounding the axons in peripheral nerves or nerve roots. Most of these tumors are anaplastic with a high mitotic index and aggressive biological behavior and are therefore classified as malignant peripheral nerve sheath tumors (PNSTs) regardless of their cell of origin. These tumors are a relatively common cause of lameness and neuropathy when they involve the nerves of the brachial plexus. Lymphoma may also involve

**A,** Traumatic brachial plexus avulsion in a Chesapeake Bay Retriever. **B,** Horner's syndrome in the same dog.

the nerve roots or peripheral nerves of dogs and cats (Fig. 71-3).

#### **Clinical Features**

Clinical signs depend on tumor location and the nerves involved. Trigeminal nerve sheath tumors cause ipsilateral atrophy of the temporalis and masseter muscles. Malignant PNSTs in dogs most commonly affect the caudal cervical (C6-C8) or cranial thoracic (T1-T2) nerve roots of the brachial plexus, resulting in lameness, muscle atrophy, pain, and lifting of the affected leg (root signature). The insidious onset of these tumors may make it difficult to differentiate them from lameness caused by a vague musculoskeletal injury or nerve root compression caused by intervertebral disk disease. With progression of the tumor, atrophy, weakness, and loss of reflexes may occur as the affected peripheral

Mapping the region of sensory loss is important in localizing lesions and monitoring improvement. This dog has a caudal brachial plexus avulsion, so he has lost superficial sensation on the limb distal to the elbow.

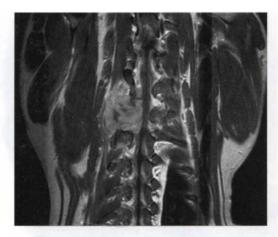

FIG 71-3
Dramatic muscle atrophy and sensory loss in a cat with lymphoma involving the L6-S1 nerve roots.

nerve is destroyed. Tumors involving the T1-T3 nerve roots commonly interrupt the sympathetic pathway and result in ipsilateral Horner's syndrome. Similarly, the ipsilateral cutaneous trunci reflex will be absent if the C8-T1 ventral nerve roots are damaged. Tumors originating in the spinal canal and extending peripherally and tumors originating in the brachial plexus and extending proximally into the vertebral canal will often cause upper motor neuron (UMN) deficits in the ipsilateral hindlimb as the tumor expands, but this may not be clinically apparent until significant spinal invasion has taken place.

#### Diagnosis

Radiographs of the spine are indicated if a neoplasm involving a spinal nerve root is suspected. Nerve sheath tumors rarely cause bony changes, although expanding tumors that pass through an intervertebral foramen may cause widening of the foramen as a result of pressure necrosis. Myelography can be useful to identify spinal cord compression.

Magnetic resonance imaging (MRI) of the spine of a dog with a nerve root tumor causing lameness, and lowor motor neuron paresis of the right forelimb reveals invasion of the tumor into the vertebral canal.

Electromyography and nerve conduction velocity determinations may confirm the presence of a peripheral nerve lesion and aid in localization. Deep palpation of the axilla under general anesthesia and ultrasound examination may reveal a mass. Advanced diagnostic imaging (i.e., computed tomography [CT], magnetic resonance imaging [MRI]), when used with contrast enhancement, is the best way to delineate tumor masses and detect vertebral canal invasion (Fig. 71-4).

# **Treatment**

The treatment of choice for a PNST is surgical removal. Aggressive removal of distally located tumors can result in a cure. Extensive neurologic damage by the tumor, damage affecting several spinal nerves or nerve roots, or severely atrophied muscles usually require amputation of the limb. Nerve root tumors that have progressed to cause spinal cord compression usually involve multiple nerve roots, are rarely completely resectable, and are associated with a poor prognosis. Postoperative irradiation may be indicated in an attempt to slow tumor recurrence.

# **FACIAL NERVE PARALYSIS**

Facial nerve (CN7) paralysis is recognized frequently in dogs and cats. In 75% of dogs and 25% of cats with acute facial nerve paralysis, there are no associated neurologic or physical abnormalities and no underlying cause can be found, prompting a diagnosis of idiopathic facial nerve paralysis. Canine hypothyroidism is occasionally associated with a mononeuropathy involving the facial nerve, but the causality is uncertain. Traumatic injury to the facial nerve can also occur at the level of the brainstem or peripherally as the nerve courses through the petrous temporal bone.

The most common identifiable cause of facial nerve paralysis, however, is damage to branches of the facial nerve within the middle ear secondary to inflammation, infection,

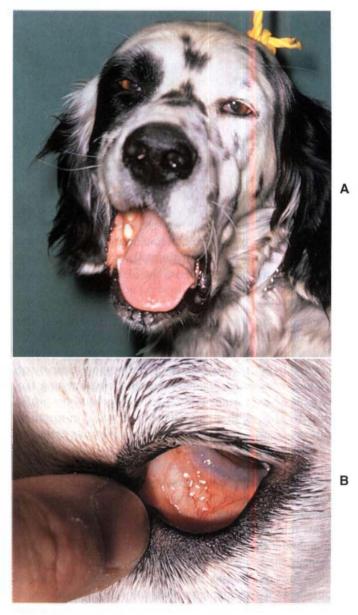

FIG 71-5
Idiopathic facial nerve paralysis in a 4-year-old English
Setter. Note the drooping lip and ear (A) and the inability
to blink (B). The paralysis resolved in 14 days without
therapy.

or neoplasia. Otitis media and otitis interna usually result from extension of bacterial otitis externa, particularly in breeds predisposed to chronic bacterial otitis externa (e.g., Cocker Spaniels, German Shepherd Dogs, and Setters. Foreign bodies (e.g., grass awns), malignant tumors (in both dogs and cats), and benign nasopharyngeal polyps (in cats) involving the middle ear can also cause facial nerve paralysis.

#### **Clinical Features**

Clinical manifestations of facial nerve paralysis include an inability to close the eyelid, move the lip, or move the ear.

Affected animals are unable to blink spontaneously or in response to visual or palpebral sensory stimulation. Corneal ulceration may occur because of an inability to distribute the tear film by blinking (neuroparalytic keratitis) and loss of facial nerve (parasympathetic)-stimulated lacrimal gland secretion (neurogenic keratitis). Drooping of the ear and lip as a result of loss of muscle tone on the affected side is common (Fig. 71-5). Many dogs and cats with facial nerve paralysis caused by middle ear disease also develop peripheral vestibular signs and/or Horner's syndrome because of the close proximity of the nerves in the area of the middle and inner ear. Rarely, a painful syndrome of hemifacial spasm with facial muscle contracture and lip retraction may occur as a result of facial nerve irritation. This should be differentiated from nonpainful muscle atrophy and contracture, which occur relatively commonly in animals with longstanding facial nerve paralysis (Fig. 71-6).

# **Diagnosis**

Idiopathic facial nerve paralysis can be diagnosed only after excluding all other causes. A complete neurologic examination should be performed to ensure that there are no other cranial nerve deficits, ataxia, or proprioceptive deficits suggesting a brainstem lesion. Clinicopathologic testing (i.e., complete blood count [CBC], serum biochemistry profile, urinalysis) is required to evaluate for systemic or metabolic disease. A suspicion of hypothyroidism warrants evaluation of thyroid function (see Chapter 51).

All dogs and cats with facial nerve paralysis should be evaluated carefully for disease of the middle and inner ear. Careful otoscopic examination is important, even if general anesthesia is required. Most animals with otitis media or otitis interna have obvious otitis externa and a tympanic membrane that appears abnormal or ruptured, but occasionally the otoscopic examination is normal. If the suspicion for middle and inner ear disease is high, general anesthesia for radiographs, advanced imaging, and myringotomy to collect a sample from the middle ear are warranted (Fig. 71-7).

#### **Treatment**

No treatment exists for idiopathic facial nerve paralysis. If keratoconjunctivitis sicca is present, the eye should be medicated as needed. The paralysis may be permanent, or spontaneous recovery may occur in 2 to 6 weeks.

If evaluation of the middle and inner ear reveals bony lysis or extensive soft tissue proliferation, this suggests that neoplasia could be the cause of facial nerve paralysis. A biopsy should be performed, and surgery to debulk or remove the tumor should be considered. The prognosis for cure with feline benign inflammatory nasopharyngeal polyps in this location is excellent. Tumors of the bulla, bony labyrinth, ear canal, or peripheral nerve are less likely to be treated effectively using surgery alone. Radiotherapy or chemotherapy may be beneficial in some cases.

Medical treatment of dogs and cats with bacterial otitis media and otitis interna is discussed in Chapter 68.

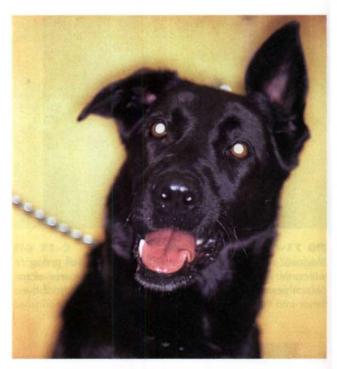

FIG 71-6
Contraction of the muscles on the left side of the face developed in an adult dog with a 2-month history of idiopathic left-sided facial nerve paralysis. Note the erect left ear and nasal deviation to the left.

#### TRIGEMINAL NERVE PARALYSIS

Bilateral motor paralysis of the trigeminal nerves results in the sudden onset of an inability to close the jaw or prehend food. The mouth hangs open, but it can be physically closed and manipulated without resistance (Fig. 71-8). Swallowing is usually normal. Severe rapid atrophy of the muscles of mastication may occur, and a few animals display concurrent Horner's syndrome. Sensory loss (trigeminal distribution) is variable, but if hyposensitization of the corneal surface occurs, there will be decreased reflex tear formation and loss of trophic factors, leading to corneal ulceration without significant discomfort (neurotrophic keratitis).

Idiopathic trigeminal paralysis is seen in middle-aged and older dogs and rarely in cats. The diagnosis relies on clinical signs and on ruling out other possible causes. Rabies and other inflammatory central nervous system (CNS) diseases are unlikely in the absence of other clinical signs. Neoplastic and traumatic disorders are not usually bilateral, although bilateral motor trigeminal nerve infiltration has been reported in a dog with multicentric lymphoma.

The etiology of this idiopathic disorder is unknown. If biopsy of the nerve is performed, it reveals bilateral nonsuppurative neuritis of all motor branches of cranial nerve 5 associated with demyelination. Treatment consists of supportive care. Most dogs can drink and maintain adequate hydration if they are given water in a deep container, such as a bucket. Hand-feeding may be necessary. Holding the mouth partially closed in a sling may facilitate eating and drinking

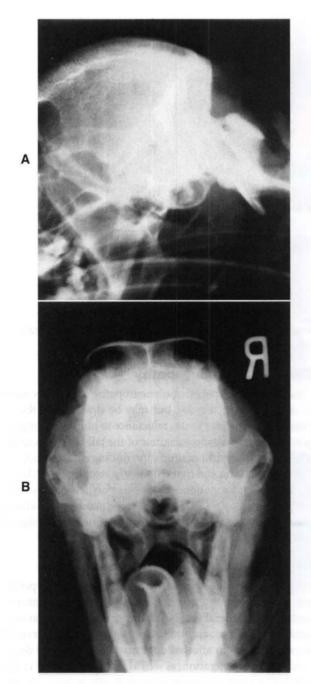

FIG 71-7
Skull radiographs of a 4-year-old Cocker Spaniel with bilateral otitis media resulting in bilateral facial nerve paralysis. Both bullae chambers are opacified, and the left bulla is thickened by irregular and slightly indistinct new bone.

during recovery (Fig. 71-9). Lubricating eye ointments may help prevent corneal ulceration. The prognosis is excellent, with most animals recovering completely within 2 to 4 weeks.

#### **HYPERCHYLOMICRONEMIA**

Peripheral neuropathies have been observed in cats of all ages with a mutation in the gene encoding lipoprotein lipase.

FIG 71-8
Idiopathic trigeminal nerve motor paralysis resulting in a dropped jaw and excessive drooling in a 9-year-old Labrador Retriever. The paralysis resolved in 14 days without therapy.

Affected cats have delayed clearance of chylomicrons from the circulation, resulting in the formation of lipid granulomas (xanthomas) in the skin and other tissues. These xanthomas may compress a nerve against bone, resulting in neuropathology. Horner's syndrome and tibial and radial nerve paralysis are most often seen. Clinicopathologic testing reveals fasting hyperchylomicronemia and blood that looks like cream-of-tomato soup. Diagnosis is by biopsy of the xanthomas or measurement of lipoprotein lipase concentration. The neurologic signs are reversible if hyperchylomicronemia can be controlled by feeding affected cats a low-fat diet (see Chapter 54).

#### ISCHEMIC NEUROMYOPATHY

Caudal aortic thromboembolism causes paralysis from ischemic damage to affected muscles and peripheral nerves. Ischemia is caused by vasoconstriction of the collateral circulation to the limbs as a result of release of thromboxane A2 and serotonin from platelets in a clot lodged in the aortic trifurcation. Caudal aortic thromboembolism is common in cats and rare in dogs. An acute onset of LMN pelvic limb paralysis or paresis is seen. Femoral pulses are weak or absent. The legs and feet are cool, and the pads are no longer pink (Fig. 71-10). Hemorrhage does not occur when a toenail is cut short on an affected foot. The affected muscles are swollen and painful. LMN paralysis with complete areflexia of the rear limbs are common, although occasionally the patellar reflex is maintained. Within hours, rigid extension of the legs may occur as a result of contracture of ischemic muscle. In cats cardiomyopathy is most common. In dogs a disorder associated with hypercoagulability can usually be identified (see Chapter 12), and the dog should be evaluated for nephrotic syndrome, hyperadrenocorticism, heartworm disease, neoplasia, and endocarditis. Treatment of feline aortic thromboembolism is discussed in Chapter 12.

FIG 71-9
The use of sling to support the jaw and hold the mouth partially closed can help dogs with idiopathic trigeminal motor paralysis to eat.

# **POLYNEUROPATHIES**

# CONGENITAL/INHERITED POLYNEUROPATHIES

A number of breed-associated degenerative peripheral neuropathies occur. They usually affect young animals and are presumed to have a hereditary basis. Most of these disorders cause progressive generalized LMN dysfunction with severe tetraparesis, muscle atrophy, and hyporeflexia. Pathologic lesions vary with each disorder but may involve the motor neurons in the ventral horn of the spinal cord, ventral nerve roots, or peripheral nerves. In Rottweilers, Dalmatians, and Great Pyrenees, concurrent laryngeal paralysis is common. Certain inherited storage diseases will cause CNS signs as well as diffuse LMN paresis. Familial sensory neuropathies causing diminished sensation /nociception and self-mutilation (English Pointers) and sometimes mild ataxia and loss of proprioception (Longhaired Dachshunds) can also occur. All of these conditions are extremely rare and are reviewed in detail in Suggested Readings. Presumptive diagnosis is by recognition of typical breed and age of onset and presentation and ruling out of other disorders. Definitive diagnosis requires electrophysiological evaluation of nerve function and nerve biopsy.

# ACQUIRED CHRONIC POLYNEUROPATHIES

Polyneuropathies affect more than one group of peripheral nerves, resulting in generalized LMN signs that include flaccid muscle weakness or paralysis, marked muscle atrophy, decreased muscle tone, and reduced or absent reflexes. Proprioceptive deficits may be evident if the sensory portions of the nerves are severely affected. Electromyography, when available, reveals evidence of denervation, and nerve conduction velocity is decreased in affected nerves. Nerve biopsies typically reveal axonal degeneration and demyelination regardless of the underlying cause, so a thorough systemic investigation of possible etiologies is required to

reach a diagnosis and recommend appropriate treatment (Box 71-1).

# **Diabetic Polyneuropathy**

Clinical signs of diabetic polyneuropathy are usually subtle or inapparent in the dog but may be dramatic in the cat. Weakness of the rear limbs, reluctance to jump, a plantigrade pelvic limb stance, and weakness of the tail are characteristic (Fig. 71-11). Physical examination findings may include rear limb hyporeflexia and marked muscle atrophy. (See Chapter 52 for more information.) If diabetic polyneuropathy is recognized early, establishing improved glucose regulation can result in stabilization or improvement of neurologic signs in some cats.

## Hypothyroid Polyneuropathy

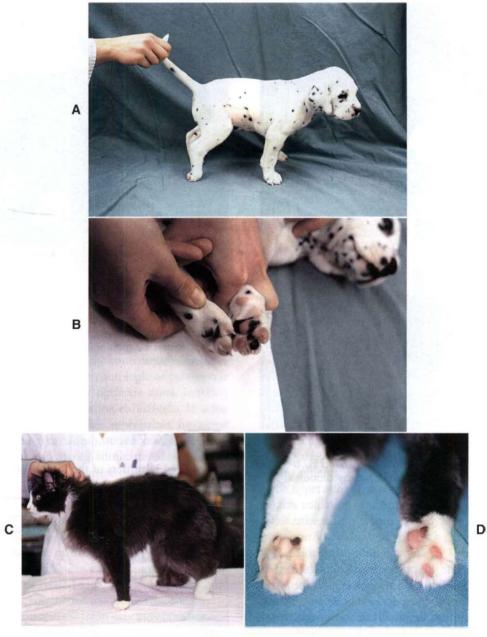

Hypothyroidism has been associated with a variety of peripheral nerve abnormalities, including diffuse LMN paralysis, unilateral peripheral vestibular disease, facial nerve paralysis, laryngeal paralysis, and megaesophagus in dogs. Nerve and muscle biopsies in affected dogs may show neuronal degeneration and regeneration, as well as muscle fiber type grouping that is most indicative of neurogenic atrophy. In some hypothyroid dogs neurologic signs resolve once supplementation with thyroid hormone is initiated (Fig. 71-12). (See Chapter 51 for more information).

## **Insulinoma Polyneuropathy**

Insulin-secreting tumors have been associated with a paraneoplastic polyneuropathy in dogs. Affected dogs may initially have a stiff rear limb gait, but this progresses to generalized weakness, muscle atrophy, and hyporeflexia. Treatment of the insulinoma may result in resolution of the polyneuropathy. (See Chapter 52 for more information.)

# **Paraneoplastic Polyneuropathy**

Although clinically significant paraneoplastic neuropathies are infrequently recognized in dogs and cats, histologic

#### FIG 71-10

**A**, Acute, severe lower motor neuron paralysis of the rear limbs occurred in this 6-week-old Dalmatian puppy. The limbs were cool, and no femoral pulses were palpable. **B**, The footpads on the front feet were warm and pink, whereas those on the rear feet were cool and pale. Ultrasound examination revealed a caudal aortic thrombus. **C**, Acute lower motor neuron paralysis in the left hindlimb of a 9-year-old cat caused by an iliac artery thrombus. **D**, The left hindlimb was cool, had no palpable femoral arterial pulse, and had pale footpads.

lesions of polyneuropathy are evident in most dogs with cancer. LMN paresis caused by paraneoplastic polyneuropathy has been reported in dogs with bronchogenic carcinoma, hemangiosarcoma, mammary carcinoma, pancreatic carcinoma, prostatic carcinoma, lymphoma, and multiple myeloma. Complete systemic evaluation and cancer search (thorough physical examination, thoracic and abdominal radiographs, abdominal ultrasound, lymph node aspirates)

are warranted in all animals presented for chronic progressive LMN dysfunction. In some cases treatment or removal of the offending neoplasm is associated with resolution of the clinical signs of polyneuropathy.

# **Immune-Mediated Polyneuritis**

Polyneuritis can occur as a primary immune-mediated disorder or as a component of a systemic immune-mediated

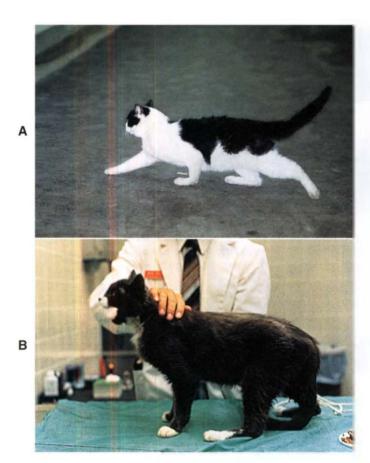

FIG 71-11
Plantigrade stance in A, an 11-year-old cat, and B, a 6-year-old cat with polyneuropathy caused by diabetes mellitus.

disease such as systemic lupus erythematosus (SLE; Fig. 71-13). Weakness and exercise intolerance may be the initial manifestations, followed by progressive muscle atrophy and hyporeflexia. Some animals have concurrent cranial nerve dysfunction. Tests should be performed to eliminate endocrine and neoplastic causes of neuropathy and to investigate other systemic manifestations of immune-mediated disease. Screening tests should include evaluation of a CBC, measurement of protein in the urine (i.e., protein : creatinine ratio), and analysis of synovial fluid. Skin lesions, if present, should be biopsied, and blood should be submitted for an antinuclear antibody (ANA) titer. Immunosuppressive therapy should be initiated using prednisone and azathioprine. The short-term prognosis for recovery may be good, but there is a tendency for these disorders to relapse and progress over time.

## **Idiopathic Polyneuropathy**

Demyelinating polyneuropathies with no known etiology have been observed in dogs and cats. Systemic evaluation does not reveal an underlying cause. Often, they are treated as an immune-mediated disorder, with no response.

FIG 71-12
Plantigrade stance and weak gait in a 6-year-old Newfoundland with severe hypothyroid neuropathy. All neurologic signs and weakness resolved, and the dog lost 60 pounds within 12 months of thyroid hormone supplementation.

The dog also had dermatitis, polyarthritis, glomerulonephritis, and a positive antinuclear antibody test. Polyneuritis was confirmed on postmortem examination.

#### **Ehrlichiosis**

Rarely, dogs are identified with a mononeuropathy or polyneuropathy and concurrent positive serologic or polymerase chain reaction (PCR) testing for Ehrlichia canis, but they have no other clinical signs indicating ehrlichiosis. In some dogs the neuropathy resolves after appropriate treatment with doxycycline (5 mg/kg, administered orally q12h) or imidocarb dipropionate (5 mg/kg, administered twice intramuscularly, 14 days apart). Definitive evidence for a causative relationship is lacking.

# **Delayed Organophosphate Intoxication**

Some toxins, including organophosphates, heavy metals, and industrial chemicals, can cause peripheral nerve damage. Organophosphates, in particular, can have a delayed neurotoxic effect that may be related to their inhibition of neurotoxic esterase, an enzyme necessary for nutrient transport within neurons. Exposure to the toxin may have been a single severe exposure with clinical signs of acute intoxication or chronic mild to moderate exposure repeated over weeks or months without acute signs. Between 1 and 6 weeks after exposure a neuropathy develops. Affected animals are weak but do not have classic autonomic signs of organophosphate intoxication, such as salivation, vomiting, diarrhea, or miosis. With chronic exposure, hair, blood, fat, or liver samples may contain the toxin. Plasma acetylcholinesterase activity is usually low. Toxic neuropathy may be suspected on the basis of nerve biopsy results. Spontaneous improvement should occur in 3 to 12 weeks, provided that the toxic substance is removed and reexposure is prevented.

# **ACQUIRED ACUTE POLYNEUROPATHIES Acute Polyradiculoneuritis**

Acute canine polyradiculoneuritis (ACP) is the only acute polyneuropathy commonly diagnosed in dogs. The disease

affects dogs of any breed and gender, and most affected dogs are adults. A similar disease occurs rarely in cats.

The popular name Coonhound paralysis originates in the fact that in many of the early cases the syndrome developed 7 to 10 days after hunting dogs were bitten by a raccoon. Although raccoon saliva injection does not reliably produce the disorder, it has been shown that in a few susceptible dogs the disorder results from an immune response against some component of raccoon saliva (Fig. 71-14).

Acute polyradiculoneuritis also occurs in many dogs with no possible exposure to raccoons. Previous systemic illness or vaccination (particularly rabies vaccination) has been implicated as an initiating factor in some of these cases, but in most cases no initiating factor can be identified. The pathologic manifestations include extensive demyelination, inflammatory cell infiltration, and disruption of the ventral root components of peripheral nerves. The disease is very similar to allergic neuritis and Guillain-Barre syndrome in humans, making an immunologic pathogenesis suspect.

#### **Clinical Features**

The first clinical sign may be a change in character of the bark; affected dogs sound hoarse. They also develop a stilted, short-strided gait with severe weakness in the rear limbs that ascends rapidly to involve all limbs. Some dogs retain voluntary movement, but most progress to complete paralysis within 5 to 10 days of onset. Neurologic examination reveals remarkably decreased muscle tone, severely diminished or absent reflexes, and rapid muscle atrophy. Some dogs seem to be hyperesthetic, reacting vigorously to mild stimulation such as palpation of the muscles or pinching of the toes. This hyperesthesia is a feature of polyradiculoneuritis that does not occur in association with tick paralysis or botulism, the two major differential diagnoses. Despite the severe paresis or paralysis, dogs remain bright and alert, continue to eat and drink when supported, and can wag their tail vigorously. Bladder and rectum functions remain normal. As a rule, cranial nerves are not involved; no problems with chewing or swallowing exist; neither do any pupillary abnormalities. A small percentage of very severely affected dogs have concurrent bilateral facial nerve paralysis. In a few dogs respiratory paralysis can lead to death.

#### **Diagnosis**

The diagnosis is suspected on the basis of clinical and neurologic findings. The most important and challenging aspect of diagnosis is differentiating this disorder from NMJ disorders causing acute LMN tetraparesis (tick paralysis, botulism, and acute fulminating myasthenia gravis) using clinical features and (when available) electrodiagnostic testing (Table 71-2). Owners should be questioned regarding any possible inciting event or exposure 7 to 14 days earlier. Normal cranial nerve and esophageal function and the presence of hyperesthesia make ACP most likely. Cerebrospinal fluid (CSF) is usually normal, although a mild increase in protein concentration may occur. Electromyography reveals diffuse dener-

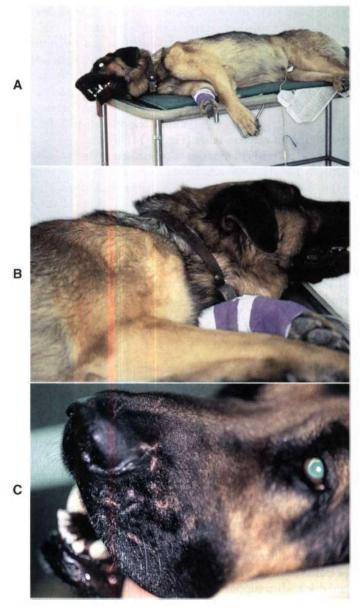

FIG 71-14

A 4-year-old German Shepherd Dog with (A) rapidly progressive ascending lower motor neuron paralysis, (B) severe appendicular muscle atrophy, and (C) healing facial wounds presumed to be from an encounter with a raccoon. The tentative diagnosis in this dog was acute polyradiculoneuritis. Supportive care was initiated, and the dog returned to normal after a prolonged recovery lasting 3 months.

vation (spontaneous activity) after 6 or more days of paralysis, a finding not expected with the NMJ disorders. Definitive diagnosis can also be established by nerve biopsy, but this is rarely necessary.

#### **Treatment**

No specific treatment exists for this disorder. During the initial progressive phase dogs must be monitored for respiratory compromise. Signs typically stabilize after 5 to 10 days, after which the patients can usually be managed with supportive care at home. They may require assistance in sitting up to eat and drink. If possible, they should be kept on an air mattress, waterbed, lounge chair, or bed of straw and turned periodically to prevent lung atelectasis and pressure sores. Corticosteroid treatment is not beneficial.

#### **Prognosis**

The prognosis for recovery is good. Most dogs begin to improve after the first week and are fully recovered within 2 to 4 weeks. Recovery may take 4 to 6 months in severely affected dogs. Some dogs never recover completely, and the prognosis for complete recovery in the cat is poor. Affected animals that have recovered may be prone to recurrences, particularly if exposed again to the initiating antigen.

# **Neospora Polyradiculoneuritis**

**Adult dogs.** Neosporosis can cause a wide range of signs in adult dogs, depending on the site of infection within the nervous system. Paraparesis, tetraparesis, cerebellar signs, muscle pain, seizures, and cranial nerve abnormalities are all reported. Rarely, a rapidly progressive LMN paralysis similar to acute idiopathic polyradiculoneuritis has been reported. Definitive diagnosis is based on a positive serum test for anti-Neospora caninum antibodies, and occasionally the organism can be demonstrated within muscle or nerve biopsies by immunohistochemistry (see Table 69-1). Treatment with clindamycin hydrochloride (10 mg/kg PO q8h for at least 4 weeks) is most effective.

**Puppies.** Young puppies infected transplacentally by *N*. caninum begin showing signs of LMN paraparesis between 6 weeks and 6 months of age. Inflammation of ventral nerve roots and peripheral nerves in the rear limbs results in progressive rear limb weakness, muscle atrophy, and hyporeflexia. Over a period of weeks these LMN signs progress to severe pelvic limb extension as muscle atrophy and fibrosis lock the pelvic limbs in extensor rigidity (see Chapter 69, p. 1062; see also Figs. 69-4 and 69-5). Diagnosis should be suspected on the basis of typical history, clinical, and neurologic findings in a young puppy. Litter mates are often affected. There may be mild to moderate elevations in serum creatine kinase (CK) and aspartate aminotransferase (AST) if muscles are involved. Diagnosis and treatment are as described for adult dogs, with most affected puppies having positive serology and organisms identified in muscle biopsies. Multifocal signs, rapid progression of signs, pelvic limb rigid hyperextension, and delayed treatment are all associated with a poor prognosis for recovery.

# DISORDERS OF THE **NEUROMUSCULAR JUNCTION**

#### TICK PARALYSIS

A flaccid, rapidly ascending motor paralysis has been recognized in dogs infested with certain species of ticks. Most of the reported cases in North America are associated with

TABLE 71-2

Clinical and Diagnostic Differences Between Disorders Causing Rapidly Progressive Lower Motor Neuron Tetraparesis in the Dog

DISEASE	WEAKNESS	MUSCLE TONE	SPINAL REFLEXES	MUSCLE ATROPHY	CRANIAL NERVES	SENSATION	CSF	EMG
Acute Canine Polyradiculoneuritis (Coonhound paralysis)	Generalized weakness, often progressing to paralysis within 5 to 10 days	Decreased	Decreased or absent	Rapid and severe	Hoarse bark Able to eat and drink normally Rarely facial paresis	Hyperesthetic	Normal or increased protein	Denervation after 4-5 days
<ul><li>Tick Paralysis</li><li>Geographic potential for exposure</li><li>Rapid recovery following tick removal</li></ul>	Generalized weakness, rapid progression	Decreased	Decreased or absent	None	Hoarse bark Dysphagia Facial paresis Decreased jaw tone	Normal	Normal	Normal
Botulism — Often a group outbreak	Generalized weakness, often progressing to paralysis within 24 hours	Decreased	Decreased or absent	None	Hoarse bark Dysphagia, mega-esophagus Facial paresis Decreased jaw tone Dilated pupils, absent PLR	Normal	Normal	Normal
Acute Fulminating Myasthenia Gravis  — Some (50%) respond to Tensilon administration (see Box 71-2)	Generalized weakness but maintains ability to move	Decreased	Normal	None	Hoarse bark  Dysphagia, mega-esophagus, aspiration pneumonia  Facial nerve paresis (+/-), fatiguable palpebral reflex	Normal	Normal	Normal

selected strains of *Dermacentor andersoni*, *Dermacentor variabilis*, or *Amblyomma americanum* ticks. The feeding of a female tick results in the elaboration and circulation of a salivary neurotoxin that interferes with acetylcholine release at the neuromuscular junction. Signs occur within 4 to 9 days after tick attachment.

#### **Clinical Features**

Dogs with tick paralysis exhibit a rapid progression from pelvic limb weakness to recumbency, usually resulting in complete LMN paralysis. Muscles are flaccid, and spinal reflexes are decreased or absent. Muscle atrophy does not occur. Pain is perceived normally, with no evidence of hyperesthesia. In most cases the cranial nerves are not significantly affected, but facial weakness, an altered voice, dysphagia, or decreased jaw tone may be recognized. Muscles of respiration may become paralyzed in severely affected patients.

#### Diagnosis

This disease can be confused with other causes of acute tetraparesis such as acute polyradiculoneuritis, botulism, and myasthenia gravis (see Table 71-2). Tick paralysis is diagnosed on the basis of the history, clinical signs, and knowledge of the geographic region. Sometimes a tick can be found on the animal, and diagnosis is confirmed by documenting rapid improvement after tick removal. When electromyography is available, there is no evidence of denervation. Diminished amplitude of the muscle action potential occurs in response to a single supramaximal stimulus, as would be expected with a defect in neuromuscular transmission.

#### **Treatment**

Removal of a tick or dipping the animal in an insecticidal solution results in dramatic recovery within 24 to 72 hours. The prognosis for complete recovery is good when the proper diagnosis is made.

#### **BOTULISM**

Botulism is rarely recognized in dogs and has not been clinically seen in cats. It results from the ingestion of spoiled food or carrion containing a preformed type C neurotoxin produced by the bacterium *Clostridium botulinum*. Only very small amounts of toxin are needed to cause clinical signs. This toxin blocks the release of acetylcholine from the neuromuscular junction, resulting in complete LMN paralysis. Clinical signs occur hours to days after ingestion of the toxin.

#### **Clinical Features**

Affected dogs are weak and develop a short-strided, shuffling gait that rapidly progresses to recumbency. Muscle tone is poor and spinal reflexes are absent, but the tail wag is preserved. Proprioception and pain perception are normal, without hyperesthesia. Affected dogs often have cranial nerve dysfunction resulting in dilated pupils, loss of the pupillary light reflex, weak voice/bark, facial weakness, decreased jaw tone, and dysphagia. Regurgitation resulting from megaesophagus is common. The amount of ingested toxin deter-

mines severity of signs. Clinical signs can last for weeks, and death can occur if respiratory muscles are impaired.

# **Diagnosis**

The diagnosis is based on clinical findings and/or a history of ingestion of spoiled food. Botulism is especially likely if an outbreak of LMN paralysis is seen in a group of dogs. Rabies must be considered as a differential diagnosis in severely affected dogs, but it is usually associated with abnormal mentation. Weakness of the muscles of the face, jaw, and pharynx is much more pronounced with botulism than would be expected with acute polyradiculoneuritis or tick paralysis. When electromyography is available, it reveals the absence of spontaneous activity (no denervation potentials) and diminished amplitude of the muscle action potential in response to a supramaximal stimulus, similar to tick paralysis. Botulinum toxin (type C) may be demonstrated in the blood, vomitus, feces, or stomach contents of affected dogs.

#### **Treatment**

No specific treatment for botulism exists. The administration of laxatives and enemas may help remove unabsorbed toxin from the gastrointestinal tract if ingestion was recent. Administration of commercially available human trivalent antitoxin (types A, B, and E) will not be effective. If Type C antitoxin is available, administration of 10,000 units intramuscularly twice, 4 hours apart, is recommended, but this will simply bind and inactivate circulating toxin that has not yet penetrated nerve endings. Most dogs recover in 1 to 3 weeks with supportive care, although aspiration pneumonia is a common complication during recovery.

# **MYASTHENIA GRAVIS**

Myasthenia gravis (MG) is a neuromuscular disorder characterized by weakness that is exacerbated by exercise and alleviated by rest. Two forms have been described: congenital and acquired. The congenital form of MG results from an inherited deficiency of acetylcholine receptors (AChRs) at the postsynaptic membranes in skeletal muscle. Signs of impaired neuromuscular transmission first become evident in puppies or kittens 6 to 9 weeks old. The disorder has been recognized in English Springer Spaniels, Smooth Fox Terriers, and Jack Russell Terriers, with rare reports in other breeds and a few cats. An unusual, poorly classified transient congenital myasthenic syndrome has also been identified in Miniature Dachshunds; the signs in these dogs resolve with maturation.

The acquired form of MG is a common immunemediated disorder in which antibodies are directed against a portion of the nicotinic AChRs of skeletal muscle. Antibodies bind to the receptors, reducing the sensitivity of the postsynaptic membrane to the transmitter acetylcholine.

The acquired form of MG affects dogs of all breeds and both genders. German Shepherd Dogs, Golden Retrievers, Labrador Retrievers, and Dachshunds are most commonly affected, but this may merely reflect the popularity of these breeds. Breeds that seem to be at increased risk for acquired MG relative to their popularity include the Akita, some terrier breeds, German Shorthaired Pointers, and Chihuahuas. Young adult dogs (mean age, 2 to 3 years) and old dogs (mean age, 9 to 10 years), make up most of the affected population. Cats are rarely affected, but breed predispositions include the Abyssinian and Somali.

#### **Clinical Features**

The characteristic clinical abnormality in most animals with MG is appendicular muscle weakness that worsens with exercise and improves with rest. Mentation, postural reactions, and reflexes are normal, although reflexes may be fatiguable with repeated stimulation. Excessive salivation and regurgitation is common, caused by megaesophagus (seen in 90% of dogs with acquired MG). Megaesophagus is less common in cats with MG and in congenital MG. Dysphagia, hoarse character of the bark or meow, persistently dilated pupils, and facial muscle weakness are sometimes seen.

A focal form of MG occurs in approximately 40% of affected dogs and 14% of affected cats, causing megaesophagus with no detectable appendicular weakness. Affected dogs exhibit weakness of the pharyngeal, laryngeal, and/or facial muscles and may have a fatiguable palpebral reflex. Approximately 25% to 40% of all dogs with adult-onset megaesophagus suffer from acquired focal MG, so this disorder should always be considered as a differential diagnosis early in the course of evaluation of dogs with megaesophagus.

An acute, fulminating form of acquired MG has also been recognized, causing a rapid onset of severe appendicular muscle weakness. Affected animals are often unable to stand and cannot even raise their head. This form of MG is usually associated with severe megaesophagus and aspiration pneumonia. Profound muscle weakness and severe pneumonia commonly lead to respiratory failure and death.

## **Diagnosis**

MG should be considered as a differential diagnosis in any dog with generalized muscular weakness and in all dogs with acquired megaesophagus. Definitive diagnosis is made by demonstrating circulating antibodies against AChRs by immunoprecipitation radioimmunoassay. This test is readily available (Comparative Neuromuscular Laboratory, University of California, San Diego) and is positive in 85% of all dogs and cats with acquired disease and in 98% of those with generalized acquired disease. False-positive results have not been documented. Although the serum anti-AChR antibody titer does not correlate directly with the severity of clinical signs, dogs with focal MG tend to have lower titers and dogs with acute fulminating MG have the highest titers. Rarely, dogs with acquired MG are negative for circulating AChR antibodies, but immune complexes can be demonstrated in muscle biopsies at the NMJ using immunocytochemical methods. These dogs may have very-high-affinity antibody that remains bound to AChRs and does not circulate or antibodies directed against junctional antigens other than AChRs.

# BOX 71-2

Tensilon Test Protocol

- 1. Place an intravenous catheter.
- 2. Premedicate with atropine (0.04 mg/kg IM) to minimize muscarinic side effects.
- 3. Have equipment available for intubation and ventilation.
- 4. Exercise to the point of detectable weakness.
- Administer Tensilon (edrophonium chloride) IV: 0.1-0.2 mg/kg

When results of the serum test for antibodies are not yet available, or in animals with suspected congenital disease, support for the diagnosis of MG can be gained by demonstrating a positive response to administration of the ultrashort-acting anticholinesterase edrophonium chloride (Tensilon; Box 71-2). This drug inhibits enzymatic hydrolysis of ACh at the NMJ, increasing the effective concentration of ACh and the duration of its effect in the synaptic cleft, optimizing the opportunities for successful interactions between ACh and the AChRs. Most animals with MG exhibit obvious improvement in clinical signs (e.g., resolution of weakness) within 30 to 60 seconds after administration of edrophonium chloride, with the effect lasting approximately 5 minutes. Some dogs with other myopathic and neuropathic disorders may also show some minor improvement, but a dramatic unequivocal response is very suggestive of MG. A failure to respond does not rule out MG. The response can be difficult to assess in dogs and cats with focal MG, and approximately 50% of dogs with acute fulminating MG will have no response because there has been marked antibodymediated destruction of AChRs.

Electrodiagnostic testing (showing a decremental response of muscle action potentials to repetitive nerve stimulation) can be performed as an aid to reaching a definitive diagnosis of MG. However, whenever possible, anesthesia should be avoided in animals with megaesophagus because of the risk of aspiration during recovery.

Thoracic radiographs should be assessed for megaesophagus, aspiration pneumonia, or thymoma, and the animal should be evaluated systemically for underlying or associated immune-mediated and neoplastic disorders. If a cranial mediastinal mass is identified, fine-needle aspiration cytology should be used to confirm the suspicion that it is a thymoma—a tumor that has been identified in fewer than 5% of dogs with acquired MG and in more than 25% of cats. Concurrent immune-mediated disorders are common in dogs with MG, including hypothyroidism, immunemediated thrombocytopenia, immune-mediated hemolytic anemia, hypoadrenocorticism, polymyositis, and SLE. MG may also develop as a paraneoplastic disorder in association with a wide variety of tumors, including hepatic carcinoma, anal sac adenocarcinoma, osteosarcoma, cutaneous lymphoma, and primary lung tumors. Acquired drug-induced

MG has also been documented in hyperthyroid cats being treated with methimazole.

#### **Treatment**

Treatment of acquired MG includes supportive care and the administration of anticholinesterase drugs and occasionally immunosuppressive agents. Surgical removal of thymoma should be considered if identified because many animals with MG will have a decrease in AChR antibody titer and dramatic resolution of their signs after thymectomy. Animals with megaesophagus and regurgitation should be maintained in an upright position during feeding and for 10 to 15 minutes after feeding to facilitate the movement of esophageal contents into the stomach, decreasing the chance of aspiration (Fig. 71-15). If severe regurgitation remains a problem, a gastrostomy tube can be placed to assist in the delivery of nutrients, fluids, and medications (see Chapter 30). Whenever aspiration pneumonia is present, a transtracheal wash (see Chapter 20) should be performed for culture and then aggressive treatment for the pneumonia should be initiated using antibiotics, fluids, nebulization, and coupage. Administration of antibiotics that impair neuromuscular transmission (ampicillin, aminoglycosides) should be avoided.

Anticholinesterase drugs are commonly administered in an attempt to improve muscular strength. Pyridostigmine bromide (Mestinon, 1 to 3 mg/kg, administered orally q8h) has been used in dogs. In cats pyridostigmine bromide syrup (0.25 to 1.0 mg/kg, administered orally q12h, diluted 1:1 with water to decrease gastric irritation) has been recommended. For both dogs and cats the dose must be individu-

Upright feeding in animals with megaesophagus facilitates emptying of esophageal contents into the stomach. Animals should be maintained in this position for 10 to 15 minutes after eating.

alized on the basis of clinical response. Ideally, feeding should be timed to coincide with peak drug effect (2 hours). In dogs initially unable to tolerate oral medication because of severe megaesophagus, neostigmine methylsulfate (Prostigmin 0.04 mg/kg , administered intramuscularly q6-8h) can be used.

If an animal appears to be responding to anticholinesterase treatment but then suddenly gets worse, it is important to determine whether the deterioration is due to underdosage of the anticholinesterase drug (myasthenic crisis) or overdosage (cholinergic crisis). Clinically, these are indistinguishable, but the administration of one dose of edrophonium (Tensilon) allows the clinician to distinguish between them. The animal in a myasthenic crisis improves after edrophonium administration, whereas the condition of an animal in a cholinergic crisis becomes transiently worse or does not change. Dosing adjustments can then be made on the basis of the observed response.

Acquired MG is an immune-mediated disease, and administration of corticosteroids and other immunosuppressive drugs may be associated with a more rapid clinical response, a decrease in AChR antibody, and an improved outcome in some dogs. Ideally, immunosuppressive drugs should be administered only to stable patients without aspiration pneumonia. Because corticosteroids at standard immunosuppressive doses commonly cause transient worsening of muscular weakness in dogs with MG, treatment should be initiated with a low-dose (oral prednisone, 0.5 mg/kg/day) and the dosage gradually increased over 2 to 4 weeks. The oral administration of azathioprine (Imuran, 2 mg/kg/day) or mycophenolate mofetil (CellCept, 10 to 20 mg/kg q12h) alone or in combination with prednisone has been associated with a positive clinical response in some dogs.

#### **Prognosis**

Response to medical management of MG can be good if aspiration pneumonia is not severe and the complications of aspiration and anticholinesterase overdosage are avoided. Severe aspiration pneumonia, persistent megaesophagus, acute fulminating MG, and the presence of a thymoma or another underlying neoplasm are all associated with a poor prognosis for recovery. Many affected dogs die of either acute fatal aspiration or euthanasia within 12 months of diagnosis. Anticholinesterase drugs effectively control appendicular muscle weakness in most animals, but their effect on esophageal function is variable. Response to various immunosuppressive protocols is difficult to determine because most dogs with acquired MG will go into a spontaneous permanent clinical and immunologic remission within 18 months after diagnosis (average, 6.4 months), regardless of the treatment used. Remission is unlikely in animals with thymoma or other neoplastic disease. Sequential antibody determinations in an individual animal are correlated with disease progression or remission; thus it is recommended that AChR antibody concentrations be measured and monitored every 4 to 8 weeks in animals being treated for MG.

#### DYSAUTONOMIA

Dysautonomia is a polyneuropathy affecting both sympathetic and parasympathetic nerves of the autonomic nervous system. Historically, it was recognized as a problem of cats in the United Kingdom, but since the late 1980s it has become a common problem affecting dogs in the Midwest United States, particularly in rural Kansas, Missouri, Oklahoma, and Wyoming. The etiology is unknown, although toxic and autoimmune mechanisms have been proposed. Clinical signs reflect failure of autonomic function in multiple organ systems.

#### **Clinical Features**

The disease affects primarily young adult dogs with a median age of 18 months. Cats are occasionally affected. Affected animals have a rapid onset of clinical signs, which progress over days to weeks. Common presenting complaints are vomiting or regurgitation, diarrhea (constipation in cats), straining to urinate, dribbling urine, photophobia, dyspnea, coughing, depression, and anorexia. Physical examination findings include decreased or absent anal tone, dilated pupils that do not respond to light, dry nose and mucous membranes, and prolapse of the nictitating membrane. The bladder may be distended and easy to express.

## Diagnosis

Diagnosis is suspected on the basis of the observed clinical signs. Thoracic and abdominal radiographs may reveal megaesophagus, aspiration pneumonia, generalized ilcus, and a large distended urinary bladder. The bladder is easily expressed, suggesting diminished urethral sphincter tone. Anal tone is usually decreased. Pharmacologic testing can be used to support the diagnosis. When very dilute (0.05% to 0.1%) pilocarpine (Isoptocarpine 1%, Alcon Laboratories, diluted with saline) is applied to the eye of a dog with dysautonomia, pupillary constriction and nictitating membrane retraction will occur within 60 minutes or less, documenting denervation hypersensitivity. Administration of bethanechol (0.04 mg/kg SQ) may also enable an affected dog with a distended bladder and urine dribbling to void normally. The subcutaneous administration of atropine (0.04 mg/kg) does not produce any change in heart rate in affected dogs. These findings suggest the diagnosis of dysautonomia, but definitive diagnosis requires the demonstration of lesions within the autonomic nervous system at postmortem examination. A loss of nerve cell bodies results in decreased neuron density

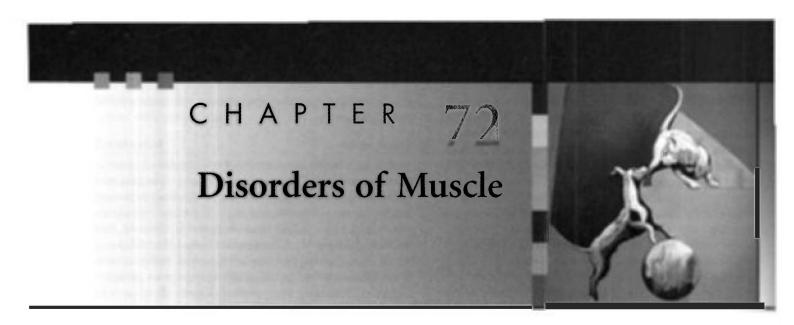

in all autonomic ganglia, especially the pelvic, mesenteric, and ciliary ganglia.

#### **Treatment**

Treatment is largely supportive and includes the administration of fluids, total parenteral nutrition or percutaneous gastrostomy tube feeding, bladder and colon emptying, lubricating eye ointments, and physical therapy. Pilocarpine (1%, one drop q6-12h) may improve lacrimation and decrease photophobia, Subcutaneous bethanechol (0.05 mg/ kg q 8-12h) may improve urinary function, and prokinetic drugs (metoclopramide, cisapride) may improve gastrointestinal tract motility. The prognosis is generally poor, with a mortality rate of about 70% to 90%.

#### **GENERAL CONSIDERATIONS**

Skeletal muscle functions to maintain posture and produce movement. Patients with generalized muscle disease generally present with weakness. This may manifest as a stiff and stilted gait, trembling while standing, a low head carriage (ventral neck flexion), and exercise intolerance. When a complete nervous system examination is performed, animals with muscle disease have normal postural reactions, are not ataxic, and usually have normal spinal reflexes. Some muscle disorders cause muscle pain and muscle swelling, whereas others cause muscle atrophy and/or fibrosis.

Myopathies in dogs and cats can be either acquired or inherited. Acquired muscle disorders include infectious and immune-mediated inflammatory disorders as well as metabolic and endocrine disorders. Characteristic clinical findings may suggest a specific diagnosis, but muscle biopsy and systemic evaluation are usually required for definitive diagnosis. Metabolic testing may be required to demonstrate and characterize functional abnormalities.

#### **EXERCISE INTOLERANCE**

Reluctance to exercise or inability to exercise for a prolonged period is a common complaint among dog owners. Exercise intolerance can result from orthopedic, cardiovascular, respiratory, hematologic, metabolic/endocrine, neurologic, neuromuscular, and muscular disorders (Box 72-1). When evaluating a dog for exercise intolerance, the veterinarian must perform a careful physical and neurologic examination. Muscle atrophy or pain and weakness at rest with normal postural reactions may suggest a muscle disorder. Joint pain may indicate that the dog has polyarthritis or degenerative joint disease. Abnormalities of cardiac auscultation or arterial pulse character should prompt thorough cardiac evaluation. Routine systemic evaluation with clinicopathologic tests and survey radiographs should be completed. When all examinations and tests are normal at rest, affected dogs should be evaluated while performing the exercise historically associated with their exercise intolerance. Characteristic clinical features during the exercise intolerance (e.g., weakness, stridor, arrhythmia) sometimes provide a clue regarding the etiology. Depending on clinical findings, additional testing may be recommended, including measuring antibodies against acetylcholine receptors (AChRs), continuous electrocardiographic monitoring, thyroid and adrenal function evaluation, arterial blood gas, and measuring preexercise and postexercise parameters (i.e., electrolytes, glucose, creatinine kinase, lactate, and pyruvate). When neurologic examination and ancillary testing suggest a muscular cause for exercise intolerance, muscle biopsies should be performed.

An inherited syndrome of exercise induced collapse (EIC) has been identified in young adult (7 months to 2 years old)

# Important Causes of Acquired Exercise Intolerance in Dogs

Exercise induced collapse (EIC) of Labrador Retrievers

Labrador Retrievers being trained for field work. Affected dogs are normal at rest and with moderate exercise. Strenuous exercise in conjunction with excitement results in ataxia and rear limb weakness, sometimes progressing to collapse (Fig. 72-1). During collapse, affected dogs are hyperthermic and they hyperventilate, but physiologic and clinicopathologic parameters are not dramatically different from those of normal exercise-tolerant Labrador Retrievers taking part in the same exercise. Patellar reflexes are absent during collapse, and many affected dogs experience a profound loss of balance (disequilibrium) during collapse and recovery. A few dogs die during an episode of collapse, but most recover within 10 to 20 minutes, with no residual clinical or clinicopathologic abnormalities. Muscle biopsies are normal. The condi-

FIG 72-1

A young Labrador Retriever with the syndrome of exercise induced collapse (EIC) walks with a crouched rear limb gait after 10 minutes of retrieving exercise.

tion is not progressive, so a normal lifespan is expected if participation in the activities triggering collapse is restricted. Diagnosis is made by eliminating other causes of exercise intolerance and demonstrating that the affected dog is homozygous for the causative mutation.

# INFLAMMATORY MYOPATHIES

#### **MASTICATORY MYOSITIS**

Masticatory muscle myositis (MMM) is a common immune-mediated disorder involving only the muscles of mastication in dogs. The masticatory muscles are composed primarily of a unique myofiber (type 2M) that is not present in limb muscles, and in dogs with MMM, IgG is directed against the unique myosin component of these fibers. Masticatory myositis can occur in any breed of dog, but the German Shepherd Dog, the retrieving breeds, the Doberman Pinscher, and other large breeds are most commonly affected. Primarily, young or middle-aged dogs are affected, and no apparent gender predilection exists. The disorder has not been documented in cats.

#### **Clinical Features**

The acute form of the disease involves recurrent painful swelling of the temporal and masseter muscles. Pyrexia, submandibular and prescapular lymphadenopathy, and tonsillitis are variably present. Dogs are reluctant to eat and are usually presented for anorexia and depression. Palpation of the muscles of the head and attempts to open the mouth are met with resistance because of pain.

As this disorder progresses, there is progressive, severe atrophy of the temporal and masseter muscles, resulting in a skull-like appearance of the head. Opening the mouth is no longer painful but is restricted by atrophy and fibrosis of the masticatory muscles (Fig. 72-2). The globes may sink deep into the orbits because of the dramatic loss of muscle mass (see Fig. 66-9). Many dogs will be presented for evaluation at a stage wherein they have pain on opening the

FIG 72-2
Chronic masticatory muscle myositis (MMM) causing
(A) severe temporalis and masseter muscle atrophy and
(B) inability to open the mouth more than a few centimeters in an adult Vizsla.

mouth together with muscle atrophy as they progress from the acute to the chronic form of the disease. Occasionally, dogs will present with nonpainful severe atrophy without any history of signs related to previous acute episodes of pain.

#### Diagnosis

Diagnosis is suspected on the basis of the clinical findings. In dogs with pain on opening the mouth, differentials must include retrobulbar abscess or mass, dental disease, and abnormalities of the temporomandibular joint or the bullae. The severe, nonpainful atrophy observed in chronically affected dogs must be differentiated from atrophy caused by disorders of the trigeminal nerve, widespread polymyositis (any etiology), or systemic disorders such as hypothyroidism or hyperadrenocorticism.

A hemogram may be normal or may reveal mild anemia and neutrophilic leukocytosis; occasionally, a peripheral eosinophilia is found. Serum creatine kinase (CK), aspartate aminotransferase (AST), and globulin concentrations may be increased. Proteinuria sometimes occurs. Circulating antibodies against type 2M fibers can be detected in the serum of many (80%) dogs with acute MMM, but they may not be present in dogs with chronic disease. Electromyography (EMG), when available, can demonstrate the presence of muscle disease in the masticatory muscles and confirm that other muscle groups are unaffected. Histopathologic evaluation of a biopsy from the affected muscles establishes the diagnosis. Fresh and formalin-fixed muscle should be submitted to permit the use of histochemical and immunohistochemical stains to identify antibody bound to type 2M muscle fibers.

#### **Treatment**

The oral administration of corticosteroids (prednisone, 1 to 2 mg/kg q12h) usually results in rapid elimination of pain in acutely affected dogs and an improved ability to open the mouth in chronically affected dogs. After approximately 3 weeks, the dose of corticosteroids can be decreased (to 1 mg/kg q24h) and then gradually tapered over 4 to 6 months to the lowest possible alternate-day dose. Inadequate dosing or treatment for an insufficient period of time is associated with a high rate of relapse. Dogs that do not respond adequately to corticosteroid therapy and dogs that relapse each time the dose is decreased may benefit from the use of other immunosuppressive drugs such as azathioprine (Imuran; Burroughs Wellcome) given 2 mg/kg orally once a day until the patient shows signs of improvement, then every 48 hours. Dogs treated aggressively have a good prognosis for recovery. They should be carefully monitored for relapse (using jaw mobility and discomfort and serum CK), particularly as the corticosteroid dose is tapered. Lifelong treatment may be required.

Historically, it was recommended that dogs with chronic MMM have their jaws opened by force under anesthesia to stretch the fibrous tissue and muscle. This practice is no longer recommended because it does not improve clinical outcome, it increases the inflammation in torn muscle fibers, and it carries an inherent risk of iatrogenic mandibular luxation or fracture.

#### **EXTRAOCULAR MYOSITIS**

A unique form of myositis confined to the extraocular muscles resulting in acute exophthalmos has been described in dogs (Fig. 72-3). Affected dogs are usually young, with a median age at presentation of 8 months. Golden Retrievers and other large-breed dogs are especially susceptible. Bilateral exophthalmos and eyelid retraction are common, often with concurrent chemosis. Vision may be impaired. Serum CK concentrations are usually normal. Orbital sonography confirms swollen extraocular muscles and eliminates retrobulbar abscess or mass as differentials. Definitive diagnosis requires biopsy of affected muscles. Treatment is as for MMM, with a good prognosis for recovery.

**FIG 72-3**Bilateral exophthalmos and upper eyelid retraction caused by extraocular myositis in a Border Collie.

#### **CANINE IDIOPATHIC POLYMYOSITIS**

Idiopathic polymyositis (PM) is a diffuse inflammation of skeletal muscle presumed to be an autoimmune process. Large-breed adult dogs are most commonly affected, with many reported cases in German Shepherd Dogs and Boxers. Newfoundlands may also be overrepresented.

#### **Clinical Features**

Mild to severe weakness and a stiff, stilted gait that may be exacerbated by exercise are the most common features. Muscles are painful in some dogs, whereas nonpainful, severe atrophy occurs in others. Affected dogs may regurgitate as a result of megaesophagus or exhibit dysphagia, excessive salivation, and a weak bark. Signs may be intermittent in mild cases or early in the course of the disease. Some dogs with acute severe disease are pyrexic and experience generalized pain. Neurologic examination reveals normal proprioception, spinal reflexes, mental status, and cranial nerve exam. Muscle atrophy is usually prominent, especially involving the temporalis and masseter muscles.

#### **Diagnosis**

The diagnosis of PM is based on clinical signs, CK determination, EMG, and muscle biopsy. High serum CK (twofold to hundredfold increase) and AST activities are seen in most affected dogs at rest, and even more dramatic increases are common after exercise. Gamma globulins may also be increased. When available, EMG can be performed to document that multiple muscle groups are involved and to select a severely affected muscle for biopsy. A definitive diagnosis of idiopathic PM requires muscle biopsy. Typical histopathologic findings include multifocal necrosis and phagocytosis of type 1 and type 2 myofibers, perivascular lymphocytic and plasmacytic infiltration, and evidence of muscle regeneration and fibrosis. Muscle biopsy results may be normal in some dogs because of the multifocal, patchy nature of the

disease. This should not preclude a diagnosis of myositis if the clinical findings, EMG, and serum CK and AST activities suggest the diagnosis.

PM can occur as an idiopathic primary immunemediated disorder, or it can be secondary to systemic immune-mediated disease (e.g., systemic lupus erythematosus), protozoal infection (e.g., Toxoplasma, Neospora myositis), or systemic neoplasia. All dogs with PM should have a complete blood count (CBC), biochemistry profile, synovial fluid analysis, urinalysis, serum antinuclear antibody (ANA) titer, and protozoal serology and/or immunohistochemical staining of muscle biopsies for protozoal antigens. Assessment of thoracic radiographs and abdominal ultrasound should focus on a search for neoplasia and identification of megaesophagus and aspiration pneumonia. Lymph node, spleen, and liver aspirates and bone marrow biopsy are indicated because lymphoma is the most common cancer associated with PM. If all of these tests are normal, a diagnosis of idiopathic PM is made.

#### **Treatment**

Prednisone administration (1 to 2 mg/kg q12h for 14 days, then q24h for 14 days, then q48h) results in dramatic clinical improvement and recovery for most dogs. In dogs with megaesophagus upright feeding of small meals (see Fig. 71-15) may be beneficial to prevent aspiration. Aspiration pneumonia, if it occurs, should be treated with antibiotics. Prednisone treatment should continue for at least 4 to 6 weeks at decreasing doses, with long-term treatment for 12 months or longer occasionally required. Azathioprine should be administered if the response to prednisone is inadequate.

#### **Prognosis**

The prognosis is good for recovery in dogs without severe megaesophagus or aspiration pneumonia if no underlying neoplastic cause for the PM can be identified.

#### FELINE IDIOPATHIC POLYMYOSITIS

An acquired inflammatory disorder of skeletal muscle similar to canine PM has been described in a few cats. Affected cats experience a sudden onset of weakness with pronounced ventral neck flexion, an inability to jump, and a tendency to sit or lie down after walking short distances. Muscle pain may be evident. Neurologic examination reveals normal mentation, cranial nerves, proprioception, and reflexes.

Diagnosis is made on the basis of clinical features, increases of serum CK and AST activities, and multifocal EMG abnormalities. Many affected cats (70%) are slightly hypokalemic, suggesting a possible relationship between this disorder and hypokalemic polymyopathy. Some clinical features of PM also mimic mild thiamine deficiency; thus evaluation of the response to treatment of affected cats with thiamine (10 to 20 mg/day, administered intramuscularly) and correction of hypokalemia are recommended before proceeding with extensive diagnostic testing for PM.

Serum titers against *Toxoplasma gondii* should be evaluated, as should tests for feline leukemia virus antigen and

feline immunodeficiency virus antibody. A complete drug history should be obtained to eliminate the possibility of drug-induced PM. Thoracic and abdominal radiographs and abdominal ultrasound should be considered to look for an underlying neoplastic cause of the PM. PM has been diagnosed in many cats with thymoma. Muscle biopsy reveals myofiber necrosis and phagocytosis, muscle regeneration, variation in muscle fiber size, lymphocytic inflammation, and fibrosis. Empiric treatment for Toxoplasma myositis is sometimes recommended (clindamycin 12.5 to 25 mg/kg, administered orally q12h); if the animal has a dramatic response to clindamycin, the treatment should be continued for at least 6 weeks. It is important to realize, however, that spontaneous recovery or remission is observed in at least one third of all cats with PM. Corticosteroid therapy (prednisone, 4 to 6 mg/kg/day initially, tapered over 2 months) may aid recovery in some cats. Recurrences are common.

#### **DERMATOMYOSITIS**

Dermatomyositis is an uncommon disease characterized by dermatitis and polymyositis. Familial canine dermatomyositis has been reported in juvenile rough-coated and smoothcoated Collies and in Shetland Sheepdogs (i.e., Shelties). Sporadic cases have been observed in a few other breeds, including Welsh Corgis, Australian Cattle Dogs, and Border Collies. The disease has not been recognized in cats. Skin lesions include erythema, ulcers, crusts, scales, and alopecia on the inner surfaces of the pinnae and on the head and skin surfaces subjected to trauma (e.g., tail, elbows, hocks, sternum; Fig. 72-4). Mild pruritus may occur. Histopathologic findings include hydropic degeneration of basal cells and separation of the dermoepidermal junction. A perivascular mononuclear infiltrate may be seen. Dermatologic lesions appear during the first 3 months of life and may improve or resolve with time. The course often fluctuates.

Dogs severely affected by dermatomyositis may develop signs of concurrent muscle disease, including generalized muscle weakness and atrophy, facial palsy, decreased jaw

A Shetland Sheepdog with typical skin lesions of dermatomyositis. This dog also had megaesophagus and generalized muscular weakness.

tone, and a stiff gait. Mentation, proprioception, and reflexes are normal. Dysphagia is common, as is regurgitation as a result of megaesophagus. EMG reveals spontaneous myofiber discharges, including fibrillation potentials, positive sharp waves, and bizarre high-frequency discharges in affected muscles. Nerve conduction velocities are normal. Muscle biopsies reveal myofiber necrosis with mononuclear cell infiltrates, atrophy, regeneration, and fibrosis. Some dogs with relatively severe dermatologic lesions exhibit no evidence of muscle disease.

Biopsies of skin and muscle, as well as EMG, may confirm a diagnosis of dermatomyositis. Breeding should be discouraged. Dogs with muscular manifestations of this disorder are usually treated with immunosuppressive doses of corticosteroids with a variable response. Dermatologic lesions may respond to oral administration of tetracycline and niacinamide (250 mg of each q8h if <10 kg, 500 mg of each q8h if >10 kg) or pentoxifylline (Trental, 10 to 25 mg/kg q 8-12h).

#### PROTOZOAL MYOSITIS

Myositis caused by T. gondii can occur alone or in conjunction with myelitis, meningitis, or polyradiculoneuritis in dogs and cats, and similar syndromes caused by Neospora caninum can occur in the dog (see Chapters 69 and 71). Clinical signs referable to protozoal myositis typically include muscle pain, swelling or atrophy, and weakness. Increases in CK and AST activities are common, and serum titers for the offending organism may be positive. EMG may reveal spontaneous activity in affected muscles (definitive diagnosis requires muscle biopsy). A mononuclear inflammatory reaction is present, and organisms are often seen. Immunohistochemical stains can be used to identify the organisms and differentiate between T. gondii and N. caninum in affected dogs. Success has been reported in the treatment of protozoal myositis with oral clindamycin (12.5 to 25 mg/kg q12h) for 14 days, but more prolonged treatment (4 to 6 weeks) is advised.

# ACQUIRED METABOLIC MYOPATHIES

In addition to the myopathies associated with infectious and inflammatory disease, myopathies may accompany hyperadrenocorticism (i.e., Cushing's disease), the administration of exogenous corticosteroids, and perhaps hypothyroidism. In cats a myopathy associated with hypokalemia has been recognized.

## **GLUCOCORTICOID EXCESS**

Glucocorticoid excess causes a degenerative myopathy. Spontaneous hyperadrenocorticism or exogenous administration of glucocorticoids, especially in high doses, can result in the syndrome. Muscle weakness and atrophy are common. Rarely, affected dogs develop limb rigidity, stiff gait, and hyperextension of all four limbs.

Diagnosis is suspected on the basis of a history of exogenous steroid administration or clinical findings consistent with steroid excess (e.g., polyuria, polydipsia, hair loss, pendulous abdomen, thin skin). Muscle biopsy reveals nonspecific changes, including type 2 myofiber atrophy, focal necrosis, and fiber size variation. Diagnostic tests for hyperadrenocorticism may confirm the diagnosis (see Chapter 53). Supplementation with L-carnitine, coenzyme Q10 and riboflavin may improve muscular strength. Control of excess glucocorticoids may result in some clinical improvement; however, in most dogs the prognosis is poor for complete resolution of the myopathy.

#### **HYPOTHYROIDISM**

Hypothyroidism may be associated with a mild myopathy in dogs, causing weakness, muscle atrophy, and reduced exercise tolerance. Spinal reflexes are normal unless concurrent polyneuropathy is present. Biopsy reveals mild type 2 myofiber atrophy. Documentation of hypothyroidism and response to thyroid hormone supplementation are required for diagnosis.

#### HYPOKALEMIC POLYMYOPATHY

A polymyopathy linked to decreased dietary intake or increased urinary excretion of potassium leading to total body potassium depletion has been recognized in cats of all breeds, ages, and genders. Cats with chronic renal failure and those consuming acidifying diets are most commonly affected, but cats with polyuria or polydipsia secondary to hyperthyroidism and cats with anorexia from any etiology may also be at risk. Cats with primary hyperaldosteronism because of functional adrenal neoplasia also present with hypokalemic polymyopathy.

The predominant clinical feature in all of these cats is weakness characterized by persistent ventroflexion of the neck (Fig. 72-5); a stiff, stilted gait; and reluctance to move. Some cats exhibit excessive scapular movement during walking. Muscle pain may be apparent, but the neurologic examination is otherwise unremarkable, with normal postural reactions and spinal reflexes. Clinical signs may have an acute onset and be episodic. Serum CK activity is usually high (10 to 30 times normal), serum potassium concentration is decreased (<3.5 mEq/L), and increased fractional urinary excretion of potassium (normal is 4.7-14.3%) may occur. Because most affected cats have renal dysfunction, serum urea and creatinine concentrations may be increased. Interpretation of these parameters and the urine specific gravity can be difficult because hypokalemia can itself decrease renal blood flow and glomerular filtration rate (GFR), interfering with urine-concentrating mechanisms.

EMG abnormalities are found in multiple muscle groups and include frequent positive sharp waves, fibrillation potentials, and occasional bizarre high-frequency discharges with normal nerve conduction velocities. Muscle histopathology usually is normal.

Signs of hypokalemic polymyopathy usually resolve after parenteral or oral supplementation of potassium. Oral treatment with potassium gluconate is recommended for mildly affected cats (Kaon Elixir; Adria Laboratories, Columbus,

FIG 72-5
Feline hypokalemic myopathy resulting in weakness and cervical ventroflexion in (A) a kitten with congenital renal disease and (B) a hyperthyroid cat. The weakness resolved in both cats after potassium supplementation.

Ohio) at a dose of 2.5 to 5.0 mEq/cat twice a day for 2 days, then once a day. The dose administered is adjusted on the basis of serum potassium levels. Cats with more dramatic hypokalemia (less than 2.5 mEq/L) or those with severe muscular weakness causing respiratory compromise require parenteral administration of lactated Ringer's solution, intravenously or subcutaneously supplemented with at least 80 mEq/L of potassium chloride per liter of fluid. Intravenous (IV) supplementation of potassium should not exceed 0.5 mEq/kg/hour. Long-term oral supplementation with potassium gluconate may be required. Periodic monitoring of serum potassium concentration is recommended.

#### INHERITED MYOPATHIES

#### **MUSCULAR DYSTROPHY**

The muscular dystrophies (MDs) are a heterogeneous group of inherited degenerative noninflammatory muscle disorders. Most of the MDs recognized in dogs are associated with an absence of the cytoskeletal protein dystrophin caused by genetic mutation of the dystrophin gene. This very large dystrophin gene is located on the X-chromosome, so MD is

generally inherited as an X-linked recessive trait, clinically apparent in male dogs and transmitted by females that are asymptomatic. Canine X-linked muscular dystrophy (CXMD) has been most completely described in Golden Retrievers but has also been reported in many other breeds of dogs, including the Irish Terrier, Samoyed, Rottweiler, Belgian Shepherd, Miniature Schnauzer, Pembroke Welsh Corgi, Alaskan Malamute, Wire-Haired Fox Terrier, German Shorthaired Pointer, Brittany Spaniel, Labrador Retriever, and Rat Terrier.

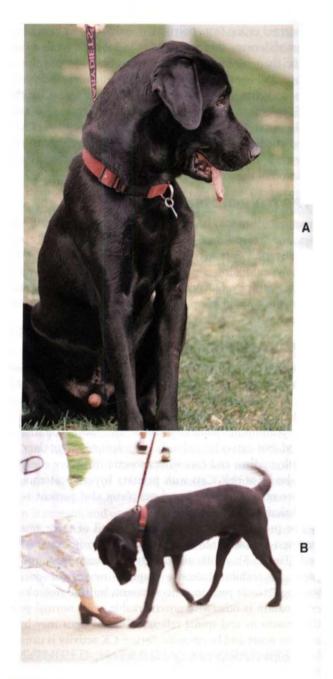

Dogs with CXMD typically show clinical signs at birth or very early in life. Golden Retriever muscular dystrophy (GRMD) has been well described, and despite the fact that all affected male dogs have the same genetic lesion, the severity of clinical expression within a litter is variable. Puppies with GRMD are often stunted even before weaning. Abduction of the elbows, a bunny-hopping gait, and difficulty opening the mouth may be noted. With time, affected puppies develop a progressively stilted gait; exercise intolerance; a plantigrade stance; atrophy of the truncal, limb, and temporalis muscles; and muscle contractures. Muscle strength deteriorates until approximately 6 months of age, when the signs tend to stabilize. Proprioceptive positioning and spinal reflexes are normal, but spinal reflexes may be difficult to elicit once muscle fibrosis and joint contractures occur. Severely affected dogs may develop pharyngeal or esophageal dysfunction. Cardiac failure occurs occasionally.

MD should be suspected when typical clinical signs are seen in a young male puppy of a predisposed breed. Serum CK levels are markedly increased as early as 1 week of age and peak at 6 to 8 weeks of age. Very dramatic increases in CK occur after exercise. EMG reveals pseudomyotonic discharges in most muscles by 10 weeks of age. Biopsies reveal marked myofiber size variation, necrosis, and regeneration with multifocal myofiber mineralization. Immunocytochemical studies document the absence of the sarcolemmal protein dystrophin. No effective treatment exists.

An X-linked MD has also been reported in the cat. Clinical signs first appear at 5 to 6 months of age. Affected cats exhibit marked generalized muscular hypertrophy, protrusion of the tongue, excessive salivation, stiff gait, and bunny hopping. Megaesophagus is common. Serum CK is greatly elevated (often >30,000 U/L). Diagnosis requires muscle biopsy and dystrophin immunostaining.

# CENTRONUCLEAR MYOPATHY OF LABRADOR RETRIEVERS

Centronuclear myopathy (CNM) is a relatively common disorder in the Labrador Retriever. This disorder has been previously reported as hereditary Labrador Retriever myopathy (HLRM), autosomal recessive muscular dystrophy, and type 2 myofiber deficiency. Affected puppies appear normal at birth. Muscular weakness, an awkward gait, exercise intolerance, and muscle atrophy without myalgia typically become apparent by 3 to 5 months of age, with a few puppies showing signs at 6 to 8 weeks. The age of onset and severity of clinical signs varies dramatically among affected litter mates.

A 1-year-old Labrador Retriever with centronuclear myopathy (CNM) exhibiting proximal muscle atrophy; a stiff, stilted gait; and ventroflexion of the neck that worsens with exercise.

Severely affected dogs exhibit a low head carriage and a short-strided, stilted gait (Fig. 72-6). Their back may be arched, and a bunny-hopping gait may develop with exercise. Muscle atrophy may be marked, especially in the proximal limbs and the muscles of mastication. Neurologic examination is normal except for consistent patellar hyporeflexia or areflexia. Megaesophagus causing regurgitation has been seen in a few affected dogs. Clinical signs are worse with stress, exercise, excitement, or cold temperatures. Muscular weakness and atrophy are typically slowly progressive, but a

few affected puppies will be recumbent within 1 to 2 months. Clinical signs stabilize after 12 months of age in mildly affected dogs. Serum CK is normal or moderately elevated, and on EMG examination spontaneous electrical activity and bizarre high-frequency discharges are seen. CNM is histologically characterized by mild to marked variation in fiber size, atrophic type 1 and type II myofibers, replacement of type 2 myofibers by type 1 myofibers resulting in a type 2 predominance, and a marked increase in centralization of nuclei within muscle cells. CNM has an autosomal recessive inheritance pattern. Recently, the causative genetic mutation has been identified and a DNA test is commercially available. No treatment is available, but mildly affected dogs can function as pets.

#### MYOTONIA

Myotonia is a rare disorder of muscle that has been recognized in Chow Chows, Cocker Spaniels, Staffordshire Bull Terriers, Miniature Schnauzers, Labrador Retrievers, Rhodesian Ridgebacks, Samoyeds, West Highland White Terriers, Great Danes, and individual dogs of a number of breeds. Affected kittens have also been identified. Myotonia causes involuntary contraction of muscle that persists after voluntary movement or stimulation. This results from altered chloride conductance, which causes postexcitement depolarization of the muscle membrane and continued contraction. In Miniature Schnauzers the mutant skeletal muscle chloride channel allele has been identified, and a PCR-based test has been developed.

Clinical signs include generalized muscle stiffness and hypertrophy that begin at a young age (i.e., 2 to 6 months). Dogs with myotonia are neurologically normal. No abnormalities of proprioception or mentation exist. Cold weather, excitement, and exercise exacerbate the clinical signs. Affected dogs may remain in rigid recumbency for up to 30 seconds if they are suddenly placed in lateral recumbency. Serum CK and AST activities may be increased, indicating muscle fiber necrosis. Bizarre high-frequency discharges that wax and wane ("dive-bomber sound") are revealed by EMG and, when present, confirm the diagnosis. Muscle biopsy alone is rarely diagnostic. Membrane-stabilizing agents such as procainamide (10 to 30 mg/kg, administered orally q6h) and phenytoin (20 to 35 mg/kg, administered orally q12h) and the sodium channel blocker mexiletine (Mexitil; Boehringer Ingelheim: 8 mg/kg, administered orally q8h), have been beneficial in the treatment of some cases. The avoidance of cold temperatures is also advised. Most dogs are euthanized because of the severity of their signs.

#### INHERITED METABOLIC MYOPATHIES

A number of genetically based metabolic myopathies have been described in dogs and cats. In each of these disorders there is a biochemical defect of the skeletal muscle energy system, resulting in inefficient muscle performance. All of these disorders cause signs of muscle dysfunction, including exercise intolerance; muscular weakness; a stiff, stilted gait; muscle pain; muscle tremors; and muscle atrophy. Mito-

chondrial myopathies, glycogen storage diseases, lipid storage myopathies, and disorders causing nemaline rod accumulation within myofibers have all been reported. Establishing the precise cause of a metabolic myopathy can be difficult because of the wide range of biochemical abnormalities that can arise and the co-dependence of all of the structural proteins making up a muscle fiber. Sometimes metabolic testing can be beneficial; for example, inappropriate lactic acid accumulation with exercise suggests mitochondrial dysfunction. Evaluation of plasma lactate and pyruvate before and after exercise and quantitative analysis of urinary organic acids and plasma, urine, and muscle carnitine will help to document that a metabolic myopathy is present and may help determine the affected biochemical pathway. After metabolic testing, histologic and ultrastructural examination of skeletal muscle should be performed. This metabolic testing and biopsy evaluation should be performed by a laboratory specializing in metabolic disorders of dog and cat muscle. When testing suggests a mitochondrial myopathy or a lipid myopathy, nonspecific treatment with an oral combination of L-carnitine (50 mg/kg q12h), coenzyme Q<sub>10</sub> (100 mg/dog q 24h), and riboflavin (100 mg/dog q 24h) may result in improved muscle strength.

# INVOLUNTARY ALTERATIONS IN MUSCLE TONE

Tetanus, opisthotonus, myoclonus, and dyskinesias are all involuntary alterations of muscle tone that are not the result of muscle disease. Tetanus is a sustained tonic contraction of the muscles. Opisthotonos is a very severe form of tetanus in which spasm of the limb and neck muscles results in lateral recumbency with dorsiflexion of the neck and extensor rigidity of the limbs. Myoclonus is the rhythmic repetitive contraction of a particular group of muscles. Dykinesias, a group of poorly defined movement disorders, are discussed in Chapter 65.

#### **OPISTHOTONOS AND TETANUS**

Loss of consciousness occurring in association with tetanus and opisthotonos (decerebrate rigidity, see Fig. 63-9, A) is seen in dogs and cats with severe brainstem disease caused by infection, trauma, or neoplasia. Brainstem disease in these animals is suspected on the basis of the history, neurologic findings, and results of clinicopathologic tests. Opisthotonos and tetanus with no altered state of consciousness may be seen after trauma to the rostral cerebellum (decerebellate rigidity, Fig. 63-9, B), and in Clostridium tetani infection.

C. tetani is a gram-positive, anaerobic bacillus that produces spores that persist for long periods in the environment. If a deep wound or an area of tissue damage becomes contaminated with these spores, the spores may be anaerobically converted to a vegetative form and a toxin (tetanospasmin) is produced. The toxin ascends peripheral nerves to the spinal cord, where it blocks the release of neurotransmitter

from the inhibitory interneurons (Renshaw cells), releasing extensor muscles from inhibition and resulting in tetany. Cats are more resistant to the toxin than dogs.

Clinical signs of tetanus appear 3 to 20 days after wound infection. Animals with mild or early tetanus show a stiff gait, erect ears, an elevated tail, and contraction of the facial muscles (risus sardonicus; Fig. 72-7). The signs may be most severe in the area of the body adjacent to where the toxin is being produced. In severe disease the animal is recumbent and shows extensor rigidity of all four limbs and opisthotonos. The animal may die as a result of an inability to ventilate adequately. Tetanus is diagnosed on the basis of clinical signs and the history of a recent wound.

Treatment should consist of rest, immediate wound debridement, antibiotics, neutralization of the toxin, and intensive supportive care. Initially, aqueous penicillin G is

FIG 72-7
Tetanus in two dogs, with the erect ears and risus sardonicus resulting from contraction of the head and facial muscles. Both dogs had wounds on a forelimb, which were

presumed to be the site of entry of the toxin.

administered intravenously (40,000 U/kg q8h), after which the procaine salt can be given by intramuscular injection (40,000 U/kg q12h). Alternatively, metronidazole (10 to 15 mg/kg IV q8h) may be administered; it is bactericidal against most anaerobes and achieves a therapeutic concentration even in necrotic tissues. Antibiotics are administered for 2 weeks or until clinical recovery occurs.

A test dose of tetanus antitoxin (equine origin) is injected intradermally 15 to 30 minutes before the administration of a treatment dose. If no wheal develops, the antitoxin is administered intravenously (200 to 1000 U/kg; maximum, 20,000 U). This dose is not repeated because a therapeutic blood concentration persists for 7 to 10 days after a single injection, and repeated administration of antitoxin increases the chance of an anaphylactic reaction. The injection of a small dose of antitoxin (1000 U) just proximal to the wound site may be beneficial in dogs and cats with localized tetanus.

The animal is maintained in a quiet, dark environment. Muscle spasms are controlled with oral or IV diazepam (0.5 to 1 mg/kg, as needed) and IV chlorpromazine (0.5 mg/kg q8h) or intramuscular acepromazine (0.1 to 0.2 mg/kg q6h). Phenobarbital (2 mg/kg q8h, administered intravenously or intramuscularly) or pentobarbital (5 to 15 mg/kg IV to effect) may be administered as needed. IV fluids are administered, and nutritional support is achieved using nasogastric or gastrotomy tube feeding. The animal is hand-fed as soon as it is able to prehend food and swallow. In some animals urinary and fecal retention must be managed by repeated catheterization and enemas. Improvement is usually noticeable within 1 week, but signs may persist for 3 to 4 weeks. The prognosis is poor if the signs progress rapidly, but approximately 50% of affected dogs survive if managed intensively.

#### **MYOCLONUS**

Myoclonus is a rhythmic, repetitive contraction of a portion of a muscle, an individual muscle, or a group of muscles occurring as often as 60 times per minute. These rhythmic contractions do not abate during sleep or general anesthesia. Limb and facial muscles are most often involved. Myoclonus is most commonly associated with canine distemper meningoencephalomyelitis, but other focal inflammatory or neoplastic lesions of the spinal cord can also produce myoclonus in rare cases. The prognosis for resolution of the myoclonus is grave.

Familial reflex myoclonus has been recognized in 4- to 6-week-old Labrador Retriever puppies. Clinical signs include intermittent spasms of the axial and appendicular muscles with occasional episodes of opisthotonos. These signs worsen when the animal is stressed or excited. Treatment with diazepam and clonazepam has not been successful. The prognosis for recovery is grave.

# Clinical Manifestations of and Diagnostic Tests for Joint Disorders

# CHAPTER OUTLINE

GENERAL CONSIDERATIONS CLINICAL MANIFESTATIONS DIAGNOSTIC APPROACH DIAGNOSTIC TESTS

Minimum Database Radiography Synovial Fluid Collection and Analysis Synovial Fluid Culture Synovial Membrane Biopsy Immunologic and Serologic Tests

#### GENERAL CONSIDERATIONS

Disorders affecting the joints can be divided into two major categories: noninflammatory and inflammatory (Box 73-1). Noninflammatory joint diseases include developmental, degenerative, neoplastic, and traumatic processes. These disorders are discussed in greater detail in surgery textbooks such as those listed in Suggested Readings. Inflammatory joint diseases can be infectious or immune-mediated. When multiple joints are inflamed, polyarthritis is said to be present. Immune-mediated polyarthritis is further classified as erosive or nonerosive disease on the basis of physical examination findings and results of radiographs of affected joints.

Immune-mediated, nonerosive polyarthritis (IMPA) is the most common inflammatory joint disorder recognized in dogs. It results from immune-complex deposition within the synovium, causing a sterile synovitis. IMPA usually occurs as an idiopathic syndrome, but it may also be a feature of systemic lupus erythematosus (SLE) or secondary to antigenic stimulation (reactive polyarthritis) caused by chronic infection, neoplasia, or administration of drugs. In addition, a few breed-associated syndromes of polyarthritis, polyarthritis/meningitis, or polyarthritis/myositis are thought to have a genetic basis in dogs (see Chapter 74).

## **CLINICAL MANIFESTATIONS**

Animals with joint disease are commonly presented with a history of lameness or gait abnormality. Traumatic or developmental disorders typically involve only one joint, with lameness consistently described in the same limb. When multiple joints are affected, a shifting-leg lameness may be reported. Animals with degenerative joint disease typically exhibit low-grade chronic discomfort that causes lameness and a reluctance to exercise without systemic signs of illness. The pain associated with polyarthritis is usually more severe, and affected animals may refuse to walk or may cry in pain when moved or touched (Fig. 73-1). Some animals with polyarthritis are not obviously lame but are presented with a vague history of decreased appetite, fever, weakness, stiffness, or exercise intolerance. Polyarthritis is one of the most common causes of cyclic fevers and nonspecific inflammation in dogs, and because many affected animals do not have obvious joint pain or detectable joint swelling, it is important to maintain a high index of suspicion for this disorder.

# DIAGNOSTIC APPROACH

Animals with nonspecific pain, a stiff gait, reluctance to exercise, or fever of unknown origin should always receive a careful physical examination in an attempt to localize a region of pain or inflammation. Observation of the animal's posture and gait and thorough manipulation and palpation of the spine and the muscles, bones, and joints of each limb are important. Palpation of the bones themselves will elicit pain in animals after trauma and in dogs affected by panosteitis, hypertrophic osteodystrophy, osteomyelitis, or bone

BOX 73-1

#### **Inflammatory Joint Disease**

Infectious

Noninfectious (immune-mediated)

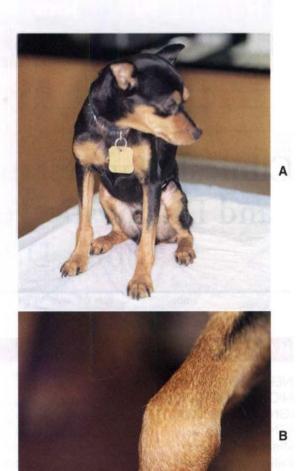

**Nonerosive** 

**Erosive** 

**A,** A 7-year-old Shetland Sheepdog was referred for suspected paralysis. The dog was neurologically normal but refused to rise because of joint pain resulting from idiopathic immune-mediated polyarthritis. **B,** The hock joint is visibly swollen.

neoplasia. Palpation of affected muscles will be painful in animals with myositis or strain/sprain injuries. Pain on palpation or manipulation of the neck could indicate a variety of spinal cord or vertebral abnormalities, intracranial disease, meningitis, or polyarthritis; inflammation of the inter-

**FIG 73-2 A,** A 4-year-old Miniature Pinscher was referred for intermittent fever and depression during the previous year. All joints are palpably and visibly swollen, particularly the carpus **(B)**.

vertebral facetal joints can manifest as neck or back pain (see Box 69-1).

Some animals with joint disease experience obvious discomfort during joint manipulation. Flexing and extending a joint affected by degenerative or erosive disease commonly reveal a restricted range of motion and crepitation, suggesting articular wear, the presence of osteophytes, or other periarticular changes. The stability of the painful joint should be evaluated to assess the integrity of the supporting ligaments. Animals with nonerosive polyarthritis are less likely to have joints that are obviously abnormal on palpation, although joint swelling and pain on manipulation are common (Fig. 73-2). Approximately 30% of dogs with IMPA have no detectable joint swelling or pain, so normal palpation should not deter further diagnostic evaluation for polyarthritis.

Synovial fluid should be collected and evaluated from multiple joints in all dogs and cats with suspected polyarthritis and those with monoarticular disease accompanied by systemic or local signs of inflammation. Synovial fluid analysis is necessary to differentiate inflammatory from noninflammatory joint disease (see Box 73-1). When synovial fluid is inflammatory, the first step is to investigate and eliminate possible infectious diseases as differential diagnoses. Infectious agents causing arthritis include bacteria, Mycoplasma spp., bacterial L-forms, spirochetes, rickettsial agents, and fungi. Diagnostic tests may include a complete blood count (CBC); urinalysis; culture of urine, blood, and synovial fluid; and serology for tick-borne diseases. Thoracic radiographs and fungal serology may also be warranted. Once infectious causes of polyarthritis have been ruled out, immune-mediated conditions should be considered.

Noninfectious IMPA is common in dogs and uncommon in cats. Immune-mediated polyarthritis can occur as an idiopathic syndrome, as a feature of SLE, or secondary to systemic antigenic stimulation (reactive polyarthritis). In reactive polyarthritis the joints are not infected but articular deposition of immune complexes results in synovitis. Reactive polyarthritis has been reported in association with chronic bacterial or fungal infections, neoplasia, or the administration of drugs or vaccines. When the history does not reveal an inciting event, a battery of tests is required to look for systemic evidence of infection or neoplasia (e.g., CBC, thoracic and abdominal radiographs, ophthalmologic examination, bacterial culture of urine and blood, lymph node aspirates, cardiac ultrasonography, abdominal ultrasound) or SLE (e.g., CBC, platelet count, urine protein: creatinine ratio, antinuclear antibody [ANA] titer). Normal results on all of these tests warrant a diagnosis of idiopathic IMPA.

Because most dogs with IMPA have nonerosive disease, radiographs are not always performed during initial evaluation. If dogs with presumed IMPA do not respond quickly and completely to treatment or if joints are unstable or deformed on palpation, radiographs should be taken to evaluate for evidence of erosive disease affecting the articular surfaces, focal "punched out" lesions of lysis in subchondral bone, and proliferation and calcification of periarticular soft tissues. Erosive polyarthritis is an uncommon immunemediated disorder in dogs, with some similarities to human rheumatoid arthritis. This disorder is characterized by progressive joint inflammation, destruction, and deformity. Serologic testing for rheumatoid factor and synovial membrane biopsy aid in the diagnosis of this rare disorder (see p. 1138).

Feline polyarthritis is uncommon. Infectious arthritis has been reported as resulting from bacteria, including bacterial L-forms and Mycoplasma spp., and calicivirus. Periosteal proliferative polyarthritis, an erosive polyarthritis syndrome, has been identified in male cats in association with feline leukemia virus and feline syncytium-forming virus infections. Noninfectious IMPA resulting from SLE also occurs occasionally in cats.

## **DIAGNOSTIC TESTS**

#### MINIMUM DATABASE

Evaluation of a minimum database consisting of a CBC, serum biochemistry profile, and urinalysis should be normal in animals with noninflammatory joint disease. In dogs and cats with polyarthritis it is common to identify a leukocytosis, hyperglobulinemia, and mild hypoalbuminemia. Many of the tick-borne pathogens causing polyarthritis also cause thrombocytopenia. Organisms may be identified within red or white blood cells in animals with some infectious causes of polyarthritis (Fig. 73-3). Proteinuria and hypoalbuminemia will be seen in dogs with concurrent glomerulonephritis. Cats with polyarthritis should always be tested for feline leukemia virus (FeLV) antigen and feline immunodeficiency virus (FIV) antibody. Normal clinical pathology does not rule out polyarthritis.

#### RADIOGRAPHY

Radiographs should routinely be taken during initial evaluation whenever only one joint is clinically affected or joint palpation reveals crepitation, instability, or a restricted range of motion. In dogs with presumed IMPA radiographs are recommended if the response to treatment is not as rapid and complete as expected. Radiographic abnormalities of the joints and periarticular region are expected in animals with degenerative joint disease (DJD), chronic septic arthritis, and immune-mediated erosive (rheumatoid-like) arthritis. Results of the physical examination usually help to identify which joints should be radiographically evaluated. Each joint evaluated requires two views (i.e., lateral and anterior/ posterior). Radiographs from patients with infectious polyarthritis caused by rickettsial agents, Lyme disease, or viruses are similar to radiographs from patients with immunemediated nonerosive polyarthritis; typically, the only abnormalities seen are mild joint capsule distention and associated soft-tissue swelling.

Radiographs of the thorax and abdomen and abdominal ultrasound are often recommended in dogs and cats with polyarthritis to evaluate for underlying infectious or neo-

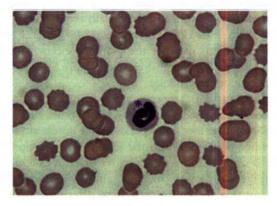

FIG 73-3 Anaplasma phagocytophilium morula in peripheral blood neutrophil from a dog with polyarthritis.

plastic disease. In addition, radiographs of the spine should be performed in dogs with concurrent polyarthritis and neck or back pain to screen for diskospondylitis as a cause for reactive polyarthritis.

Radiography is an important tool, but it is limited. Many of the bony changes seen with DJD and erosive immune disease are not apparent for weeks to months after the onset of signs. Although positive findings contribute a great deal to the diagnosis, negative findings should be interpreted with caution. Sequential radiographic studies may be warranted.

# SYNOVIAL FLUID COLLECTION AND ANALYSIS

Synovial fluid collection and analysis is the most useful test for establishing a diagnosis in dogs and cats with joint disease. It is of greatest value in confirming that a specific joint is abnormal and in differentiating inflammatory from noninflammatory disease. Synovial fluid collection and analysis may also provide information regarding a specific diagnosis.

#### **Collection Method**

Arthrocentesis requires little in the way of expertise or equipment, involves minimal risk to the animal, is inexpensive to perform, and has a high diagnostic yield. In dogs and cats, although synovial fluid can sometimes be collected without sedation or anesthesia, light tranquilization or sedation is usually used to prevent the animal from moving during sample collection and thereby contaminating the sample. Immunologically mediated disease tends to be most prominent in the distal small joints, such as the hock and carpus. Whenever polyarthritis is suspected, synovial fluid should be analyzed from at least six joints, including both carpi, both hocks, and both stifles. Elbows and shoulders should be tapped in animals with poorly localized forelimb lameness. When they are swollen or painful, the smaller metacarpophalangeal and interphalangeal joints can also be sampled. Even if only one joint is clinically affected, synovial fluid should be analyzed from multiple joints.

The hair should be clipped from the area and the skin washed as for surgery. Wearing sterile gloves is necessary if the area where the needle will be inserted is to be palpated. Arthrocentesis in dogs and cats typically requires a 25-gauge needle attached to a 3-ml syringe (Fig. 73-4). A 22-gauge, 1<sup>1</sup>/<sub>2</sub>-inch needle is used for the shoulder, elbow, and stifle joints of larger dogs. Large dogs may require a 3-inch spinal needle to enter the hip joint.

Landmarks for arthrocentesis vary according to personal preference, but some recommended approaches are outlined in Fig. 73-5. After aseptic preparation, the needle attached to the syringe is inserted into the joint. Once the tip of the needle is in the joint, gentle negative pressure is applied to the syringe. Only a very small amount of joint fluid (one to three drops) is needed for the critical determination of viscosity, estimated cell count, differential white blood cell (WBC) count, and culture. The negative pressure on the syringe is released before withdrawal of the needle through

FIG 73-4
Arthrocentesis is performed using a small-gauge needle attached to a 3-ml syringe.

the skin. The appearance of blood should prompt immediate release of suction and withdrawal of the needle. Slides are made immediately (Fig. 73-6), with one drop of synovial fluid used for each slide.

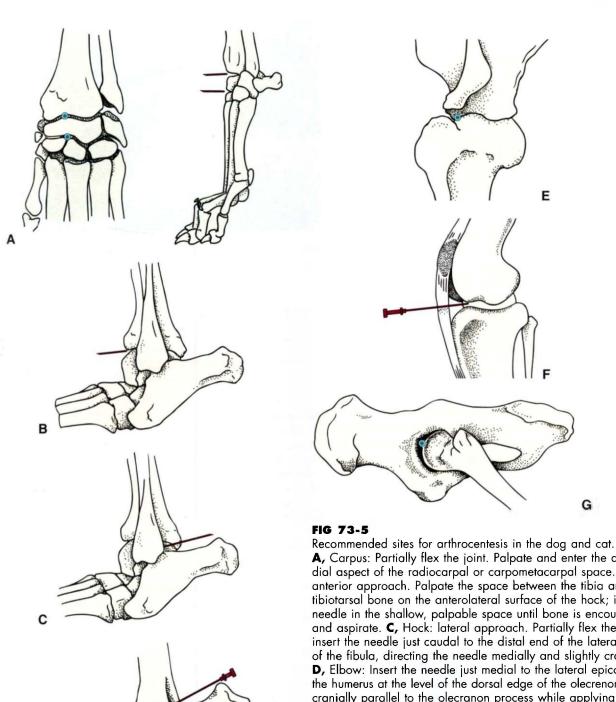

After the collection of samples for cytologic evaluation, a larger sample should be collected for culture and sensitivity. Selection of the most appropriate joint to culture is based on clinical findings or on the gross characteristics of the joint fluid. Aseptic preparation of the joint is repeated, and as much fluid as possible is obtained with gentle suction. This fluid can be either submitted for culture in a sterile tube or directly inoculated into enrichment media.

#### **Analysis of Gross Appearance**

Normal synovial fluid is clear and colorless. Cloudiness or turbidity is seen in any condition that causes red blood cells (RBCs) or WBCs to enter the joint in high numbers. Color change may be an indication of blood contamination or a pathologic condition. Hemorrhage from an earlier puncture attempt or an ongoing disease process typically results in a diffuse red discoloration of the synovial fluid, whereas blood from a traumatic tap is not usually homogeneously mixed with the joint fluid. A yellowish fluid (xanthochromia) may indicate previous hemorrhage into the joint and is occasionally seen in degenerative, traumatic, and inflammatory joint diseases

Normal synovial fluid is very viscous. It forms a long string when allowed to drop from the tip of a needle onto a slide (Fig. 73-7). A thin or watery consistency indicates that

D

A, Carpus: Partially flex the joint. Palpate and enter the anteromedial aspect of the radiocarpal or carpometacarpal space. **B,** Hock: anterior approach. Palpate the space between the tibia and tibiotarsal bone on the anterolateral surface of the hock; insert the needle in the shallow, palpable space until bone is encountered and aspirate. C, Hock: lateral approach. Partially flex the joint, and insert the needle just caudal to the distal end of the lateral malleolus of the fibula, directing the needle medially and slightly cranially. D, Elbow: Insert the needle just medial to the lateral epicondyle of the humerus at the level of the dorsal edge of the olecrenon. Advance cranially parallel to the olecranon process while applying medial pressure on the shaft of the needle. E, Shoulder: lateral approach. With the joint held in partial flexion as if weight bearing, insert the needle just distal to the acromion process cranial to the glenohumeral ligament and direct the needle medially. F, Stifle: With the joint in partial flexion, insert the needle just lateral to the straight patellar ligament equidistant between the distal patella and the tibial tuberosity. Direct the needle slightly medially as it is inserted caudally toward the center of the joint. **G,** Coxofemoral: Support the limb parallel to the table as though the dog were standing. Insert a spinal needle straight in medially just dorsal to the greater

trochanter until bone is encountered, then abduct and medially rotate the limb while advancing the needle ventrally and caudally.

G

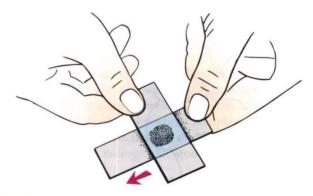

FIG 73-6
Preparing a smear of synovial fluid. A drop of fluid is placed onto a slide. A second slide is used to gently spread the fluid using a pull smear technique.

the synovial fluid is deficient in polymerized hyaluronic acid. This may occur after dilution by serum or through degradation by an intense intraarticular inflammatory reaction.

# **Analysis of Microscopic Appearance**

Cytologic evaluation is the most important aspect of synovial fluid analysis. Usually, only a few drops of synovial fluid are collected, and estimates of cell numbers are made from a stained direct smear of the fluid. One drop of fluid can be placed on a slide and a second slide used to spread the fluid to make a thin smear (see Fig. 73-6). This smear should be air dried and then stained with Diff-Quik or Wrights-Giemsa stain. Because normal synovial fluid contains fewer than 3000 WBCs/µl, no more than three WBCs should be seen per high-dry power (40×) field on a stained smear. Experienced clinicians find simple microscopic scanning of a stained slide of synovial fluid sufficient to estimate cell numbers as normal, mildly increased, or greatly increased.

Normal synovial fluid contains a mixture of large and small mononuclear cells that frequently contain many vacuoles and granules. An occasional neutrophil may be observed, but these cells should represent less than 10% of the total. Blood contamination during synovial fluid collection will result in approximately 1 neutrophil for every 500 RBCs contaminating the fluid. The presence of platelets indicates recent intraarticular hemorrhage or significant blood contamination. Hemosiderin-laden macrophages and erythrophagia confirm prior hemorrhage.

Degenerative joint disease causes a slightly increased cell count (<6000 cells/µl) and an increased volume of synovial fluid, but almost all of the cells are mononuclear cells (Table 73-1). An increase in the number of neutrophils within a joint indicates inflammation of the synovial lining. The more inflamed the synovium, the greater is the concentration of WBCs in the synovial fluid, and the greater the percentage of neutrophils (Fig. 73-8).

In addition to the actual or estimated WBC count and WBC differential, cytologic evaluation of the cells in the joint

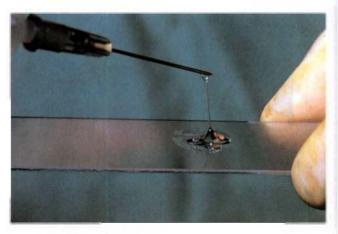

FIG 73-7 Normal synovial fluid is clear and viscous.

TABLE 73-1

Synovial Fluid Cytology in Common Joint Disorders

	WBC/ L	% PMN
Normal	200-3,000	<10
Degenerative	1,000-6,000	0-12
Traumatic	Variable	<25
Septic	40,000-280,000	90-99
Immune-mediated disease		
Nonerosive immune	4,000-370,000	15-95
Erosive arthritis (Rheumatoid-like)	6,000-80,000	20-80

WBC, white blood cell; PMN, polymorphonuclear neutrophil leukocytes.

fluid is important. Neutrophils in the synovial fluid of dogs and cats with immune-mediated disease should have a normal appearance. In acute or severe cases of septic arthritis, it is common to see bacteria within the cells, and neutrophils in the joint may be toxic, ruptured, and degranulated. Organisms may occasionally be observed within the cells in the synovial fluid of animals with polyarthritis caused by rickettsial infections or Leishmania. In dogs with SLE-induced polyarthritis, lupus erythromatosus (LE) cells are in rare cases seen within the synovial fluid (Fig. 73-9).

#### SYNOVIAL FLUID CULTURE

Bacteria are the most common cause of joint infection. Septic arthritis can often be diagnosed on the basis of the appearance of toxic changes within neutrophils and the identification of bacteria on stained smears of synovial fluid. Some organisms, such as *Mycoplasma* spp., do not, however, induce characteristic cytologic abnormalities. Any joint fluid with an increased nucleated cell count and a high percentage of neutrophils warrants a culture. Synovial fluid should be submitted for aerobic and anaerobic culture and for specific *Mycoplasma* spp. culture. Because direct bacterial culture of

synovial fluid is positive in only approximately half of all cases of septic arthritis, failure to grow bacteria in synovial fluid does not rule out septic arthritis. The diagnostic yield can be greatly improved (85% to 100% positive) if infected synovial fluid is collected and inoculated into brothenrichment media (e.g., thioglycolate blood culture bottles), incubated for 24 hours, and then recultured. Microbiologic culture of blood, urine, and synovial membrane biopsy specimens should also be considered to improve chances of recovering the offending organism.

# SYNOVIAL MEMBRANE BIOPSY

Performing synovial membrane biopsy can support a diagnosis already suspected on the basis of the history, physical examination, radiographic studies, and synovial fluid analysis. It may also be used to collect a sample for microbiologic

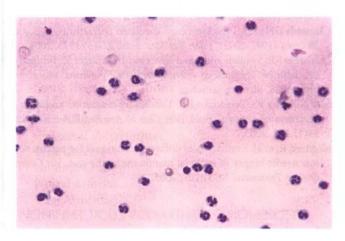

FIG 73-8
Synovial fluid with an increased nucleated cell count consisting primarily of neutrophils from an adult dog with idiopathic immune-mediated polyarthritis.

culture in cases of suspected septic arthritis. Examination of the synovial membrane is especially valuable in the diagnosis of neoplasia and in the differentiation of infectious arthritis from the immune-mediated disorders. An undetermined cause of joint disease or ineffective routine therapy warrants synovial membrane analysis.

Synovial membrane biopsies may be obtained by needle biopsy or surgical arthrotomy. Surgical excision of a wedge of synovial membrane allows visualization of the entire joint and selection of a specific site from which to obtain the biopsy. Needle biopsy of the synovial membrane is quick and minimally traumatic, but samples are small and easily obtained only from the stifle joint. Techniques for both procedures are described in Suggested Readings.

# IMMUNOLOGIC AND SEROLOGIC TESTS Lyme Disease Titers

Infection with the spirochete Borrelia burgdorferi, the etiologic agent for Lyme disease, causes primary infectious synovitis as well as immunologically mediated synovitis resulting from immune complex deposition. Affected dogs develop an antibody response that can be detected using an indirect fluorescent antibody (IFA) test or an enzyme-linked immunosorbent assay (ELISA). Dogs with clinical signs of Lyme disease generally have high titers, but asymptomatic dogs in endemic areas may also have titers greater than 1:8000. Therefore a positive antibody titer merely indicates exposure to the organism and cannot be used to diagnose active disease. The varied, nonspecific clinical signs of Lyme arthritis warrant questioning of the significance of a positive titer. A diagnosis of Lyme disease polyarthritis must rely on a combination of the history (i.e., recent exposure to an area in which the disease is enzootic), clinical signs, elimination of other known causes of polyarthritis, serologic testing, and response to therapy (see p. 1132).

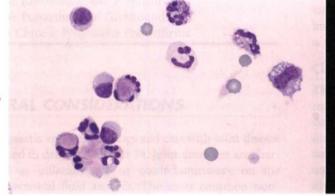

FIG 73-9

Synovial fluid from an adult German Shepherd Dog with polyarthritis. **A,** Some of the cells are lupus erythromatosus cells containing phagocytized, opsonized, amorphous nuclear material. Finding these lupus erythromatosus cells supports a diagnosis of systemic lupus erythromatosus. **B,** This dog also has proteinuria, tongue ulcers caused by vasculitis, and a positive antinuclear antibody test.

#### **Rickettsial Titers**

Serologic testing plays an important role in the diagnosis of Rocky Mountain spotted fever (RMSF), canine monocytc ehrlichiosis, canine granulocytic anaplasmosis, and bartonellosis (see Chapter 96 for more discussion of rickettsial diseases and Chapter 100 for more discussion of bartonellosis). Demonstration of a rising titer is necessary to make the diagnosis of acute RMSF, with a fourfold increase between acute and convalescent titers expected. Demonstration of antibody against *Ehrlichia canis* and *Anaplasma phagocytophilium* indicate prior exposure, with antibody levels remaining elevated for months after successful treatment.

# **Systemic Lupus Erythematosus**

Tests used to help identify SLE include the LE cell test and the ANA test. The LE cell test requires identification of the LE cell, which is a neutrophil or other WBC that has phagocytized opsonized nuclear material. The cytoplasm of these cells is filled with amorphous purple material (see Fig. 73-9). The LE cell test reliability is laboratory dependent, requiring an experienced technician. The ANA test detects circulating antibodies to nuclear material. These antibodies are the most prominent of the autoantibodies associated with canine and feline SLE. The ANA test is a sensitive indicator for the diagnosis of SLE and is positive (>1:10) in 55% to 90% of SLE cases. The ANA is constant from day to day and is less steroid labile than the LE cell test. Unfortunately, a positive ANA test is not specific for SLE, and false-positive results may be seen

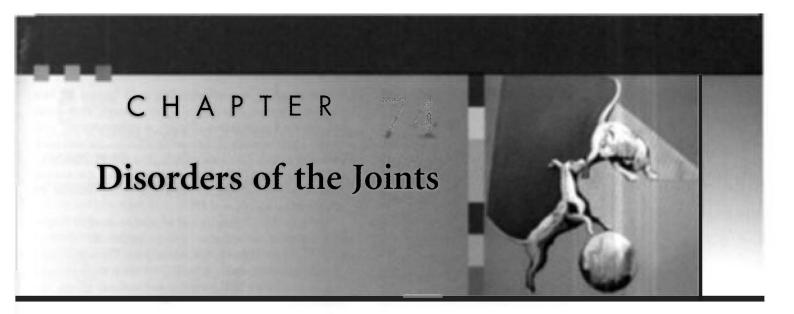

in dogs and cats with many other systemic inflammatory or neoplastic diseases.

#### Rheumatoid Factor

The laboratory test for rheumatoid factor (RF) detects serum agglutinating antibody directed against the patient's own IgG. A titer of 1:16 or higher is generally considered positive, and a titer of 1:8 is considered suspect and should be repeated. The reliability of the test increases with the severity and chronicity of the disease. The test is reported to be positive in 20% to 70% of dogs with erosive (rheumatoid-like) arthritis. Any disease associated with systemic inflammation and immune-complex generation and deposition can result in weak, false-positive results.

Feline Chronic Progressive Polyarthritis

#### **GENERAL CONSIDERATIONS**

The diagnostic approach to dogs and cats with joint disease is discussed in detail in Chapter 74. Joint disorders are characterized as inflammatory or noninflammatory on the basis of synovial fluid analysis. The most common noninflammatory joint disease is degenerative joint disease (DJD), with characteristic clinical and radiographic featuers. When synovial fluid is inflammatory, careful evaluation for an infectious cause should be performed. Noninfectious inflammatory polyarthritis is considered to be immune mediated. Animals with immune-mediated polyarthritis

usually have primary idiopathic immune-mediated disease, but some have systemic lupus erythematosus (SLE), and others develop immune complex—mediated polyarthritis secondary to prolonged systemic antigenic stimulation (reactive polyarthritis; see Chapter 73). Most immune-mediated polyarthritis syndromes are nonerosive. Disorders causing radiographic evidence of bone destruction (erosive disease) are rare.

# NONINFLAMMATORY JOINT DISEASE

#### **DEGENERATIVE JOINT DISEASE**

#### Etiology

Degenerative joint disease (DJD), or osteoarthritis, is a chronic, progressive disorder of joints that results in articular cartilage damage and degenerative and proliferative changes in the periarticular tissues. Joint instability, trauma, and developmental orthopedic diseases are the most commonly identified underlying causes. Although considered noninflammatory on the basis of synovial fluid cytology, inflammatory mediators are involved in the clinical manifestations and progression of DJD. It is estimated that approximately 20% of the adult canine population in North America is affected by DJD in at least one joint.

#### **Clinical Features**

The clinical signs of DJD are usually insidious in onset and confined to the musculoskeletal system, with no associated systemic signs. Lameness and stiffness may initially be prominent only after periods of overexertion and may worsen in cold and damp weather. Mildly affected dogs may "warm out" of their lameness with exercise. As DJD progresses, fibrosis and pain lead to decreased exercise tolerance; constant lameness; and, in severe cases, muscular atrophy. Either a single joint or multiple joints may be affected.

#### **Diagnosis**

DJD is usually diagnosed on the basis of history, physical examination findings, and characteristic radiographic fea-

FIG 74-1 Close-up mediolateral radiograph of left elbow joint of a 14-month-old female German Shepherd Dog with severe degenerative changes secondary to a fragmented coronoid process.

tures. Clinical examination may reveal pain in the affected joint or joints, decreased range of motion, crepitation on flexion and extension of the joint, and (perhaps) appreciable joint swelling. Radiographic changes characteristic of DJD include joint effusion, subchondral bone sclerosis, joint space narrowing, periarticular osteophyte formation, and bone remodeling (Fig. 74-1). A predisposing condition is often identified, such as trauma, rupture of supporting ligaments, poor conformation, or a congenital deformity. Animals with DJD do not exhibit the fever, leukocytosis, and depression commonly seen in animals with inflammatory joint disease.

Synovial fluid from a joint with DJD may be slightly less viscous than normal. The total nucleated cell count is normal or slightly increased, but it rarely exceeds 5000 cells/ l. Characteristically, mononuclear cells constitute at least 80% of the cells and neutrophils are rare (<10%). Acute joint injury or ligament rupture occasionally incites a more inflammatory response, with moderate increases in synovial fluid neutrophils for days to weeks following injury.

## **Treatment**

The goals of treatment in dogs with DJD are to alleviate discomfort and prevent further degeneration. Surgical intervention may be necessary to stabilize the joint or correct a deformity and to relieve discomfort. Medical treatment is symptomatic and nonspecific. Weight reduction may decrease the stresses acting on the joint. Rest often helps to decrease the discomfort associated with acute exacerbations of disease. High-impact exercise, such as running and jumping, should be discouraged, whereas low-impact exercise done in moderation, such as swimming and leash walking, is recommended to maintain the animal's strength and mobility. Other forms of physical therapy may include

passive range of motion exercises, cold (acute) or heat (chronic) therapy, muscle and joint massage, ultrasound, and electrical stimulation. Dietary supplementation with omega-3 polyunsaturated fatty acids (PUFAs), eicosapentaenoic acid (EPA), and antioxidants (vitamin E, vitamin C, beta carotene, zinc and selenium) or feeding commercial "joint diets" containing these supplements may decrease the inflammation and pain of DJD.

Pharmacologic therapies may be used to decrease further degradation of the articular cartilage, inhibit the release of inflammatory mediators, and control pain. The nonsteroidal antiinflammatory drugs (NSAIDs) are often recommended because of their antiinflammatory and analgesic effects. The primary action of most NSAIDs is reversible inhibition of cyclooxygenase, preventing synthesis of the prostaglandins responsible for pain and inflammation. Selective inhibition of two forms of cyclooxygenase (COX-1 and COX-2) may explain some of the differences in efficacy and toxicity among the available NSAID agents. Preferential inhibition of COX-2 with relative sparing of COX-1 by an NSAID may be associated with improved control of inflammation and decreased potential for gastric irritation and ulceration or renal toxicity. Renal function should be assessed before prescribing any NSAID, after 7 days of treatment, and then at least every 6 months during chronic administration. Owners should also be instructed to monitor for inappetence, vomiting, or melena, which could indicate gastrointestinal toxicity. Because the clinical response to each NSAID varies between dogs, it is often advised to switch drugs to determine which one is most effective (Table 74-1). When switching from one NSAID to another, a washout period of at least 3 days without NSAID administration is recommended to prevent toxicity. In dogs that are intolerant of NSAIDs or those that require further analgesia, oral tramadol (2-5 mg/kg q8-12h) can provide relief.

Oral and injectable disease-modifying chondroprotective agents may improve cartilage biosynthetic activity, decrease synovial inflammation, and inhibit intraarticular degradative enzymes. Oral glucosamine and chondroitin sulfate can be administered separately or in combination. An orally administered combination of glucosamine HCl, chondroitin sulfate, and manganese ascorbate has also been recommended (Cosequin RS, 1 to 2 tablets q24h in cats or small dogs; Cosequin DS, 2 to 4 tablets q24h in large dogs; Nutramax Labs). Polysulfated glycosaminoglycans or pentosan polysulfate may be beneficial when administered intramuscularly (see Table 74-1). Hyaluronic acid is a nonsulfated glycosaminoglycan that can be administered as an intraarticular injection to improve synovial viscosity and decrease inflammation. To achieve the maximum theoretic benefit from all of these products, they should be administered before DJD has occurred. Therefore they may be indicated for the treatment of dogs that have sustained trauma or undergone surgery that is known to have damaged articular cartilage. Clinical trials are necessary to evaluate their efficacy.

Dosages of Selected Drugs for the Treatment of Degenerative Joint Disease in Dogs

GENERIC NAME	DRUG NAME	DOSE
Nonsteroidal Antiinflammatory Drugs (N	NSAIDs)	
Acetylsalicylic acid	(Aspirin)	10-20 mg/kg PO q8-12h acid
Carprofen	(Rimadyl)	2.2 mg/kg PO q12h
Deracoxib	(Deramaxx)	1-2 mg/kg PO q24h
Etodolac	(Etogesic)	10-15 mg/kg PO q24h
Firocoxib	(Previcox)	5mg/kg PO q24h
Meloxicam	(Metacam)	0.2 mg/kg PO once, then 0.1 mg/kg PO q24h
Piroxicam	(Feldene)	0.3 mg/kg PO q48h
Disease-Modifying Chondroprotective As	gents	
Chondroitin sulfate		15-20 mg/kg PO q12h
Glucosamine		15-20 mg/kg PO q12h
Pentosan polysulphate	(Pentosan 100)	3 mg/kg IM q7d
Polysulfated glycosaminoglycans	(Adequan)	3-5 mg/kg IM q4d for 8 tx, then q30d
Analgesics	, , ,	
Tramadol		2-5 mg/kg PO q8-12h
Gabapentin	(Neurontin)	5-20 mg/kg PO q8-12h

PO, oral; IM, intramuscular.

# INFECTIOUS INFLAMMATORY JOINT DISEASES

# SEPTIC (BACTERIAL) ARTHRITIS

#### Etiology

Septic arthritis can result from a blood-borne infection or from direct inoculation of a joint. Bacterial infection of multiple joints suggests hematogenous spread of bacteria from a local site of infection. This is uncommon, except in neonates with omphalophlebitis, immunosuppressed animals, and dogs with preexisting polyarticular DJD. Monoarticular septic arthritis is much more common and usually follows direct inoculation of bacteria into a single joint as a result of surgery, a bite wound, foreign body penetration, or trauma. *Staphylococcus* spp., *Streptococcus* spp., and coliform organisms are most often incriminated in the dog, and *Pasteurella* spp. are most commonly identified in cats. Septic arthritis, regardless of the cause, is more common in dogs than cats, is most common in large-breed dogs, and more frequently affects males than females.

#### Clinical Features

Animals with septic polyarthritis are often systemically ill, febrile, and depressed. The affected joints are usually very painful, especially when manipulated, and may be palpably distended with synovial fluid. The periarticular soft tissues may be inflamed and edematous. Septic arthritis stemming from bacteremia usually involves one or a few of the large proximal joints.

# Diagnosis

For septic arthritis to be diagnosed, bacteria must be identified in cytologic preparations of synovial fluid or cultured in synovial fluid, blood, or urine from an animal with appropriate clinical signs and inflammatory joint disease. Synovial fluid obtained by arthrocentesis is often yellow, cloudy, or bloody. The joint fluid is less viscous than normal as a result of the dilution and degradation of synovial mucin by bacterial hyaluronidase and the enzymes released from the inflammatory cells within the joint. Smears of the fluid should be made for the purpose of Gram's staining and cytologic evaluation. Because it is common for synovial fluid from infected joints to clot rapidly, a portion of the fluid should be immediately placed in an anticoagulant (i.e., ethylenediaminetetraacetic acid [EDTA]) tube for future cytologic evaluation if an adequate sample is obtained. Cytologically, animals with septic arthritis show a marked increase in the number (40,000 to 280,000/µl) of nucleated cells in the synovial fluid, with neutrophils predominating (usually >90%). In very acute or severe cases it is common to see bacteria within the cells and the neutrophils may be toxic, ruptured, and degranulated. Organisms that do not cause rapid destruction of articular cartilage (i.e., streptococci, Mycoplasma) may not cause remarkable toxic or degenerative changes in synovial fluid neutrophils. In chronic infections bacteria may no longer be evident and the neutrophils may appear healthy.

Synovial fluid should be cultured for aerobic and anaerobic bacteria. A few drops of fluid should be removed from the joint and the smears stained for cytologic analysis.

**FIG 74-2 (A)** Lateral and **(B)** dorsopalmar. Radiographs of the swollen left carpus of a 2-year-old Bullmastiff with a 1-week history of lameness caused by septic arthritis. Surgical exploration revealed two porcupine quills within the infected joint.

A larger sample should then be obtained from an affected joint for culture. Direct bacterial culture of the synovial fluid is positive in approximately half of all animals with septic arthritis; improved diagnostic yield may be obtained by inoculating synovial fluid into blood culture medium (9:1 ratio) and incubating it for 24 hours at 37° C before inoculation. Bacteria can also be recovered from cultures of synovial membrane biopsy, blood, or urine specimens.

Radiographic changes of the involved joints in septic arthritis may be minimal or nonspecific initially and limited to thickening of the joint capsule, widening of the joint space, and irregular thickening of periarticular soft tissues (Fig. 74-2). In chronic infections cartilage degeneration, periarticular new bone formation, a marked periosteal reaction, and subchondral bone lysis may be seen (Fig. 74-3).

If septic arthritis is suspected and the animal has no history of direct inoculation of the joint with bacteria, a septic site in the body should be sought. Radiography of the thorax, abdomen, and spine and cardiac and abdominal ultrasonography are especially helpful in identifying a focal site of infection. If possible, cultures of material from any suspected site of infection should be performed.

#### **Treatment**

The goals of therapy are to rapidly resolve the bacterial infection and remove intraarticular accumulations of enzymes and fibrin debris. Identifiable systemic sources of infection should also be eliminated. Antibiotics should be administered as soon as possible after all samples are collected in an animal suspected of having septic arthritis. Until culture results are available, a broad-spectrum, 1-lactamaseresistant antibiotic such as a first-generation cephalosporin (e.g., cephalexin, 20 to 40 mg/kg q8h) or clavamox (Smith Kline-Beecham Animal Health; 12 to 25 mg/kg q8h) is indicated. Initially, the antibiotic can be administered parenterally, followed by long-term oral administration. Quinolones should be used if gram-negative organisms are suspected, and metronidazole should be added if anaerobic infection is suspected. Animals with acute septic arthritis can be treated conservatively initially with joint drainage and systemic antibiotics; however, if dramatic improvement is not seen within 3 days, surgery should be performed. Chronic infections, suspected intraarticular foreign bodies, postoperative joint infections, and infection in immature animals with open growth plates should all be treated with immediate surgical debridement and lavage. A minimum of 6 weeks of antibi-

A, A Very swollen elbow in a Husky-cross dog with a 3-month history of a nonweightbearing lameness not responding to antibiotics. B, Radiographs reveal marked swelling within the joint and diffuse periosteal proliferation. Synovial fluid showed septic inflammation, and surgical exploration revealed a single porcupine quill within the joint. The dog recovered completely.

otic therapy is administered, and cage rest is recommended to facilitate healing of articular cartilage.

#### **Prognosis**

The prognosis for a return to normal function depends on the severity of the damage to the articular cartilage at the time the infection is brought under control. Secondary DJD commonly occurs.

#### **MYCOPLASMA POLYARTHRITIS**

Mycoplasma spp. are normal inhabitants of the upper respiratory and urogenital tracts of most species and are generally considered nonpathogenic. Systemic Mycoplasma infection may occasionally occur in debilitated or immunosuppressed animals, but the prevalence of Mycoplasma arthritis is low. Mycoplasma gatea and Mycoplasma felis are the two organisms that have been associated with polyarthritis and tenosynovitis in cats.

Mycoplasma polyarthritis results in a chronic polyarthritis indistinguishable from idiopathic immune-mediated, nonerosive polyarthritis. Clinical signs include lameness, joint pain, depression, and fever. Synovial fluid analysis reveals an increased nucleated cell count consisting predominantly of nondegenerate neutrophils. Routine aerobic and anaerobic cultures of joint fluid are negative because Mycoplasma organisms are deficient in cell walls and cannot revert to a

parental state. Definitive diagnosis requires the isolation of organisms from synovial fluid cultured in special Mycoplasma medium. Idiopathic immune-mediated joint disease is very rare in cats, so empirical treatment with oral doxycycline (5 to 10 mg/kg q12h) for 3 weeks may be recommended in all cats with polyarthritis. Cats with polyarthritis should also be tested for feline leukemia virus (FeLV) and feline immunodeficiency virus (FIV), and radiographs should be taken of the affected joints to look for erosive changes suggesting chronic progressive polyarthritis (see p. 1140).

#### BACTERIAL L FORM-ASSOCIATED ARTHRITIS

A rare syndrome of pyogenic subcutaneous (SC) abscesses with associated polyarthritis has been observed in cats. This syndrome appears to be infectious in nature and transmitted from one cat to another by bite wounds. No age or gender predilection exists. A bacterial L-form mutant bacteria that has lost its cell wall but can revert to its original form has been implicated. Affected cats have swollen, painful joints and fever. Fistulating SC wounds develop over the affected joints. Exudate from the joints or the SC abscesses contains degenerate and nondegenerate neutrophils and macrophages. Cultures for aerobic and anaerobic bacteria, Mycoplasma, and fungal organisms are all negative. Specific L-form media must be used to grow the organism. Radiographically, severely affected joints show extensive soft tissue swelling, periosteal proliferation, and destruction of articular cartilage and subchondral bone, resulting in subluxation and joint space collapse. Electron microscopic studies and antibiotic sensitivity testing can yield findings that help support a diagnosis of L-form bacterial infection. Rarely, cats are concurrently infected with FeIV or FIV. Treatment with doxycycline (5 mg/kg q12h) or chloramphenicol (10 to 15 mg/kg q12h) is effective, with improvement noted within 48 hours. Therapy should continue for 10 to 14 days.

#### RICKETTSIAL POLYARTHRITIS

Nonerosive polyarthritis has been recognized in association with several tick-borne rickettsial diseases, including Rocky Mountain spotted fever (RMSF) caused by Rickettsia rickettsii, canine monocytic ehrlichiosis caused by Ehrlichia canis, and canine granulocytic anaplasmosis (GA) caused by Anaplasma phagocytophilium (formerly Ehrlichia equi). The polyarthritis in these disorders may be related to immune complex deposition in the joints. Most infected dogs have other systemic signs of illness (see Chapter 96). Joint pain and effusion are noted, and increased numbers of nondegenerate neutrophils are identified in the joint fluid; occasionally, Ehrlichia or Anaplasma morulae can be identified in cytologic preparations of joint fluid. Fever and polyarthritis may be the only clinical abnormalities in dogs with ehrlichiosis and anaplasmosis, although hematologic abnormalities such as thrombocytopenia and anemia are common. Serologic testing for Ehrlichia canis and Anaplasma phagocytophilium is widely available, but positive results merely indicate prior exposure and do not necessarily indicate active infection.

Dogs with polyarthritis caused by RMSF are more likely to show a variety of clinical signs resulting from widespread vasculitis, including fever, petechiae, lymphadenopathy, neurologic signs, edema of the face or extremities, and pneumonitis. Hematologic abnormalities, including thrombocytopenia, are common. Diagnosis is made on the basis of the results of serologic testing and demonstration of a fourfold increase in serum IgG concentrations over 2 to 3 weeks (see Chapter 96).

Acute rickettsial infections causing polyarthritis are best treated with oral doxycycline (5 mg/kg q12h). Empirical antibiotic treatment is warranted in all dogs from endemic areas with confirmed polyarthritis, especially if there is concurrent thrombocytopenia or other evidence of rickettsial infection. Concurrent glucocorticoid therapy (prednisone, 0.5 to 2.0 mg/kg PO q24h) may be necessary in some dogs with confirmed rickettsial polyarthritis if antimicrobial therapy alone does not eliminate the fever, lameness, and joint swelling. Antibiotic treatment should continue for at least 3 weeks.

#### LYME DISEASE

#### Etiology

Infection by the tick-borne spirochete Borrelia burgdorferi (Bb) can cause illness (Lyme disease) in dogs. Ticks of the

genus *Ixodes* transmit the spirochete, requiring at least 50 hours of tick attachment for transmission. Although serologic evidence of exposure is common in dogs throughout North America, most reports of canine Lyme disease have occurred in dogs from the northeastern and mid-Atlantic states, with Minnesota, Wisconsin, California, and Oregon accounting for most of the remaining cases.

#### **Clinical Features**

Most dogs bitten by ticks infected with Bb never develop clinical signs of illness. Experimentally infected healthy adult dogs remain asymptomatic, while 6- to 12-week-old puppies develop self-limiting, often recurrent polyarthritis. Acute polyarthritis is the most common form of Lyme borreliosis diagnosed in naturally infected dogs. Clinical features of Lyme polyarthritis include shifting leg lameness, joint swelling, fever, lymphadenopathy, and anorexia. Cytologic examination of synovial fluid reveals neutrophilic inflammation. Cardiac, renal, and neurologic manifestations (e.g., seizure, behavior change) have also been attributed to Bb infection in dogs. There are numerous reports of dogs with Bb antibody developing a unique progressive renal disorder characterized by immune-mediated glomerulonephritis, tubular necrosis, and lymphocytic-plasmacytic interstitial nephritis. This disorder is most common in Labrador and Golden Retrievers, resulting in uremia, proteinuria, peripheral edema, body cavity effusions, and death. Because of the high rate of seropositivity in endemic areas and the frequency of concurrent infection with other tick-borne diseases, it is difficult to determine how common Lyme disease is in clinical practice. The rate of veterinary diagnosis of canine Lyme polyarthritis certainly far exceeds its actual prevalence.

#### Diagnosis

Lyme disease should be suspected in dogs from endemic areas with fever, lameness, and anorexia. Synovial fluid analysis confirms polyarthritis. Attempts to culture Bb from the blood, urine, and synovial fluid of affected dogs are usually unsuccessful. Lyme disease polyarthritis should be diagnosed only if the animal has a history of recent potential exposure, the synovial fluid is confirmed to be inflammatory and sterile, serologic testing is positive, infection with other tickborne diseases is eliminated, and a prompt and permanent response to appropriate antibiotic therapy is seen. The diagnosis can be supported by the identification of *Borrelia* organisms in biopsy specimens of tissues prepared using special stains and monoclonal antibodies.

#### **Treatment**

Antibiotics are the treatment of choice. Doxycycline (5 mg/kg, administered orally q12h), amoxicillin (22 mg/kg, administered orally q12h), ampicillin (22 mg/kg, administered orally q8h), Clavamox (12.5 to 25 mg/kg, administered orally q8-12h), and Cephalexin (20 to 40 mg/kg, administered orally q8h) are all effective. Treatment during the acute stage of the disease should result in rapid clinical improvement (i.e., within 2 to 3 days). Treatment for at least 4 weeks is advised.

Failure to recognize acute disease or the institution of inappropriate treatment can allow chronic disease to develop, including relapsing polyarthritis, glomerulonephritis, and cardiac abnormalities.

#### **Prevention**

The prevention of Lyme disease is discussed in Chapter 69.

#### **LEISHMANIASIS**

Leishmaniasis is a chronic systemic disease caused by a protozoan parasite found mainly in Central and South America and in Africa, India, and the Mediterranean. In the United States *Leishmania* spp. are endemic in Ohio, Oklahoma, and Texas. Clinical abnormalities develop 3 months to 7 years after infection and typically consist of vague signs, including weight loss, lymphadenopathy, and splenomegaly. Hyperglobulinemia, hypoalbuminemia, and proteinuria are expected. Polyarthritis causing lameness and exercise intolerance is common. Many affected dogs will have erosive disease, with radiographic evidence of periarticular lysis and periosteal proliferation. Diagnosis is made when organisms are identified within macrophages in lymph node or splenic aspirates or in joint fluid (see Chapter 94).

#### **FUNGAL ARTHRITIS**

Fungal infection of the joints is very rare. When it does occur, it is usually as an extension of fungal osteomyelitis caused by *Coccidioides immitis, Blastomyces dermatitidis*, or *Cryptococcus neoformans*. More commonly a reactive, immunologically mediated, culture-negative polyarthritis occurs in dogs and cats with systemic fungal infections.

## VIRAL ARTHRITIS Calicivirus

Natural calicivirus infection and attenuated live calicivirus vaccination have been associated with the development of transient polyarthritis in 6- to 12-week-old kittens. Clinical signs include lameness, stiffness, and fever, which usually resolve spontaneously after 2 to 4 days (Fig. 74-4). Some kittens go on to develop overt calicivirus infection, with glossal and palatine vesicles or ulcers and signs of upper respiratory tract disease. Synovial fluid analysis reveals a mildly to greatly increased nucleated cell count, with small mononuclear cells and macrophages predominating, some of which contain phagocytosed neutrophils. Two specific strains of calicivirus have been implicated. Isolation of the virus from affected joints has been unrewarding, although the virus can be found in the oropharynx of some infected cats.

## NONINFECTIOUS POLYARTHRITIS: NONEROSIVE

Noninfectious inflammatory joint diseases are very common in the dog and rare in the cat. These immune-mediated polyarthritis syndromes are routinely classified as being

FIG 74-4
Presumed calicivirus polyarthritis in a 10-week-old kitten exhibiting swollen joints, lameness, and fever 6 days after modified-live virus vaccination.

erosive or nonerosive on the basis of the presence or absence of radiographically evident joint destruction. Erosive disorders are very rare, consisting of fewer than 1% of canine polyarthritis cases. The nonerosive immune-mediated polyarthritis (IMPA) syndromes are all thought to be mediated through immune complex formation and deposition. Immune-mediated nonerosive polyarthritis occurs as a feature of systemic lupus erythematosus (SLE), secondary to antigenic stimulation from chronic infection, neoplasia, or drugs (i.e., reactive polyarthritis), or as an idiopathic syndrome. Breed-associated syndromes of polyarthritis or polyarthritis/meningitis or polyarthritis/myositis also exist and are thought to have a genetic basis.

#### SYSTEMIC LUPUS ERYTHEMATOSUS-INDUCED POLYARTHRITIS

SLE is a condition in which autoantibodies against tissue proteins and DNA result in circulating immune complexes that, when deposited in tissues, induce inflammation and organ damage (see Chapter 104). German Shepherd Dogs may be predisposed, but any breed of dog may be affected. SLE is most commonly diagnosed in dogs 2 to 4 years old. Criteria for SLE diagnosis vary between studies, but SLE is considered to be the cause of fewer than 20% of all cases of immune-mediated nonerosive polyarthritis in dogs. Although SLE is a relatively uncommon cause of polyarthritis in dogs compared with idiopathic immune-mediated polyarthritis, its effects on other organ systems can be devastating, which makes accurate diagnosis important.

#### **Clinical Features**

The clinical manifestations of SLE vary with the organ involved and include intermittent fevers, polyarthritis, glomerulonephritis, skin lesions, hemolytic anemia, immunemediated thrombocytopenia, myositis, and polyneuritis. Polyarthritis is the most common manifestation, occurring in 70% to 90% of dogs diagnosed with SLE. Some affected dogs show no signs referable to their joint disease, and polyarthritis is detected when synovial fluid is examined as part of a workup for fever, inflammatory clinicopathologic tests, or polysystemic immune-medicated disease. More often, dogs with SLE polyarthritis show generalized stiffness, joint swelling, or a shifting leg lameness. SLE causes a sterile, nonerosive polyarthritis, with distal joints (i.e., hocks, carpi) usually more severely affected than proximal joints. Synovial fluid analysis reveals an increased white blood cell count (5000 to 350,000/ml) consisting primarily of nondegenerate neutrophils (>80%). In rare instances, lupus erythematosus (LE) cells are detected in the synovial fluid (see Fig. 73-9).

#### Diagnosis

SLE should be considered in any dog with non-infectious polyarthritis. A complete blood count (CBC), platelet count, biochemistry profile, urinalysis, urine protein : creatinine ratio determination, and careful physical examination should be performed to search for other manifestations of this disease. Laboratory tests that may aid in the diagnosis of SLE polyarthritis include the LE cell test (positive in 30% to 90% of cases) and the antinuclear antibody (ANA) test (positive in 55% to 90% of cases). An animal may be said to have SLE if one or more of these "specific" diagnostic tests (e.g., ANA, LE) are positive and the animal has two or more of the clinical abnormalities known to be associated with SLE (e.g., polyarthritis, glomerulonephritis, anemia, thrombocytopenia, dermatitis; see Chapter 104). When two or more of the common clinical syndromes are recognized but none of the serologic tests are positive, the dog is determined to have an SLE-like multisystemic immune-mediated disease.

#### **Treatment**

Treatment for SLE-associated polyarthritis is the same as that used for idiopathic, immune-mediated polyarthritis (Chapter 74). If the animal is clinically normal and synovial fluid is non-inflammatory after 6 months of therapy, it may be worthwhile to discontinue medications because long periods of drug-free remission can occur.

#### **Prognosis**

The prognosis is good from the standpoint of controlling the polyarthritis, but multisystemic involvement (particularly glomerulonephritis) may progress despite therapy, occasionally resulting in death.

#### REACTIVE POLYARTHRITIS

Reactive polyarthritis accounts for approximately 25% of all nonerosive immune-mediated polyarthritis cases. Reactive polyarthritis is most often seen in association with chronic bacterial, fungal, or rickettsial infections; neoplasia; or drug administration. Reactive polyarthritis has been documented in dogs with endocarditis, foreign body abscesses or granulomas, diskospondylitis, heartworm disease, pancreatitis, pro-

FIG 74-5

A 2-year-old German Shepherd Dog/Labrador Retriever cross with reactive polyarthritis (A). The dog was seen because of a 3-month history of shifting leg lameness and weight loss. There was joint swelling and pain and a grade IV/VI diastolic cardiac murmur. Synovial fluid was inflamed but sterile. A cardiac ultrasound study suggested infective endocarditis of the aortic valve, which was confirmed by postmortem evaluation (B).

statitis, pyelonephritis, pneumonia, other chronic infections, and a variety of tumors (Fig. 74-5). Drugs that have been implicated in causing reactive polyarthritis include sulfadiazine-trimethoprim, phenobarbital, erythropoietin, penicillin, cephalexin, and routine vaccinations. Rarely, gastrointestinal disorders such as inflammatory bowel disease, salmonellosis, and chronic active hepatitis have also been associated with reactive polyarthritis.

Because many animals with reactive polyarthritis have vague or minimal clinical signs referable to their underlying disease, they will be presented for veterinary evaluation when their joint inflammation makes them reluctant to walk. Therefore it is important to perform a thorough physical examination of every animal with polyarthritis and to obtain a complete history regarding the administration of medications and the presence or absence of systemic signs. Once infectious causes of polyarthritis have been eliminated, screening tests (i.e., CBC, biochemical panel, urinalysis, thoracic and abdominal radiography, abdominal ultrasonogra-

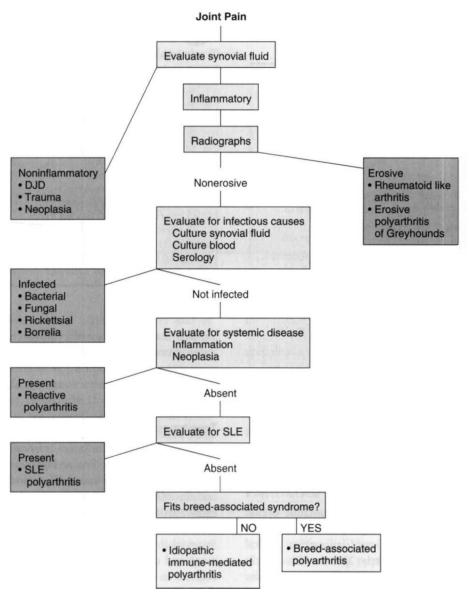

FIG 74-6
Algorithm for diagnostic evaluation of dogs with joint pain.

phy, culture of urine and blood, lymph node aspirates, cardiac ultrasonography) may be required to identify underlying chronic infections or neoplasia (Fig. 74-6).

Clinical signs in dogs with reactive polyarthritis typically include cyclic fevers, stiffness, and lameness. Synovial fluid analysis reveals an increase in the WBC count and the percentage of neutrophils in affected joints, but synovial fluid culture is negative. Even if the underlying inflammatory disease is infectious, the polyarthritis in these patients is caused by synovial deposition of circulating immune complexes, not by infection of the joints. Radiographically, the only finding is joint swelling.

Treatment must be directed at eliminating the underlying disease or antigenic stimulus using medications or surgery whenever possible. If this can be done, the polyarthritis usually resolves without additional therapy. Short-term, low-

dose corticosteroid therapy (prednisone, 0.25 to 1.0 mg/kg q24h) or NSAID therapy may be warranted to control the synovitis in severe cases.

## IDIOPATHIC, IMMUNE-MEDIATED, NONEROSIVE POLYARTHRITIS

Nonerosive, noninfectious polyarthritis in which a primary or underlying disease cannot be identified is referred to as *idiopathic immune-mediated polyarthritis (IMPA)*. This disorder can be diagnosed only by ruling out the other causes of polyarthritis, but it is the most common form of polyarthritis diagnosed in dogs (Box 74-1). It is especially common in sporting and large breeds. Dogs of any age can be affected, but the incidence peaks at 2.5 to 4.5 years. Idiopathic, immune-mediated, nonerosive polyarthritis is uncommon in cats.

BOX 74-1

Classification of Polyarthritis in Dogs

#### Infectious

**Bacterial** Mycoplasma Rickettsial Lyme borreliosis Leishmaniasis Fungal Viral

#### Noninfectious, Nonerosive

Idiopathic, immune-mediated polyarthritis Systemic lupus erythematosus Reactive polyarthritis (bacterial, fungal, parasitic, neoplastic, enterohepatic, drug reaction, vaccine induced) Breed-associated syndromes Polyarthritis (Akita, Newfoundland, Weimaraner) Polyarthritis/meningitis (Akita, Beagle, Bernese Mountain Dog, Boxer, German Shorthair Pointer) Polyarthritis/polymyositis (Spaniels) Familial Shar-Pei fever

#### Noninfectious, Erosive

lymphoplasmacytic synovitis

Rheumatoid-like arthritis Erosive polyarthritis of Greyhounds

#### **Clinical Features**

The clinical signs of idiopathic IMPA may include cyclic fevers, stiffness, and lameness. Multiple joints are usually involved, with the small distal joints (i.e., carpus, hock) affected most severely. Approximately 20% to 50% of all affected dogs may not have palpable joint effusion or localizable pain. Cervical pain and vertebral hypersensitivity are common complaints, reflecting either intervertebral facetal joint involvement or the presence of concurrent steroid-responsive meningitis-arteritis (see Chapter 69). Some dogs are evaluated because of a vague history of decreased appetite or because of fever of unknown origin.

#### Diagnosis

Idiopathic IMPA is diagnosed on the basis of the results of synovial fluid analysis, failure to identify an infectious cause, and the absence of evidence to support a diagnosis of SLE or reason to suspect reactive polyarthritis (Fig. 74-6). A CBC typically reveals neutrophilia, although some dogs have a normal CBC. Hyperglobulinemia and hypoalbuminemia are common, reflecting ongoing systemic inflammation. When radiographs are taken, the findings are normal or limited to joint and periarticular swelling with no bone or cartilage abnormalities. Synovial fluid is thin and may be turbid. Nucleated cell counts are increased (4000 to 370,000 cells/ µl), and nondegenerate neutrophils predominate (usually >80%). In animals with less severe or fluctuating disease and

Treatment Recommendations for Idiopathic Immune-Mediated Polyarthritis

- Prednisone 2 mg/kg q12h orally for 3-4 days
- 2. Prednisone 2mg/kg q24h orally for 14 days
- 3. Assess clinical response and synovial fluid cytology If clinical signs have resolved, the dose of prednisone is gradually tapered, evaluating clinical response and synovial fluid before each dose reduction.
- 1 mg/kg q24h ×4 weeks
- 1 mg/kg q48h ×4 weeks
- 0.5 mg/kg q48h ×4 weeks 0.25 mg/kg q48h ×8 weeks
- If clinical signs of joint inflammation are present at any recheck, return to step 2 and add azathioprine (2 mg/kg/day) to treatment. Continue prednisone taper after signs resolve and synovial fluid is normal.

animals that have received corticosteroids, there may be a lower synovial fluid white blood cell count and a lower percentage of neutrophils (15% to 80%). Blood, urine, and synovial fluid cultures are negative for bacteria and Mycoplasma spp.

#### **Treatment**

Glucocorticoids are the initial treatment of choice for dogs with idiopathic IMPA. Prednisone treatment alone results in remission in 50% of cases. Immunosuppressive doses are initially administered, and the dosage is gradually decreased every 3 to 4 weeks if the animal is clinically normal and the inflammation in the synovial fluid has subsided (Box 74-2). Synovial fluid should be monitored carefully during treatment and determined to be noninflammatory before each decrease in drug dose. If the joints are not inflamed, the drug doses may be slowly tapered. If a dog can be maintained on a low, alternate-day dose of prednisone (0.25 mg/kg q48h) for 2 months and the synovial fluid is not inflammatory, it should be possible to discontinue all therapy. Approximately 50% of affected dogs will need at least alternate-day lowdose prednisone therapy for the remainder of their lives. In dogs receiving a stable dose of medication, synovial fluid should be evaluated every 4 to 6 months.

Azathioprine (Imuran; Burroughs Wellcome) should be administered to dogs with persistent inflammation of synovial fluid despite prednisone therapy and to dogs that cannot be tapered to a low dose of prednisone without relapse. Azathioprine may also be used from the beginning in dogs that do not tolerate prednisone therapy. Azathioprine (2.2 mg/kg) is administered once daily for 4 to 6 weeks and then only on alternate days if the animal is doing well clinically and the synovial fluid is no longer inflammatory. Some dogs will require lifelong azathioprine therapy. In most dogs azathioprine is well tolerated, with myelosuppression its major toxicity. A CBC and platelet count should be performed initially every 2 weeks and then every 6 to 8 weeks

#### Drugs Used in the Treatment of Immune-Mediated Polyarthritis

DRUG	DOSAGE						
Prednisone	Variable						
Azathioprine (Imuran, GlaxoSmithKline)	2.2 mg/kg PO q24-48h						
Cyclosporine (Neoral, Novartis)	2.5 mg/kg PO q12 h						
	Target blood level 400 ng/ml						
Leflunomide (Arava, Aventis Pharma)	4 mg/kg q24h						
	Target trough blood level 20 µg/ml						
Gold salt injections (Solganol, Shering)	0.5-1.0 mg/kg weekly IM for 8 weeks, then monthly						
Cyclophosphamide (Cytoxan, Bristol-Myers-Squibb	50 mg/M <sup>2</sup> PO q48h						
Chlorambucil (Leukeran, GlaxoSmithKline)	2 mg/M <sup>2</sup> PO q48h						
Methotrexate (Rheumatrex, Lederle)	2.5 mg/M <sup>2</sup> PO q48h						

PO, oral; IM, intramuscular.

during therapy. Hepatic enzyme activities should also be monitored to facilitate the early detection of hepatotoxicity. Dogs treated with azathioprine and prednisone may also be at increased risk for developing pancreatitis.

Additional immunosuppressive agents are rarely necessary because idiopathic, nonerosive IMPA is easy to control in most patients. If the polyarthritis is refractory to treatment, the patient should be reevaluated for infectious disease, reactive polyarthritis, and erosive disease. When necessary, other immunosuppressive agents can be administered (Table 74-2). In addition to medical treatment, management should initially include restricted exercise, followed by regular gentle exercise and weight control. Chondroprotective agents, omega-3 fatty acids, and antioxidants may also prove beneficial. (See Chapter 103 for more information on immunosuppressive treatment.)

#### **Prognosis**

The prognosis for animals with idiopathic, immunemediated, nonerosive polyarthritis is good. One dog in 50 is very difficult to treat and keep in remission. Dogs that require long-term (4 to 5 years) high-dose immunosuppressive drug therapy for this disorder may develop symptomatic DJD secondary to chronic low-grade synovial inflammation or the detrimental effects of corticosteroids on cartilage synthesis and repair.

#### **BREED-SPECIFIC POLYARTHRITIS SYNDROMES**

Immune-mediated polyarthritis has been shown to be a problem in a number of breeds. A heritable polyarthritis has been documented in Akitas younger than 1 year of age and sporadically in Newfoundlands and Weimaraners. Many of these dogs have a concurrent meningitis resembling the meningeal vasculitis syndromes seen in a few other breeds (see Chapter 69). ANA tests are negative in these animals, and generally they respond poorly to immunosuppressive therapy. In contrast, polyarthritis that accompanies meningeal vasculitis in some Boxers, Bernese Mountain dogs, German Shorthair Pointers, and Beagles often responds completely to immunosuppressive therapy.

Familial polyarthritis with concurrent myositis has been rarely reported in a few Spaniel breeds. Affected dogs are exercise intolerant and exhibit a crouched stance at rest. Widespread muscle atrophy is common, occasionally leading to muscle fibrosis, contracture, and reduced mobility. Muscle enzymes (CK, AST) may be increased. Response to therapy is often poor.

#### FAMILIAL CHINESE SHAR-PEI FEVER

A disorder characterized by recurrent fevers and periarticular swelling has been documented in the Shar-Pei and is known as "familial Shar-Pei fever" (FSF) or "Sharpei hock" syndrome. Growing pups or young adult dogs are initially affected by episodes of fever lasting 24 to 36 hours. Approximately 50% of affected dogs develop swelling of the tissues around the hock joint during the febrile episodes, and a few dogs develop polyarthritis. Affected dogs are at increased risk for systemic amyloidosis, leading to renal or hepatic failure. Renal amyloid deposition is primarily medullary, and not all dogs will exhibit proteinuria. Hyperglobulinemia and increased serum concentrations of the cytokine interleukin-6 are common. Glomerulonephritis, pyelonephritis, renal infarcts, and systemic thromboembolic disease may occur. This disorder is inherited as an autosomal trait. Treatment is symptomatic to control the fevers and inflammation. Oral administration of colchicine (0.03 mg/kg q24h) may decrease amyloid deposition.

#### LYMPHOPLASMACYTIC SYNOVITIS

Lymphoplasmacytic synovitis is present in some dogs with partial and complete tears of the cranial cruciate ligament, but the relationship between the immune-mediated response and the ligament rupture is uncertain. Partial tears or ruptures of the cruciate ligament commonly initiate an inflammatory reaction directed against the collagen of the ligament, resulting in mildly inflammatory synovial fluid and synovial fluid antibodies directed against type 1 and type 2 collagen. An alternative theory is that lymphoplasmacytic synovitis is a primary immune-mediated disorder that causes joint laxity and instability, eventually leading to rupture of the cranial cruciate ligament. Some investigators have estimated that perhaps as many as 10% to 25% of cruciate ruptures in dogs are caused by this immunologic disorder, but this is a controversial claim.

Dogs diagnosed with lymphoplasmacytic synovitis are the same dogs typically presented for cruciate ligament rupture, with Rottweilers, Newfoundlands, Staffordshire Bull Terriers, and Labrador Retrievers most commonly affected. Clinical signs are limited to acute or chronic lameness involving one or both stifles. Cruciate ligament rupture at the time of diagnosis may be partial or complete and not usually historically associated with trauma. Arthroscopy or magnetic resonance imaging (MRI) may be required to confirm the diagnosis of partial rupture. Affected animals are in good body condition and are not systemically ill; CBC is normal. Synovial fluid is thin and turbid, with an increased nucleated cell count (5000 to 20,000 cells/1 l, but occasionally >200,000/11). Lymphocytes and plasma cells predominate (60% to 90%) in the synovial fluid. Characteristic histopathologic changes in the synovial lining include lymphocytic and plasmacytic infiltration and villous hyperplasia. Biopsy of ligament and synovium should be performed at the time of surgical exploration and repair in all dogs with nontraumatic cruciate ligament ruptures. Surgical stabilization of the stifle and treatment with NSAIDs usually results in rapid resolution of clinical signs. Some dogs will have persistent effusion and discomfort that responds well to immunosuppressive treatment with prednisone and/or azathioprine, initiated a minimum of 3 days after NSAID therapy is discontinued.

## NONINFECTIOUS POLYARTHRITIS: EROSIVE

## CANINE RHEUMATOID-LIKE POLYARTHRITIS

A disorder resembling human rheumatoid arthritis (RA) rarely results in erosive polyarthritis and progressive joint destruction in dogs. Small and toy breeds are most commonly affected. The age of onset is variable (i.e., 9 months to 13 years), but most affected dogs are young or middle-aged. Initially, the disease is indistinguishable from idiopathic nonerosive polyarthritis, but the joints are destroyed over time (weeks to months), with distal joints most severely affected.

#### Etiology

The pathogenesis of canine RA-like polyarthritis is poorly understood. Antibodies directed against immunoglobulin G (i.e., rheumatoid factors [RF]) form and complex with IgG within the synovium. This results in complement activation

and the chemotactic attraction of plasma cells, lymphocytes and neutrophils into the joint fluid. The synovial membrane thickens and develops a fibrous, vascular granulation tissue (pannus), which invades articular cartilage, tendons, ligaments, and subchondral bone. Proteolytic enzymes are released that erode the articular cartilage and the subchondral bone, leading to joint collapse and the radiographically visible "punched-out" subchondral bone lesions. Articular and periarticular inflammation and instability lead to joint subluxation and luxation, resulting in joint deformity.

#### **Clinical Features**

Affected dogs initially have signs indistinguishable from those of other forms of polyarthritis. A low-grade fever, depression, anorexia, and reluctance to exercise are common. Joint-related clinical signs such as joint pain and stiff gait are prominent. Signs may be sporadic initially, and stiffness is generally worse after rest and improves with mild exercise. The joints may appear normal or be swollen and painful. The joints most commonly affected are the carpi, hocks, and phalanges, although elbows, shoulders, and stifles can also be affected. As the disease progresses, clinical examination reveals crepitus, laxity, luxation, and deformity of affected joints (Fig. 74-7).

Radiographic features may be subtle at the time of initial diagnosis, with intracapsular swelling the only consistent finding. Later, characteristic changes consist of focal, irregular, radiolucent, cystlike areas of subchondral bone destruction (Fig. 74-8); joint space collapse; and joint subluxation and luxation. If RA is suspected, carpi and hocks should be radiographed bilaterally.

#### Diagnosis

of Saskatchewan.)

RA-like polyarthritis should be suspected in any dog with erosive polyarthritis once infectious causes have been eliminated. The synovial fluid in affected joints is thin, cloudy,

FIG 74-7
Complete collapse of both carpi resulting in luxation and severe distortion of the forelimbs in a Dachshund with rheumatoid arthritis (RA). (Courtesy Dr. D. Haines, University

FIG 74-8
Radiographs of both carpal joints of a 9-year-old female Shih Tzu. Both carpi are severely deformed secondary to erosive rheumatoid-like polyarthritis. The intercarpal spaces have thinned laterally, and there are focal radiolucent cystlike areas of subchondral bone destruction and regional soft-tissue swelling. There is dislocation of the radius and ulna from the carpus bilaterally.

and hypercellular (6000 to 80,000 white blood cells/µl; mean, 30,000/µl). Neutrophils may be the predominant cell (20% to 95%; average 74%), or mononuclear cells may predominate. Culture of the synovial fluid is negative. Whenever possible, the synovial fluid should be collected during a period when the dog is most symptomatic because the cyclical nature of the disease occasionally makes diagnosis difficult.

Serologic tests for circulating RF are positive in 20% to 70% of affected dogs (see Chapter 73). Weak false-positive results are common in dogs with other systemic inflammatory diseases. Synovial biopsy may help to establish the diagnosis, revealing synovial thickening, hyperplasia, and proliferation with pannus formation. The pannus is composed primarily of proliferating activated synoviocytes, lymphocytes, plasma cells, macrophages, and neutrophils. Culture of the synovial biopsy is negative. RA is diagnosed on the basis of the typical clinical findings and radiographic features, characteristic synovial fluid features, a positive RF test result, and the typical histopathologic changes seen in a synovial biopsy specimen.

#### **Treatment**

Early treatment of RA is important to prevent irreversible changes and progressive disease. Medical treatment usually includes immunosuppressive drugs and chondroprotective agents. Initially, most dogs are treated with oral prednisone (2 to 4 mg/kg q24h for 14 days, then 1 to 2 mg/kg q24h for 14 days) and azathioprine (2.2 mg/kg q24h), administered as described for the treatment of refractory idiopathic, nonerosive polyarthritis. Oral chondroprotective agents (see Table 74-1) are routinely administered. Subjective improvement has also been observed in dogs receiving injectable chondroprotective agents (e.g., Adequan).

After 1 month of therapy, the dog is reexamined and synovial fluid is evaluated. If the fluid is non-inflammatory, the corticosteroid dose is decreased to 1 to 2 mg/kg orally every 48 hours and treatment with azathioprine is continued. If the fluid is still inflammatory, then daily administration of prednisone (1 to 2 mg/kg) and azathioprine (2.2 mg/kg) continues and oral methotrexate (Rheumatrex, Lederle; 2.5 mg/m<sup>2</sup> q48h) may be added to the treatment regimen. Monthly evaluation of synovial fluid is recommended. If inflammation of the synovial fluid persists after 2 months, additional therapy such as Leflunomide (Arava; Aventis Pharma), a pyrimidine synthesis inhibitor, may be added to the treatment regimen (see Table 74-2). Leflunomide is administered at an initial dose of 4 mg/kg q24h, and the dose is adjusted to maintain a trough plasma level of 20 mg/ml (the usual maintenance dose is 0.5 mg/kg q24h). (See Chapter 103 for more information on immunosuppressive treatment.)

Some therapeutic success may be expected if treatment is initiated before joint damage is severe. In most cases, however, damage to the articular cartilage is severe before the diagnosis is made. Many dogs require additional therapy with analgesics such as tramadol to control joint discomfort. RA is a relentlessly progressive disorder, and even with appropriate therapy most dogs show deterioration with time. Surgical procedures can occasionally be used to improve joint stability and pain. Synovectomy, arthroplasty, joint replacement, and arthrodesis may decrease pain and improve function.

## EROSIVE POLYARTHRITIS OF GREYHOUNDS

An erosive, immune-mediated polyarthritis occurs in Greyhounds from 3 to 30 months of age. This disorder is primarily seen in Australia and Britain. The proximal interphalangeal joints, carpi, hocks, elbows and stifles are most commonly affected. Clinical signs include generalized stiffness, joint pain or swelling, and a single or multiple limb lameness that may be intermittent. The synovial membrane is infiltrated with lymphocytes, and plasma cells and synovial fluid analysis reveals an increase in these same cells. There is extensive necrosis of deep articular cartilage zones, with relative sparing of the superficial surface cartilage. Therapy is as for refractory idiopathic, immune-mediated, nonerosive polyarthritis: administering prednisone, azathioprine, and chondroprotective agents. Response to treatment is variable.

## FELINE CHRONIC PROGRESSIVE POLYARTHRITIS

An uncommon syndrome of erosive polyarthritis has been reported in cats. This disorder affects primarily intact and castrated male cats, and the onset of signs is usually between 1.5 and 4 years of age, although older cats are occasionally affected. The pathogenesis of the disorder is not well understood, but all affected cats are infected with FeSFV (feline syncytium-forming virus) and approximately 60% are infected with FeLV or FIV or both. Two clinical variants of this disorder affect cats: (1) a proliferative periosteal form and (2) a more severe, deforming erosive arthritis that resembles RA.

The periosteal proliferative form is most common and is characterized by the acute onset of fever, stiff gait, joint pain, lymphadenopathy, and edema of the skin and soft tissues overlying the joint. Synovial fluid analysis initially reveals inflammation with an increased white blood cell count, particularly neutrophils. As the disease becomes chronic, the proportion of lymphocytes and plasma cells increase. Initially, the radiographic changes are mild and include periarticular soft tissue swelling and mild periosteal proliferation. With time, the periosteal proliferation worsens and periarticular osteophytes, subchondral cysts, and collapse of the joint space may be noted.

The deforming type of chronic progressive polyarthritis is rare and has an insidious onset, with the slow development of lameness and stiffness. Deformation of the carpal and distal joints is common. Severe subchondral central and marginal erosions, luxations, and subluxations can be seen radiographically, which can lead to joint instability and deformities. Cytologic findings in synovial fluid are less remarkable than those in the periosteal proliferative form and consist of a mild to moderate increase in inflammatory cells (i.e., neutrophils, lymphocytes, macrophages).

#### Diagnosis

The diagnosis is based on the typical signalment, clinical signs, radiographic features, and results of synovial fluid

analysis. Tests for FeSFV (when available) and FeLV may be positive. In addition, cultures of synovial fluid are negative, and no evidence of an underlying disorder causing a reactive polyarthritis is seen.

#### **Treatment**

Treatment with prednisone (4 to 6 mg/kg/day) may slow the progression of these diseases. If the cat shows clinical improvement after 2 weeks, the dose of prednisone can be decreased to 2 mg/kg daily. Long-term alternate-day prednisone therapy (2 mg/kg q48h) may be adequate in some cats. Combination therapy with chlorambucil (Leukeran; Burroughs Wellcome; 20 mg/m², administered orally every 2 weeks) may aid in long-term control. Concurrent treatment with analgesics such as amantadine (3 mg/kg, administered orally q24h), amitryptyline (0.5-2.0 mg/kg, administered orally q24h), or gabapentin (2-10 mg/kg, administered orally q24h) may make affected cats more comfortable. Although many cats respond initially to therapy, the prognosis for adequate long-term control is poor, and most affected cats are euthanized.

#### CHAPTER OUTLINE

GENERAL CONSIDERATIONS
FINE-NEEDLE ASPIRATION
IMPRESSION SMEARS
STAINING OF CYTOLOGIC SPECIMENS
INTERPRETATION OF CYTOLOGIC SPECIMENS

Normal Tissues Hyperplastic Processes Inflammatory Processes Malignant Cells Lymph Nodes

#### **GENERAL CONSIDERATIONS**

Evaluation of a cytologic specimen obtained by fine-needle aspiration (FNA) in small animals with suspected neoplastic lesions often yields information that can be used to make a definitive diagnosis, thereby circumventing the immediate need to perform a surgical biopsy. At our hospital, almost every mass or enlarged organ is evaluated cytologically before a surgical biopsy is performed because the risks and costs associated with FNA are considerably lower than those associated with surgical biopsy. Quite frequently, a definitive cytologic diagnosis allows for the clinician to institute a specific treatment (i.e., multicentric lymphoma treated with chemotherapy).

In a recent study of 269 cytologic specimens from dogs, cats, horses, and other animal species, the cytologic diagnosis completely agreed with the histopathologic diagnosis in approximately 40% of cases and partially agreed in 18% of the cases; complete agreement ranged from 33% to 66%, depending on the lesion and location, and was highest for skin/subcutaneous lesions and for neoplastic lesions (Cohen et al). Clinically applicable diagnostic cytologic techniques are summarized in this chapter, with emphasis on sample

collection and the cursory interpretation of the specimens. Although some clinicians are able to obtain sufficient diagnostic information, a board-certified veterinary clinical pathologist should always evaluate a cytologic specimen before any prognostic or therapeutic decisions are made.

#### FINE-NEEDLE ASPIRATION

In FNA a single cell suspension is obtained using a small-gauge needle (i.e., 23 to 25 gauge) of the appropriate length for the desired target organ or mass; this needle can be coupled to a 12- or 20-ml sterile, dry plastic syringe, but frequently this is not necessary. Tissues easily accessible using this technique include the skin and subcutis, deep and superficial lymph nodes, spleen, liver, kidneys, lungs, thyroid, prostate, and intracavitary masses of unknown origin (e.g., mediastinal mass).

If the clinician is aspirating superficial masses, sterile preparation of the site is not necessary. However, clipping and sterile surgical preparation should always be done when aspirating organs or masses within body cavities. Once the mass or organ has been identified by palpation or radiography, it should be manually isolated; manual isolation is not necessary when performing ultrasound-, computed tomography (CT)-, or fluoroscopy-guided FNAs. A needle, either by itself or coupled to a syringe, is then introduced into the mass or organ; if the "needle alone" technique is used, the needle is reinserted into the tissue/mass several times. If the needle-syringe technique is used, suction is applied to the syringe three or four times. If the size of the mass or lesion allows it, the needle is then redirected two or three times and the procedure is repeated. Before withdrawing the needle and syringe, the clinician should release the suction so as not to aspirate blood that would contaminate the sample or air that would make the sample irretrievable from the barrel of the syringe. The needle is then detached, air is aspirated into the syringe, the needle is recoupled, and the sample is expelled onto a glass slide. In most cases no material is seen

in the syringe, and the amount of cells present within the hub of the needle is usually adequate to obtain four to eight good-quality smears. When the clinician is using the "needle alone" technique, the mass or lesion is isolated as described, and the needle is inserted into the lesion four to six times. This allows the clinician to core out small samples, which will be completely contained within the hub of the needle. Once a sample has been obtained, a clean disposable syringe is loaded with air and coupled to the needle, and the specimen is then gently expelled onto slides.

An aspiration gun (or handle) facilitates the acquisition of specimens by FNA, particularly in hard-to-reach areas such as a solitary small mass in the abdominal cavity. A 12-or 20-ml AspirGun (The Everest Co., Linden, N.J.), which easily fits onto a Monoject syringe, can be used.

Superficial ulcerated masses can easily be sampled by scraping their surface with a sterile scalpel blade, wooden tongue depressor, or gauze. Smears are then made either by touching a glass slide onto the ulcerated lesion (see the following section on impression smears) or by further scraping the surface with a tongue depressor and transferring the material thus obtained onto the slide. "Pull" smears made using two glass slides are preferable over "push" smears. Once the smears have been made, they are air-dried and stained using any of the techniques described in the next section.

#### IMPRESSION SMEARS

Impression smears of surgical specimens or open lesions are commonly used in practice. At our clinic, we evaluate numerous intraoperative impression smears to determine the therapeutic course to follow in a given patient.

When making impression smears from surgical specimens, the clinician first gently blots the tissue onto a gauze pad or paper towel to remove any blood or debris, then gently grasps it with forceps from one end. Touch imprints are made on a glass slide by gently touching the slide with the tissue specimen. I usually make two or three rows of impressions along the slide and then stain it. It is advisable to submit a different tissue specimen for histopathologic evaluation.

#### STAINING OF CYTOLOGIC SPECIMENS

Several staining techniques are practical for in-office use, including rapid Romanowsky's (e.g., Diff-Quik; various manufacturers) and new methylene blue (NMB) stains. Most commercial laboratories use Romanowsky's stains, such as Wright's or Giemsa.

There are some differences between these staining techniques. Romanowsky's stains are slightly more time consuming, but they produce better cellular detail and offer worse contrast between nucleus and cytoplasm; moreover, the smears can be permanently archived. NMB, on the other hand, is a quick stain (it takes literally seconds to stain a

smear), but it is not permanent, which means that slides cannot be saved for consultation; moreover, cellular details are not as sharp as they are on Romanowsky-stained smears. In addition, because nuclear DNA and RNA stain extremely well with this technique, most cells appear to be malignant. I routinely use Diff-Quik to get both a quick appreciation of the quality of the sample and, possibly, to arrive at a tentative diagnosis. This frequently allows a tentative diagnosis to be made while the client is still in the office. The main difference between rapid hematologic stains (e.g., Diff-Quik) and Giemsa or Wright-Giemsa stains is that, in a variable proportion of canine and feline mast cell tumors, the former do not stain the granules. In addition, rapid hematologic stains do not stain granules in some large granular lymphocytes (LGLs) or in eosinophils from Greyhounds (and some Golden Retrievers).

## INTERPRETATION OF CYTOLOGIC SPECIMENS

Although the clinician should strive to evaluate cytologic specimens proficiently, the ultimate cytologic diagnosis should be made by a board-certified veterinary clinical pathologist. The following are guidelines for cytologic interpretation. As a general rule, cytologic specimens are classified into one of the following six categories: normal tissue, hyperplasia/dysplasia (difficult to diagnose), inflammation, neoplasia, cystic lesions (contains fluid of various types), or mixed cellular infiltrate. The latter is usually either a malignant tumor with ongoing inflammation (e.g., squamous cell carcinoma with neutrophilic inflammation) or a hyperplastic tissue secondary to chronic inflammation (e.g., chronic cystitis with epithelial hyperplasia/dysplasia). Cytology of cystic lesions will not be discussed in this chapter.

## **NORMAL TISSUES**Epithelial Tissues

Most epithelial cells, particularly those of the glandular or secretory epithelium, tend to cling together (i.e., they have desmosomes), forming clusters or sheets. Individual cells are easily identifiable and are round or polygonal; nuclei and cytoplasms are well differentiated. Most cells in Romanowsky-stained smears have blue cytoplasm and round nuclei.

#### Mesenchymal Tissues

Cells from mesenchymal tissues (e.g., fibroblasts, fibrocytes, chondroblasts) are difficult to obtain in routine FNA material or tissue scrapings because they are usually surrounded by intercellular matrix. Mesenchymal cells are typically spindle shaped, polygonal, or oval and have irregular nuclei; cytoplasmic boundaries are usually indistinct, and cell clumps are seen rarely.

#### **Hematopoietic Tissues**

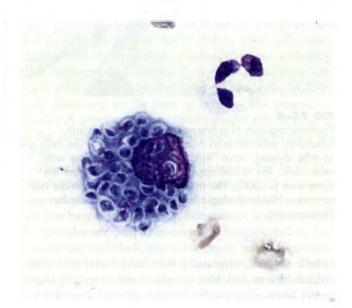

A detailed morphologic description of circulating blood cells is beyond the scope of this chapter. Briefly, however, most cells from hemolymphatic organs are round, individual cells (with no tendency to clump); they have a blue cytoplasm on Romanowsky-stained smears and a variable nuclear size; most nuclei are round or kidney shaped. Tissue such as bone marrow has cells in different stages of development (i.e., from blasts to well-differentiated circulating cells).

#### **HYPERPLASTIC PROCESSES**

Hyperplasia of different tissues commonly results in enlargement of glandular organs and lymphoid structures. The cytologic features of epithelial and lymphoid hyperplasia differ; lymphoid hyperplasia is discussed later in this chapter. Cytologically, hyperplastic changes may be difficult to recognize because they may mimic either normal or neoplastic tissues. Care should be taken when evaluating specimens from organs such as enlarged prostates or thickened urinary bladders because the high degree of hyperplasia and dysplasia frequently suggests malignancy.

#### **INFLAMMATORY PROCESSES**

Most inflammatory reactions are characterized cytologically by the presence of inflammatory cells and debris in the smear. The type of cell present depends on the etiologic agent (e.g., neutrophils in pyogenic infections, eosinophils in parasitic or allergic reactions) and the duration of the inflammatory process (i.e., acute processes are usually characterized by a predominance of granulocytes, whereas macrophages and lymphocytes predominate in chronic processes). The following pathogens are frequently identified in cytologic specimens: *Histoplasma*, *Blastomyces*, *Sporothrix*, *Cryptococcus*, *Coccidioides*, *Aspergillus/Penicillium*, *Toxoplasma*, *Leishmania*, other rickettsial agents (e.g., salmon poisoning), bacteria, and *Demodex* (Fig. 75-1).

Photomicrograph of a *Histoplasma capsulatum*–laden macrophage obtained from an ulcerated mucocutaneous lesion in a 6-year-old female, spayed black Labrador Retriever (×1000).

#### **MALIGNANT CELLS**

The cells that make up most normal organs and tissues (with the exception of bone marrow precursors) are well differentiated in that most of them are similar in size and shape, they have a normal nuclear: cytoplasmic (N:C) ratio, the nuclei usually have condensed chromatin and no nucleoli, and the cytoplasm may exhibit features of differentiation (e.g., keratin formation in squamous epithelium).

Malignant cells have one or more of the following features (Box 75-1): a high N: C ratio (i.e., larger nucleus and smaller cytoplasm); a delicate chromatin pattern; nucleoli (usually multiple); anisokaryosis (i.e., cells have nuclei of different sizes); nuclear molding (i.e., a nucleus in a multinucleated cell is compressed by a neighboring one); morphologic homogeneity (i.e., all cells look alike); pleomorphism (i.e., cells in different stages of development); vacuolization (primarily in malignant epithelial tumors); anisocytosis (i.e., cells are of different sizes); multinucleated giant cells; and, occasionally, phagocytic activity. Another feature of malignancy is heterotopia (i.e., the presence of a given cell type where it is not found anatomically); for example, epithelial cells can appear in a lymph node only as a consequence of metastasis from a carcinoma. In addition, malignant cells tend to be morphologically different from the progenitor cell population (see Box 75-1). On the basis of the predominant cytologic features, malignancies can be classified as carcinomas (epithelial), sarcomas (mesenchymal), or round (or discrete) cell tumors (Fig. 75-2).

#### Carcinomas

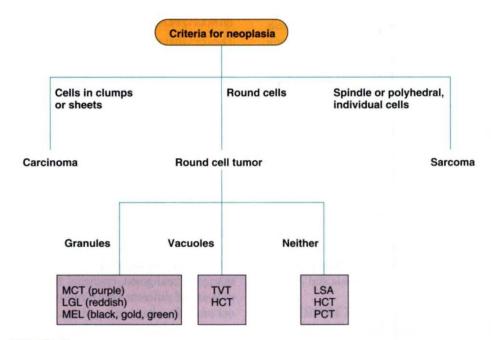

Most carcinomas are composed of round or polygonal cells that tend to cling together, forming clusters or large sheets. Their cytoplasms are usually deep blue, and in most adenocarcinomas vacuolization is evident. Cytoplasmic boundaries are difficult to recognize, and the cells resemble a mass of protoplasm rather than a sheet of individual cells. In squamous cell carcinomas cells are usually individualized, can be irregular or polygonal, have a deep blue cytoplasm (with an

occasional eosinophilic fringe), and have large vacuoles; neoplastic cells in squamous cell carcinomas frequently exhibit leukophagia. Nuclei in both adenocarcinomas and squamous cell carcinomas are large, with a fine chromatin pattern and evident nucleoli (Fig. 75-3).

#### Sarcomas

The cytologic features of sarcomas vary according to the histologic type. However, most mesenchymal tumors have

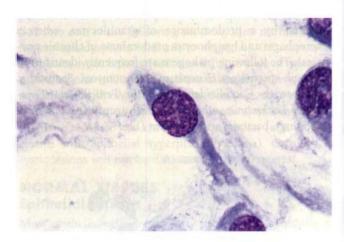

FIG 75-4

Photomicrograph of a fine-needle aspirate of a firm, lobulated, subcutaneous mass in an older dog. The cells are spindle shaped, have "tails," and do not associate with other cells. The nuclei appear to be protruding from the cytoplasm (×1000). The cytologic diagnosis is spindle cell sarcoma. Histopathologic findings were diagnostic for fibrosarcoma.

spindle shaped, polygonal, polyhedral, or oval cells, with a reddish blue to dark blue cytoplasm and irregularly shaped nuclei. Most cells are individualized, although clumping may occur (particularly in impression smears). The cells in most sarcomas have a tendency to form "tails," and the nuclei protrude from the cytoplasm (Fig. 75-4). The presence of spindle-shaped or polygonal cells with a vacuolated bluegray cytoplasm is highly suggestive of hemangiosarcoma.

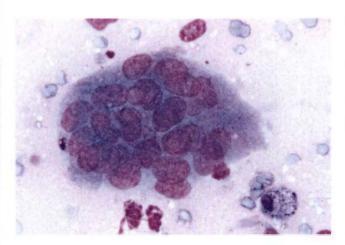

FIG 75-5
Photomicrograph of a multinucleated giant cell from a soft tissue sarcoma in a 13-year-old cat with tumor-associated hypercalcemia that resolved after surgical excision of the primary mass (×400).

Intercellular matrix (e.g., osteoid, chrondroid) is found occasionally; in these two tumor types the cells are usually round or ovoid. Multinucleated giant cells are common in some sarcomas in cats (Fig. 75-5).

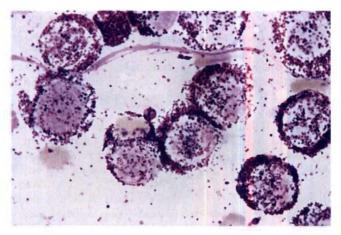

As a general rule, because sarcoma cells do not exfoliate easily, aspirates of these masses may yield false-negative results. Therefore, if a mass is clinically suspected to be a sarcoma and FNA findings are negative, a core biopsy specimen of the mass should be obtained.

#### **Round (Discrete) Cell Tumors**

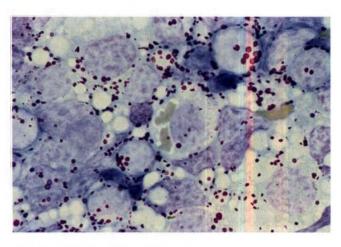

Tumors composed of a homogeneous population of round (or discrete) cells are referred to as *round* (or *discrete*) cell tumors (RCTs). These tumors are common in dogs and cats and include lymphoma, histiocytoma, mast cell tumor, transmissible venereal tumor, plasma cell tumor, and malignant melanoma; as discussed above, osteosarcomas and chondrosarcomas can be composed of round cells. RCTs are easily diagnosed on the basis of cytology; the presence or absence of cytoplasmic granules or vacuoles and the location of the nucleus aid in the classification of RCTs (see Fig. 75-2).

The cells that make up mast cell tumors (Fig. 75-6), LGL lymphomas (Fig. 75-7), and melanomas (Fig. 75-8) usually have cytoplasmic granules; cells in neuroendocrine tumors can also have granules. When hematologic stains are used, the granules are purple in mast cell tumors; red in LGL lymphomas; and black, green, brown, or yellow in melanomas. Lymphomas (Fig. 75-9), histiocytomas (Fig. 75-10), plasma cell tumors, and transmissible venereal tumors do not have cytoplasmic granules. Cells in osteosarcomas occasionally have small to large pink cytoplasmic granules (osteoid). Cytoplasmic vacuoles are common in transmissible venereal tumors and in histiocytomas.

Briefly, large cell lymphomas are characterized by a monomorphic population of individual undifferentiated

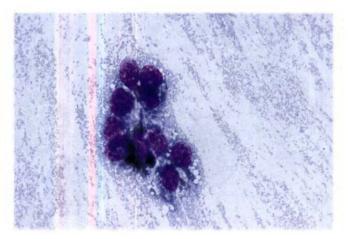

Photomicrograph of a fine-needle aspirate from a subcutaneous mass in an older Boxer with multiple dermoepidermal and subcutaneous masses and marked multifocal lymphadenopathy. Note the monomorphic population of round cells containing purple granules. The cytologic diagnosis was mast cell tumor (×1000).

Photomicrograph of an impression smear from a mesenteric lymph node in an old cat evaluated because of vomiting and diarrhea. Note the large round cells with red, large cytoplasmic granules. The diagnosis was lymphoma of large granular lymphocytes (×1000).

round cells with large nuclei, a coarse chromatin pattern, and one or two nucleoli; occasional cells may be vacuolated (see Fig. 75-9). Small and intermediate cell lymphomas may be difficult to recognize cytologically because the neoplastic population may resemble normal lymphocytes. Cells in histiocytomas are similar to those in lymphomas except that the chromatin pattern is fine rather than coarse, they have more abundant cytoplasm, and they are frequently vacuolated (see Fig. 75-10). Because inflammation is an important component of histiocytomas, inflammatory cells (i.e., neutrophils, lymphocytes) are commonly found in these tumors. Mast cell tumors are distinctive in that the cytoplasm of the cells

Photomicrograph of a fine-needle aspirate from a mass in the oral cavity of a 10-year-old Schnauzer. Note the dark, fine granules in the cytoplasm. The diagnosis was melanoma (×400).

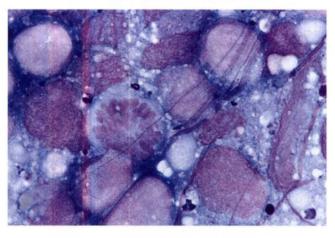

FIG 75-9

Photomicrograph of a fine-needle aspirate from the kidney of a middle-aged Boxer with bilateral renomegaly. Note the monomorphic population of round cells, with large nuclei, prominent nucleoli, and no cytoplasmic granules or vacuoles. A mitotic figure is seen in the center. The cytologic diagnosis was lymphoma (×1000).

contains purple (metachromatic) granules, which can be so numerous as to obscure the nuclear features; eosinophils are also a common feature in these tumors. Mast cell granules may be absent in poorly differentiated tumors or in tumors stained with Diff-Quik.

#### LYMPH NODES

Cytologic evaluation of lymph node aspirates is commonly done in practice. At our clinic, a cytologically based diagnosis is obtained in approximately 90% of dogs and 60% to 75% of cats with lymphadenopathy. If the cytologic findings of an enlarged lymph node are inconclusive, the node should be surgically excised and submitted for histopathologic evaluation.

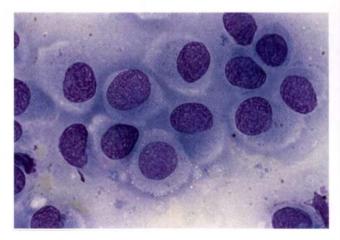

FIG 75-10

Photomicrograph of a fine-needle aspirate from a small, round, dermoepidermal mass in the head of a 1-year-old dog. Note the large round cells with abundant clear cytoplasm and fine chromatin pattern. The diagnosis was histiocytoma (×1000).

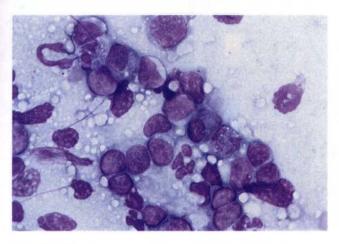

When evaluating cytologic specimens prepared from lymph node aspirates or impression smears, the clinician should keep in mind that these organs react to a variety of stimuli following a distinct pattern. In general, four cytologic patterns are recognized: normal lymph node, reactive or hyperplastic lymphadenopathy, lymphadenitis, and neoplasia.

#### **Normal Lymph Node**

Cytologic specimens from normal nodes are composed predominantly (75% to 90%) of small lymphocytes. These cells are approximately 7 to 10 µm in diameter (1 to 1.5 times the diameter of a red blood cell) and have a dense chromatin pattern and no nucleoli. The remaining cells are macrophages, lymphoblasts, plasma cells, and other immune cells.

## Reactive or Hyperplastic Lymphadenopathy

Lymphoid tissues reacting to different antigenic stimuli (e.g., bacterial, immunologic, neoplastic, fungal) are cytologically similar in that the cell population is composed of a mixture of small, intermediate, and large lymphocytes; lymphoblasts; plasma cells; and macrophages (Fig. 75-11). In addition, other cell types may be present, depending on the specific agent (e.g., eosinophils in parasitic or allergic reactions). The first impression when evaluating a reactive or hyperplastic node cytologically is that of a heterogeneous population of cells. The presence of cells in different stages of development indicates that the lymphoid tissue is undergoing polyclonal expansion (i.e., response to multiple antigens). Reactive lymph nodes in cats frequently lack plasma cells but contain large numbers of lymphoblasts, so they may be difficult to distinguish from lymphoma.

#### FIG 75-11

Photomicrograph of a fine-needle aspirate from a reactive lymph node in a dog. Note the heterogeneous population of lymphoid cells (small, medium, and large), plasma cells, and macrophages (×1000).

#### Lymphadenitis

Inflammatory processes affecting the lymph nodes produce cytologic changes similar to the ones seen in reactive lymphadenopathy, although there is a profusion of inflammatory cells (e.g., neutrophils in suppurative infections) and degenerative changes (e.g., pyknosis, karyorrhexis) in most cell lines. The etiologic agents may be visualized.

#### Neoplasia

Neoplastic cells can appear in a lymph node either as a result of lymphatic or vascular dissemination (i.e., metastasis from a primary tumor distal to the node) or as a primary process affecting these structures (i.e., lymphomas). Cytologic features of metastatic lymph node lesions consist of a reactive pattern and the presence of neoplastic cells; in advanced metastatic lesions it is frequently difficult to identify normal lymphoid cells. The morphology of the metastatic cells depends on the primary tumor type. As discussed in the preceding section, lymphomas are characterized by a monomorphous population of large, immature lymphoid cells; these cells are usually large and have an abnormally low N:C ratio, coarse chromatin, and evident nucleoli (see Fig. 75-9). As discussed previously, small cell lymphomas are difficult to diagnose cytologically.

### CHAPTER

# Principles of Cancer Treatment

#### CHAPTER OUTLINE

GENERAL CONSIDERATIONS
PATIENT-RELATED FACTORS
OWNER-RELATED FACTORS
TREATMENT-RELATED FACTORS

#### **GENERAL CONSIDERATIONS**

Over the past several decades, a variety of therapeutic modalities have been used in dogs and cats with cancer (Box 76-1). However, until two or three decades ago, surgery remained the mainstay of cancer treatment for pets. Today, nonresectable or metastatic malignancies can be treated with varied degrees of success, using some of the modalities listed in Box 76-1.

When evaluating a cat or a dog with malignancy, the clinician should bear in mind that in most cases owners elect to treat their pets, if given the option. Although euthanasia still remains a reasonable choice in some small animals with cancer, every effort should be made to investigate treatment options.

Depending on the tumor type, biologic behavior, and clinical stage, a clinician may recommend one or more of the treatments listed in Box 76-1. However, in addition to tumor-related factors, many other factors influence the selection of the optimal treatment for a pet with cancer. These include patient-related, owner-related, and treatment-related factors.

#### PATIENT-RELATED FACTORS

It is important to remember that the best treatment for a particular tumor does not necessarily constitute the best treatment for a particular patient or the best treatment from the owner's perspective. The most important patient-related factor to be considered is the animal's general health and activity or performance status (Table 76-1). For example, a

cat or dog with markedly diminished activity and severe constitutional signs (i.e., poor performance status) may not be a good candidate for aggressive chemotherapy or the repeated anesthetic episodes required for external beam radiotherapy. Age by itself is not a factor that should be considered when discussing cancer therapy with the owner (i.e., "age is not a disease"). For example, a 14-year-old dog in excellent health is a better candidate for chemotherapy or radiotherapy than a 9-year-old dog with chronic kidney disease or decompensated congestive heart failure. Patient-related factors should be addressed before instituting specific cancer treatment (e.g., correct the azotemia, improve the nutritional status with enteral feeding).

#### OWNER-RELATED FACTORS

Owner-related factors play an important role in determining the treatment to be implemented in small animals with cancer. Every clinician is aware of the impact of the ownerpet bond. This bond is so important that it often dictates the treatment approach used in a given patient. For example, owners may be so apprehensive about having their dog with lymphoma receive chemotherapy that they refuse such treatment; thus the optimal treatment cannot be used in this patient.

In my experience, pet owners should be made a part of the medical team. If they are assigned tasks to perform at home, such as measuring the tumors to monitor the response to treatment, taking their pet's temperature daily, and monitoring their pet's performance status, they assume responsibility for the fate of their pet and are therefore quite cooperative. The clinician should always be available to answer concerned pet owners' questions and guide them through difficult times. The clinician should discuss all potential treatment options with the owner, emphasizing the pros and cons of each (e.g., beneficial effects and potential for adverse effects of treatment A versus B versus C versus no treatment). The clinician should also clearly explain what will (or should) happen during the pet's treatment, including a thorough description of the potential adverse effects by

#### Treatment Options for Animals with Cancer

Surgery Radiotherapy Chemotherapy Targeted molecular therapy Immunotherapy (biologic response modifiers) Hyperthermia Cryotherapy Phototherapy Photochemotherapy Thermochemotherapy Unconventional (alternative)

TABLE 76-1

Modified Karnovsky's Performance Scheme for Dogs and Cats

GRADE	ACTIVITY/PERFORMANCE					
0-Normal	Fully active, able to perform at predisease level					
1 — Restricted	Restricted activity from predisease level but able to function as an acceptable pet					
2—Compromised	Severely restricted activity level; ambulatory only to the point of eating but consistently defecating and urinating in acceptable areas					
3—Disabled	Completely disabled; must be force- fed; unable to confine urinations and defecations to acceptable areas					
4-Dead						

Modified from International Histological Classification of Tumors of Domestic Animals, Bull World Health Organ 53:145, 1976.

presenting different case scenarios (i.e., best-case scenario versus worst-case scenario). By observing these easy steps, the clinician usually cultivates realistic expectations on the part of the owner and ensures that the interaction with the owner is smooth and uneventful. As discussed in later paragraphs, the option of euthanasia may also be addressed at this time, either as an immediate option or as an eventual option if treatments fail.

Another very important owner-related factor is finances. In general, the treatment of a cat or dog with disseminated or metastatic malignancy is relatively expensive, as judged by the average clinician. However, it is the owner who should determine whether this treatment is indeed too costly. It is relatively common for an owner to spend \$3,000 to \$10,000 to treat a dog or cat with surgery, radiotherapy, or chemotherapy. In other words, all treatment options should be described and offered to the pet owner, regardless of their cost. Occasionally, owners spend what most people consider to be exorbitant amounts of money to treat their pet with cancer or other diseases.

#### TREATMENT-RELATED FACTORS

Several important treatment-related factors must be considered when planning cancer therapy. First, the specific indication should be considered. Surgery, radiotherapy, and hyperthermia are treatments aimed at eradicating a locally invasive tumor with a low metastatic potential (and potentially curing the patient), although they can be used palliatively in dogs or cats with extensive (bulky) disease or in those with metastatic disease. On the other hand, chemotherapy usually does not constitute a curative treatment, although palliation of advanced disease can easily be accomplished for several tumor types. Immunotherapy (the use of biologic response modifiers) also constitutes an adjuvant or palliative approach (i.e., tumors are not cured by immunotherapy alone). Recently, targeted molecular therapy aims at blocking specific pathways present in neoplastic but not in normal cells. In general, it is best to use an aggressive treatment when the tumor is first detected (because this is when the chances of eradicating every single tumor cell are the highest) rather than to wait until the tumor is in an advanced stage—that is, to "treat big when the disease is small." Removing "only" 99% of the tumor cells will not lead to a cure.

In some cases, the highest success rates are obtained by combining two or more treatment modalities. For example, the combination of surgery and chemotherapy (with or without immunotherapy) has resulted in a significant prolongation of disease-free survival in dogs with osteosarcoma of the appendicular skeleton and in dogs with splenic hemangiosarcoma. Similarly, the combination of surgery and radiotherapy has resulted in a prolongation of disease-free survival in dogs and cats with spindle cell sarcomas.

The complications and adverse effects of different treatments also constitute treatment-related factors to be considered when planning therapy. Complications of chemotherapy are addressed in Chapter 78. As discussed later, the animal's quality of life should be maintained (or improved) during cancer treatment. At our clinic, this is the priority in a cat or a dog with cancer receiving treatment. Our motto is "The patient should feel better with the treatment than with the disease."

Cancer treatment can be either palliative or curative. Given the current paucity of information regarding specific tumor types and treatments, these two approaches sometimes overlap (i.e., a treatment initially thought to be palliative may result in cure, or vice versa). As discussed earlier, every effort should be made to eradicate every single cancer cell in the body (i.e., obtain a cure) shortly after diagnosis. This means taking immediate action rather than adopting a wait-and-see attitude. With very few exceptions, malignancies do not regress spontaneously. In other words, by delaying treatment in an animal with confirmed malignancy, the

BOX 76-2

#### Criteria Used to Assess Tumor Response to Treatment

Complete remission (CR): complete disappearance of all tumors

Partial remission (PR): decrease in the bidimensional tumor diameter by more than 50%

Stable disease (SD): less than 25% variation in bidimensional tumor diameter

Progressive disease (PD): increase in the bidimensional tumor diameter by more than 25%

clinician is only increasing the probability that the tumor will disseminate locally or systemically, thereby decreasing the likelihood of a cure. As discussed earlier, surgery and radiotherapy are potentially curative treatments, whereas chemotherapy and immunotherapy are usually palliative.

If a cure cannot be obtained, the two main goals of treatment are to induce remission while achieving a good quality of life. The term remission refers to shrinkage of the tumor. When objectively evaluating the effects of therapy, the clinician should measure the tumor or tumors and assess the response using the criteria given in Box 76-2. The qualityof-life issue is quite important in small animal oncology (see preceding paragraphs). In a quality-of-life survey of owners whose pets had undergone chemotherapy for nonresectable or metastatic malignancy conducted in our clinic, more than 80% responded that the quality of life of their pets was maintained or improved during treatment. If a good quality of life cannot be maintained (i.e., the animal's performance status deteriorates), the treatment being used should be modified or discontinued. We are currently conducting a prospective study evaluating quality of life and pain before, during, and after therapy in dogs and cats with cancer.

Palliative treatments are quite acceptable for small animals with cancer and to their owners. For example, even though chemotherapy rarely achieves a cure for most tumors, veterinarians can provide a cat or dog (and its owner) with a prolonged, good-quality survival. Although these patients ultimately die of tumor-related causes, the owners are usually pleased to have a pet that is asymptomatic for a long time. Another common example that is frequently forgotten is palliative surgery; for example, in dogs or cats with ulcerated mammary carcinomas and small pulmonary metastases, euthanasia was once recommended. However, it is now known that performing a mastectomy or lumpectomy (even if the owners decline chemotherapy) is likely to result in several months of good-quality survival, until the metastatic

lesions finally cause respiratory compromise. In another example, dogs with apocrine gland adenocarcinoma of the anal sacs and metastatic sublumbar lymphadenopathy benefit from surgical resection of the primary tumor and/or metastatic nodes, even if adjuvant chemotherapy will not be considered. Removal of the primary mass improves clinical signs of straining in these patients; because the colon and rectum are compressed ventrally by the enlarged lymph nodes and laterally or dorsally by the primary mass, removal of one of the lesions easily alleviates clinical signs. Sublumbar (or iliac) lymphadenectomy and chemotherapy in dogs with metastatic apocrine gland adenocarcinoma of the anal sacs in our clinic result in survival times of 1 to 3 years.

Needless to say, the clinician should also address the presence of paraneoplastic syndromes even if specific antineoplastic therapy is not contemplated. For example, treatment of hypercalcemia of malignancy with bisphosphonates causes remarkable improvement in the quality of life of affected dogs. We have used either etidronate (Didronel, Procter and Gamble Pharmaceuticals, Cincinnati, Ohio, at a dosage of 10 to 20 mg/kg, administered orally q12h) or pamidronate (Aredia, Novartis Pharmaceuticals, East Hannover, N.J., at a dosage of 1 to 2 mg/kg, administered intravenously q6-8 weeks) in dogs with tumor-associated hypercalcemia in which the neoplastic disease could not be surgically removed or that had failed chemotherapy. In most dogs serum calcium concentrations were maintained within normal limits, and no appreciable toxicity was detected.

Finally, most cats and dogs with cancer are treated using a team approach. This team includes the pet, the owner, the medical oncologist, the oncologic nurse, the surgical oncologist, the radiotherapist, the clinical pathologist, and the pathologist. A smooth interaction among the members of the team results in marked benefits for the pet and its owner.

CELL AND TUMOR KINETICS
BASIC PRINCIPLES OF CHEMOTHERAPY
INDICATIONS AND CONTRAINDICATIONS OF
CHEMOTHERAPY
MECHANISM OF ACTION OF ANTICANCER DRUGS
TYPES OF ANTICANCER DRUGS
SAFE HANDLING OF ANTICANCER DRUGS

#### **CELL AND TUMOR KINETICS**

To better understand the effects of chemotherapy on both neoplastic and normal tissues, it is necessary to have a basic understanding of cell biology and tumor kinetics. As a general rule, the biologic characteristics of neoplastic cells are similar to those of their normal counterparts, with the main difference being that neoplastic cells usually do not undergo terminal differentiation. Therefore the cell cycles of normal and neoplastic cells are similar.

The mammalian cell cycle has two apparent phases: mitosis and the resting phase. The resting phase is actually composed of four phases (Fig. 77-1):

- 1. Synthesis phase (S): DNA is synthesized.
- Gap 1 phase (G1): RNA and the enzymes needed for DNA production are synthesized.
- 3. Gap 2 phase (G2): The mitotic spindle apparatus forms
- 4. Gap 0 phase (G0): This is the true resting phase.

The mitosis phase is termed the *M phase*.

Oncogenes serve as checkpoints between different phases of the cell cycle.

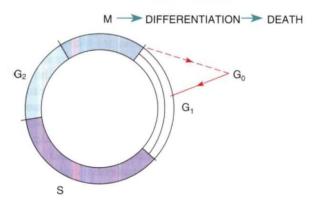

Several terms must be defined before chemotherapy is discussed. The *mitotic index* (*MI*) refers to the proportion of cells in the process of mitosis within a tumor; the pathologist often provides information about the mitotic activity in a given tumor sample, reported as the MI or as the number of

mitoses per high-power field (or per X number of highpower fields). The growth fraction (GF) refers to the proportion of proliferating cells within a tumor and cannot be quantified in a patient. The doubling time (DT) refers to the time it takes for a tumor to double in size; it can be calculated by using sequential measurements of the tumor volume  $[V = 1/6 \times (mean diameter)^3]$  seen on radiographs or ultrasonograms or determined by direct palpation. In dogs the DT ranges from 2 days (for metastatic osteosarcoma) to 24 days (for metastatic melanoma), whereas in humans it ranges from 29 days (for malignant lymphomas) to 83 days (for metastases from breast cancer). We recently evaluated the DT of pulmonary metastases in dogs with appendicular osteosarcoma treated with amputation and adjuvant chemotherapy; the median DT of the metastases was 13 days for Greyhounds and 21 days for nonGreyhounds. The DT depends on the time spent in mitosis, the cell cycle duration, the GF, and the cell loss resulting from death or metastasis. Given our knowledge of tumor kinetics, by the time a pulmonary metastatic nodule is visualized on radiographs, it consists of 200,000,000 cells, weighs less than 150 mg, and has already divided 25 to 35 times. A 1-cm palpable nodule has 109 tumor cells (1,000,000,000) and weighs 1 g (Fig. 77-2). As a general rule, most nonneoplastic tissues (with the exception of bone marrow stem cells and intestinal crypt epithelium) have a low GF, low MI, and prolonged DT, whereas most neoplastic tissues have a high MI, high GF, and short DT (at least initially; see Fig. 77-2).

Surgical cytoreduction (debulking) of a tumor that has reached a plateau of growth decreases the total number of cells, thus increasing the MI and GF and shortening the DT through yet unknown mechanisms (Fig. 77-3). In theory, this renders the neoplasm more susceptible to chemotherapy or radiotherapy.

#### **BASIC PRINCIPLES OF CHEMOTHERAPY**

Chemotherapeutic agents predominantly kill cells in rapidly dividing tissues. To exploit the tumoricidal effect of different chemotherapeutic drugs, it is common practice to combine three or more drugs to treat a given malignancy. These drugs are selected on the basis of the following principles: Each should be active against the given tumor type, each should act by a different mechanism of action, and they should not have superimposed toxicities. It is customary to name the protocol after the first letters of each drug in the combination (e.g., VAC for vincristine, doxorubicin [or Adriamycin], and cyclophosphamide). As a general rule, combination chemotherapy results in more sustained remissions and prolonged survival times, as compared with those achieved

Mammalian cell cycle. Cells in mitosis (M) can differentiate and subsequently die (the rule in normal tissues); they can also progress to  $G_0$  (true resting phase), from which they can be recruited by a variety of stimuli (see text).  $G_1$ ,  $G_2$ ,  $G_3$ ,  $G_4$ ,  $G_5$ ,  $G_7$ ,  $G_9$ 

using single-agent chemotherapy; this is thought to result from the fact that multichemotherapy delays (or even prevents) the development of drug-resistant clones. However, some exceptions to this rule include the treatment of dogs with osteosarcoma using cisplatin, carboplatin, or doxorubicin as single agents; the treatment of dogs with chronic lymphocytic leukemia using chlorambucil alone; and the treatment of dogs with transmissible venereal tumors with vincristine alone.

Another general concept of chemotherapy from the standpoint of cell kinetics is that it is more effective in a relatively small tumor than in a large one, even though the inherent sensitivity to the drug or drugs may be the same. As can be seen in Fig. 77-3, a small tumor (e.g., 10<sup>6</sup> cells) is more likely than a larger one (e.g., 10<sup>11</sup> cells) to be completely eradicated by the drugs because the smaller mass has a higher MI, a higher GF, and consequently a shorter DT than the larger mass (i.e., more cells are actively dividing at a given time).

Despite continued controversy, the doses of most chemotherapeutic agents are still determined on a body surface area (BSA) basis; exceptions will be listed later. This appears to provide a more constant metabolic parameter for comparing doses across species. It can be calculated using the following formula:

$$\frac{\text{Weight } (g)^{2/3} \times \text{K (constant)}}{10^4} = \text{m}^2 \text{ BSA}$$

The constant is 10.1 for the dog and 10 for the cat. Table 77-1 is a conversion table of weight (in kilograms) to BSA

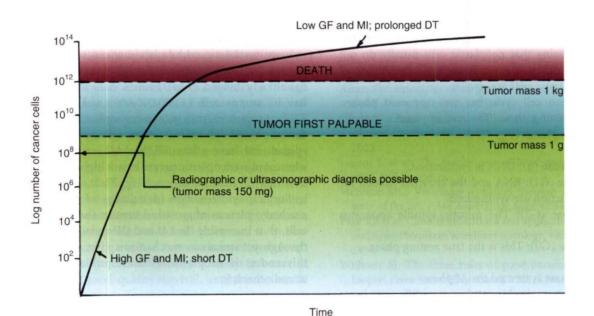

FIG 77-2

#### FIG 77-3

The effect of surgical or radiotherapeutic intervention on tumor kinetics. After cytoreduction, cells are recruited from the G<sub>0</sub> phase and the tumor returns to the exponential phase. XRT, Radiation therapy; GF, growth factor; MI, mitotic index; DT, doubling time. (From Couto CG: Principles of chemotherapy. In Proceedings of the Tenth Annual Kal Kan Symposium for the Treatment of Small Animal Diseases: Oncology, Kalkan Foods, Inc, Vernon, Calif, 1986, p. 37.)

Time

(in squared meters) for dogs. Table 77-2 is a conversion table of pounds (and kilograms) to BSA for cats. When drugs such as doxorubicin are being used, doses determined on the basis of BSA usually lead to adverse effects in very small dogs (i.e., those under 10 kg) and cats. A dose determined on the basis of weight (e.g., 1 mg/kg) is more appropriate in such small animals.

## INDICATIONS AND CONTRAINDICATIONS OF CHEMOTHERAPY

Chemotherapy is primarily indicated for animals with systemic (e.g., lymphoma, leukemias) or metastatic neoplasms, although it can also be used for the management of nonresectable, chemoresponsive neoplasms that have historically proved refractory to radiotherapy or hyperthermia (primary chemotherapy). It can also be used as an adjuvant treatment after partial surgical debulking of a neoplasm (e.g., partial excision of an undifferentiated sarcoma) and is indicated for the control of micrometastatic disease after the surgical excision of a primary neoplasm (e.g., cisplatin, carboplatin, or doxorubicin therapy after limb amputation in dogs with osteosarcoma; VAC after splenectomy for dogs with hemangiosarcoma). Chemotherapy can also be administered intracavitarily in dogs and cats with malignant effusions or neoplastic involvement of the cavity/area in question (e.g., intrapleurally administered cisplatin or 5-fluoruracil in dogs with pleural carcinomatosis). Finally, neoadjuvant, or primary, chemotherapy is the approach used in animals with bulky tumors not amenable to surgical excision. After the drugs cause the tumor to shrink, the tumor can be surgically

excised; chemotherapy is then continued to eliminate any residual neoplastic cells (e.g., VAC chemotherapy for dogs with subcutaneous hemangiosarcomas).

As a general rule, chemotherapy should not be used as a substitute for surgery, radiotherapy, or hyperthermia; nor should it be used in animals with severe underlying multiple-organ dysfunction (or it should be used cautiously, with a dose modification) because this increases the risk of systemic toxicity.

## MECHANISM OF ACTION OF ANTICANCER DRUGS

The effects of anticancer drugs on a neoplastic cell population follow first-order kinetic principles (i.e., the number of cells killed by a drug or drug combination is directly proportional to one variable: the dose used). These drugs kill a constant proportion of cells, rather than a constant number of cells. Therefore the efficacy of a drug or drug combination depends on the number of cells in a given tumor (e.g., a drug combination that kills 99% of the cells in a tumor containing 100,000,000 [10<sup>9</sup>] cells leaves 1,000,000 [10<sup>6</sup>] viable cells).

As discussed in the following paragraphs, different types of anticancer drugs kill tumor cells by different mechanisms. Drugs that kill only dividing tumor cells (i.e., that do not kill cells in the G<sub>0</sub> phase) by acting on several phases of the cycle are termed *cell cycle phase-nonspecific drugs*. Alkylating agents belong to this group. Drugs that selectively kill tumor cells during a given phase of the cell cycle are termed *cell cycle phase-specific drugs*. Most antimetabolites and plant alkaloids are phase-specific drugs. Finally, drugs that kill neo-

#### Miscellaneous Agents

- DTIC
- L-Asparaginase

plastic cells regardless of their cycle status (i.e., they kill both dividing and resting cells) are termed *cell cycle-nonspecific drugs*. These latter drugs are extremely myelosuppressive (e.g., nitrosoureas) and are infrequently used in veterinary medicine.

#### **TYPES OF ANTICANCER DRUGS**

Anticancer drugs are commonly classified into six categories (Box 77-1). Most of these drugs are currently available as generic products.

Alkylating agents cross-link DNA, thus preventing its duplication. Because they mimic the effects of radiotherapy, they are also referred to as *radiomimetics*. These drugs are active during several phases of the cell cycle (i.e., they are cell cycle phase-nonspecific) and are more active if given intermittently at high doses. The major toxicities of these drugs are myelosuppressive and gastrointestinal in nature. Alkylating agents commonly used in pets with cancer are listed in Box 77-1.

Antimetabolites exert their activity during the S phase of the cell cycle (cell cycle phase-specific) and are more active if given repeatedly at low doses or as continuous intravenous infusions. These drugs are structural analogs of naturally occurring metabolites (fake metabolites) that substitute for normal purines or pyrimidines. The major toxicities of these drugs are myelosuppressive and gastrointestinal. Box 77-1 lists the antimetabolites commonly used in small animals with cancer.

Antitumor antibiotics act by several mechanisms (i.e., cell cycle phase-nonspecific), the most important of which appears to be DNA damage produced by free radicals or by a topoisomerase-II-dependent mechanism. There are now several synthetic or semisynthetic antibiotics. The major toxicities of these drugs are myelosuppressive and gastrointestinal in nature; doxorubicin and actinomycin D are extremely caustic if given perivascularly, and the former has cumulative cardiotoxic effects. Antitumor antibiotics are listed in Box 77-1.

Plant alkaloids are derived from the periwinkle plant (Vinca rosea) and the May apple plant (Podophyllum peltatum). Vinca derivatives disrupt the mitotic spindle and are therefore cell cycle phase-specific (active during M phase), whereas Podophyllum derivatives cross-link DNA. The major toxicity is perivascular sloughing if the agent extravasates. Etoposide should not be administered intravenously because the vehicle (Tween 80) causes anaphylaxis. Box 77-1 lists commonly used plant alkaloids.

Hormones are commonly used for the treatment of hemolymphatic malignancies or endocrine-related tumors. Commonly used hormones are listed in Box 77-1.

With the exception of corticosteroids, hormones are not recommended as antineoplastics because they are associated with relevant adverse effects in animals.

Miscellaneous agents consist of drugs with a mechanism of action that is either unknown or differs from those of agents already described. Box 77-1 lists miscellaneous agents commonly used in small animals with cancer.

A novel approach to anticancer chemotherapy is to exploit the use of molecular targets. For example, c-KIT mutations are commonly identified in human with chronic myelogenous leukemia; imatinib (Gleevec, Novartis) selectively block this tyrosine kinase (TK) pathway and induces apoptosis of neoplastic (but not normal) cells. Mutations of c-KIT are also common in canine mast cell tumors, where small molecule TK inhibitors other than imatinib have been effective. A new TK inhibitor is now available for veterinary use (Palladia, Pfizer). In the dog imatinib appears to be hepatotoxic.

## SAFE HANDLING OF ANTICANCER DRUGS

Cytotoxic drugs have very narrow therapeutic indices, with toxic effects very often noted at the standard therapeutic dosages. Occupational exposure, as might occur in personnel who commonly administer these drugs, has been docu-

mented in the literature; adverse effects, including headache, nausea, liver disease, and reproductive abnormalities, have been associated with this exposure. As such, no safe exposure level has been identified, and all possible measures to limit personnel exposure to cytotoxic drugs must be taken during their preparation and administration.

Reconstitution of cytotoxic drugs for administration must be performed in a biosafety level II vertical laminar airflow hood. Although the cost for this equipment is not prohibitively expensive for a large equine hospital (~\$6,000-\$10,000), this cost is currently not justified by the frequency of use. A new closed system (PhaSeal<sup>TM</sup>, Carmel Pharma, Columbus, OH) is practical and relatively inexpensive and limits operator and environmental drug exposure to almost zero. If containment devices are not available, cytotoxic drugs can be reconstituted at a human hospital or pharmacy or at a nearby small animal clinic with a sufficiently large oncology caseload. Care should be taken to respect the storage half-life of reconstituted drugs, and they should be administered to the patient as soon as possible after reconstitution. Drugs should be delivered in a clearly labeled, sealed plastic bag, and any handling of the drugs should be performed while wearing the appropriate personal protective gear.

Personal protective gear has been shown to all but eliminate detectable occupational exposure to cytotoxic drugs in human oncology nurses when combined with safe, conservative handling practices. All personnel present during chemotherapy administration to animal patients, including veterinarians, technicians, and ward staff, must wear thick latex chemotherapy gloves or two pairs of regular latex examination gloves. The thickness of the gloves is more important than the composition for barrier protection. Ideally, personnel should also wear impermeable disposable gowns, eye protection, and particle-filtering face masks. All fluid lines should be primed before addition of cytotoxic drugs to reduce environmental contamination, and all potentially contaminated supplies, including gowns, gloves, fluid bags, lines, and so forth, should be disposed of in properly labeled biohazard bags or plastic sharps containers. Disposal of material potentially contaminated with cytotoxic drugs may be arranged through a local human hospital; alternatively, an EPA-approved disposal facility should be located. Materials used in the preparation and administration of chemotherapy should not be reused. Patient waste, including urine and feces, should be disposed of similarly 24 to 48 hours after chemotherapy administration, and personnel involved in the husbandry of these patients should wear the above-recommended personal protective gear when attending patients.

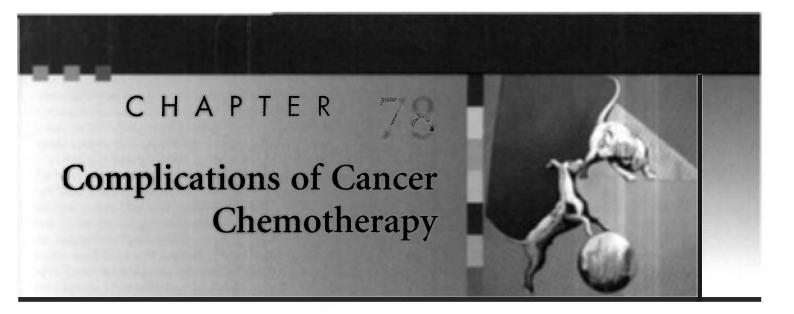

Protocols for handling spills should be prepared in advance and posted in areas where patients may be receiving chemotherapy. This area should be a designated area of the hospital with low traffic and minimal drafts; a stall may be selected for this purpose in equine hospitals. Isolation stalls will minimize exposure of personnel to chemotherapeutic agents. Once the patient has received chemotherapy, its cage should be clearly identified with a notice that contains

#### 1158 PART XI Oncology

information about precautions to be taken during handling of the animal and its wastes.

#### CHAPTER OUTLINE

GENERAL CONSIDERATIONS
HEMATOLOGIC TOXICITY
GASTROINTESTINAL TOXICITY
HYPERSENSITIVITY REACTIONS
DERMATOLOGIC TOXICITY
PANCREATITIS
CARDIOTOXICITY
UROTOXICITY
HEPATOTOXICITY
NEUROTOXICITY
PULMONARY TOXICITY
ACUTE TUMOR LYSIS SYNDROME

#### GENERAL CONSIDERATIONS

Because most anticancer agents are relatively nonselective, they kill not only rapidly dividing neoplastic tissues but also some of the rapidly dividing normal tissues in the host (e.g., villus epithelium, bone marrow cells). In addition, similar to other commonly used agents (e.g., digitalis glycosides), most anticancer agents have low therapeutic indices (i.e., narrow therapeutic:toxic ratios).

Because anticancer agents follow first-order kinetic principles (i.e., the fraction of cells killed is directly proportional to the dose used), increasing the dose of a particular drug increases the proportion of the neoplastic cells killed, but it also enhances its toxicity. This is commonly seen when a tumor relapses and higher doses of a previously prescribed chemotherapeutic agent are administered.

Because toxicity generally tends to affect rapidly dividing tissues, given the short doubling times of the bone marrow and villal epithelial cells, myelosuppression and gastrointestinal signs are the most common toxicities encountered in practice. Other rare complications of chemotherapy include anaphylactoid (or anaphylactic) reactions, dermatologic toxicity, pancreatitis, cardiotoxicity, pulmonary toxicity, neurotoxicity, hepatopathies, and urotoxicity. Table 78-1 lists

anticancer drugs commonly used in small animals and their toxicities.

Several factors can potentiate the effects of anticancer agents and thereby enhance their toxicity. For example, drugs that are excreted primarily through the kidneys (e.g., cisplatin, carboplatin, methotrexate) are more toxic to animals with renal disease; thus a dose reduction or the use of an alternative drug is usually recommended in such cases.

In addition to the direct effects of some drugs on different organ systems, rapid killing of certain neoplastic cells (i.e., lymphoma cells) can lead to sudden metabolic derangements that result in acute clinical signs mimicking those of drug toxicity (i.e., depression, vomiting, diarrhea). This syndrome is referred to as acute tumor lysis syndrome (ATLS) (see p. 1167).

In general, cats appear to be more susceptible than dogs to some of the adverse effects of chemotherapy (e.g., anorexia, vomiting) but not to others (e.g., myelosuppression). Certain breeds of dogs, including Collies and Collie crosses, Old English Sheepdogs, Cocker Spaniels, and West Highland White Terriers, also appear to be more prone to some of the acute adverse reactions to chemotherapy (i.e., gastrointestinal signs, myelosuppression) than the general dog population.

The overall prevalence of toxicity of different chemotherapy protocols is considerably lower in dogs and cats (approximately 5% to 40%) than in humans (75% to 100%) treated with similar drugs or combinations. A recent survey of owners whose pets had been treated with a variety of chemotherapy protocols at The Ohio State University Veterinary Teaching Hospital revealed that more than 80% considered their pets' quality of life to be equal to or better than that before the start of chemotherapy.

#### HEMATOLOGIC TOXICITY

The high mitotic rate and growth fraction (i.e., 40% to 60%) of the bone marrow cells predispose this organ to relevant toxicity from anticancer drugs. Hematologic toxicity constitutes the most common complication of chemotherapy, and

often the severe and potentially life-threatening cytopenias that occur necessitate the temporary or permanent discontinuation of the offending agent or agents. Table 78-1 lists agents commonly implicated in this type of toxicity.

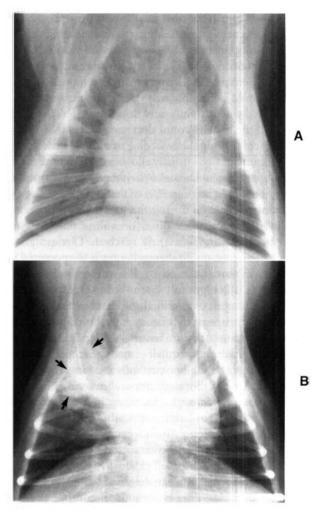

It is easy to anticipate the cell line that will be affected on the basis of the bone marrow transit times and circulating half-lives of blood-formed elements. For example, the bone marrow transit time and circulating half-life of red blood cells in the dog are approximately 7 and 120 days, those of the platelets are 3 days and 4 to 6 days, and those of granulocytes are 6 days and 4 to 8 hours, respectively. On the basis of this, neutropenia usually occurs first, followed by thrombocytopenia. Chemotherapy-induced anemia is rare in dogs and cats and, if it occurs, is of late onset (3 to 4 months after initiation of therapy). Other patient-related factors (e.g., malnutrition, old age, concurrent organ dysfunction, prior extensive chemotherapy) and tumor-related factors (e.g., bone marrow infiltration, widespread parenchymal organ metastases) can also affect the degree of myelosuppression.

Although thrombocytopenia is probably as common as neutropenia, it is rarely severe enough to cause spontaneous bleeding, and therefore it is not discussed at length here. In general, in most dogs with chemotherapy-induced thrombocytopenia, the platelet counts remain above 50,000 cells/µl. Spontaneous bleeding usually does not occur until platelet counts are below 30,000/µl. Some drugs and protocols are associated with predictable thrombocytopenia, including doxorubicin and dacarbazine (ADIC), D-MAC (see the table on cancer chemotherapy protocols at the end of Part 11), lomustine, and melphalan in dogs; platelet counts associated with these protocols are usually less than 50,000/µl. Chemotherapy-induced thrombocytopenia is extremely rare in cats. Thrombocytosis is common in cats and dogs receiving vincristine.

Neutropenia usually constitutes the dose-limiting cytopenia and occasionally leads to life-threatening sepsis in dogs; although neutropenia does occur in cats receiving chemotherapy, it rarely leads to the development of clinically recognizable sepsis. The nadir of neutropenia for most drugs (i.e., lowest point in the curve) usually occurs 5 to 7 days after treatment, and the neutrophil counts return to normal within 36 to 72 hours of the nadir. With certain drugs the nadir of neutropenia is delayed (i.e., approximately 3 weeks for carboplatin in dogs and cats). Dogs with neutrophil counts less than 2000 cells/ I should be closely monitored for the development of sepsis, although overwhelming sepsis rarely occurs in animals with neutrophil counts of more than 1000 cells/µl. The development of sepsis in neutropenic cats is extremely rare, or it goes unrecognized.

The pathogenesis of sepsis in neutropenic animals is as follows: First, the chemotherapy-induced death and desquamation of gastrointestinal crypt epithelial cells occur simultaneously with myelosuppression; next, enteric bacteria are absorbed through the damaged mucosal barrier into the systemic circulation (bacterial translocation); and, finally, because the number of neutrophils in the circulation is not sufficient to phagocytose and kill the invading organisms, multiple organs become colonized with the bacteria and death ensues, unless the animal is treated appropriately.

It is important to identify the septic neutropenic animal using laboratory means because the cardinal signs of inflammation (i.e., redness, swelling, increased temperature, pain, abnormal function) may be absent because there are not enough neutrophils to participate in the inflammatory process. The same holds true for radiographic changes compatible with inflammation; for example, dogs with neutropenia and bacterial pneumonia diagnosed on the basis of cytologic and microbiologic findings in transtracheal wash material often have normal thoracic radiographic findings (Fig. 78-1). As a general rule, if a severely neutropenic animal

Thoracic radiographs from a 5-year-old male, castrated Boston Terrier with multicentric lymphoma treated with doxorubicin and dacarbazine (ADIC) chemotherapy. This dog presented as an emergency because of depression, fever, and mild bilateral nasal discharge. The neutrophil count on admission was 1500/I. A, Thoracic radiograph findings were considered normal at the time, but a transtracheal wash specimen contained bacteria. B, Two days later, when the neutrophil count increased to 16,300/1, focal areas of pneumonia became evident. (From Couto CG: Management of complications of cancer chemotherapy, Vet Clin North Am 20:1037, 1990.)

(neutrophil count <500/ $\mu$ l) is evaluated because of pyrexia (>104° F [>40° C]), the fever should be attributed to bacterial pyrogens until proved otherwise and the patient should be treated aggressively with antimicrobial therapy (see following paragraphs). Neutropenic septic patients can also be hypothermic.

All dogs and cats undergoing chemotherapy should be up to date on their vaccines; it is controversial whether the use of modified-live vaccines should be avoided because of the potential for inducing illness in immunosuppressed animals. Recent evidence suggests that dogs with cancer undergoing chemotherapy have protective serum antibody titers for commonly used vaccines.

Hematologic monitoring of the patient receiving chemotherapy constitutes the most effective way to prevent (or anticipate) severe, life-threatening sepsis or bleeding secondary to myelosuppression. Complete blood counts (CBCs) should be obtained weekly or every other week (depending on the treatment protocol), and the myelosuppressive agent or agents should be temporarily discontinued (or the dose decreased) if the neutrophil count decreases to less than 2000 cells/µl or if the platelet count decreases to less than 50,000 cells/µl. Discontinuing the offending agent or agents for two or three administrations usually allows sufficient time for the cell counts to return to normal. When therapy is reinstituted, it is recommended that only 75% of the initial dose be given and the doses increased during the next 2 to 3 weeks until the initially recommended dose (or a dose that does not produce marked cytopenias) is reached. Obviously, the drawback of discontinuing chemotherapy is the potential for tumor relapse, so the clinician and owner must weigh the pros and cons of temporarily discontinuing treatment.

Clinically, neutropenic animals can be classified as febrile or afebrile. Neutropenic, febrile animals should be managed aggressively because they are usually septic. Thus fever in a neutropenic patient constitutes a medical emergency. The following protocol is the one currently used in such patients at our clinic. First, a thorough physical examination is performed to search for a septic focus, an indwelling intravenous (IV) catheter is placed aseptically, and IV fluids are administered as required. All anticancer agents are discontinued immediately, with the exception of corticosteroids, which should be discontinued gradually, if at all, because acute hypoadrenocorticism can develop in animals receiving steroid therapy if the drug is abruptly discontinued. Blood samples for a CBC and serum biochemical profile are obtained immediately. A urine sample for urinalysis and bacterial culture is also obtained, unless the patient is thrombocytopenic, in which case cystocentesis should be avoided to prevent intravesical bleeding. Two or three sets of aseptically collected blood samples can be obtained at 30-minute intervals for aerobic and anaerobic bacterial cultures and antibiotic susceptibility tests, although this is usually not necessary because the bacterial isolates are quite predictable (see following paragraph) and because the results of these tests will not be available for several days. After the second set of samples for blood cultures is collected, therapy with an

empirical bactericidal antibiotic combination is instituted. We use a combination of enrofloxacin (5 to 10 mg/kg IV q24h) and ampicillin (22 mg/kg IV q8h) because most bacterial isolates in such animals are Enterobacteriaceae and staphylococci, organisms commonly susceptible to these agents. Once the neutrophil count returns to normal and the animal's condition is clinically normal (usually within 72 to 96 hours), the antibiotic combination is discontinued and the animal is allowed to go home, with instructions to the owner to administer sulfadiazine-trimethoprim (ST) at a dosage of 13 to 15 mg/kg by mouth (PO) q12h or enrofloxacin (5 to 10 mg/kg PO q24h) for 5 to 7 days. When the patient returns for additional chemotherapy, the dose of the offending agent or agents should be decreased by 15% to 20%.

At our clinic the yield for three sets of blood cultures in dogs with cancer, fever, and normal-to-high neutrophil counts is approximately 40%, whereas it is approximately 30% in dogs with cancer, fever, and neutropenia. Isolates in the former group usually include *Streptococcus* spp., *Staphylococcus* spp., *Enterobacter* spp., *Klebsiella* spp., and *Escherichia coli*, in decreasing order of frequency. In neutropenic, febrile dogs the isolates include mainly *Klebsiella* spp. and *E. coli*; *Staphylococcus* spp. is isolated in fewer than 20% of the dogs.

Neutropenic, afebrile, asymptomatic patients can be treated as outpatients by discontinuing the drug or drugs as described earlier and administering ST (13 to 15 mg/kg PO q12h). The patient that is afebrile but has constitutional signs should be considered to be septic and treated as described in previous paragraphs. If the neutropenia is not severe (i.e., >2000 cells/µl), no therapy is required and the animal should only be observed by the owner. Owners should be instructed to take their pet's rectal temperature twice daily and to call the veterinarian if pyrexia develops, in which case the animal is treated as neutropenic and febrile. ST eliminates the aerobic intestinal florae but preserves the anacrobic bacteria, which are an important component of the local defense system because of their ability to produce local antibiotic factors. In addition, ST is active against many pathogens isolated from animals with cancer, and it achieves therapeutic blood and tissue concentrations and also high intragranulocytic concentrations.

Myelosuppression may be alleviated through the use of lithium carbonate (10 mg/kg PO q12h) in dogs or recombinant human granulocyte colony–stimulating factor (G-CSF; Neupogen; 5 µg/kg subcutaneously [SC] q24h) in dogs and cats. Although several studies have reported the beneficial role of G-CSF or granulocyte-macrophage colony–stimulating factor (GM-CSF) in dogs and cats, it is unlikely that these agents will find their way into the clinic owing to their high cost (approximately \$50 to \$150/day) and the fact that dogs and cats can mount an antibody response to this protein of human origin and inactivate it; moreover, in dogs with chemotherapy-induced neutropenia the activity of endogenous G-CSF is extremely high, and neutrophil counts return to normal within 36 to 72 hours, the same interval

reported for "response" to G-CSF. In our clinic G-CSF is typically reserved for patients that received accidental chemotherapy overdoses and in which the predicted duration of neutropenia is unknown.

#### GASTROINTESTINAL TOXICITY

Although less common than myelosuppression, gastrointestinal toxicity is a relatively common complication of cancer chemotherapy in pets. From a clinical standpoint, two major types of gastrointestinal complications can occur: gastroenterocolitis and the combination of anorexia, nausea, and vomiting.

Although results of controlled studies are not available, nausea and vomiting are not apparently as common in pets as they are in humans receiving similar drugs and dosages. Drugs associated with nausea and vomiting in dogs or cats include dacarbazine (DTIC), cisplatin, doxorubicin (primarily in cats), methotrexate, actinomycin D, cyclophosphamide, and 5-fluorouracil (5-FU; see Table 78-1).

Acute anorexia, nausea, and vomiting caused by injectable drugs are usually prevented by administering the offending agents by slow IV infusion. If these problems persist despite this tactic, antiemetics such as metoclopramide can be given at a dosage of 0.1 to 0.3 mg/kg IV, SC, or PO q8h, or prochlorperazinecan be administered intramuscularly at a dosage of 0.5 mg/kg q8-12h. Other antiemetics that may be effective in dogs with chemotherapy-induced emesis are butorphanol (Torbugesic; Fort Dodge Labs, Fort Dodge, Iowa) at a dosage of 0.1 to 0.4 mg/kg intramuscularly or intravenously every 6 to 8 hours and IV ondansetron (Zofran; Glaxo, Research Triangle Park, N.C.) at a dosage of 0.1 mg/kg immediately before chemotherapy and every 6 hours thereafter, or maropitant (Cerenia, Pfizer Animal Health, Kalamazoo, MI) at a dosage of 2 mg/kg, PO q24h. (For additional information on this subject, see Chapter 30.) Methotrexate and cyclophosphamide, two drugs that are commonly administered PO, can also cause anorexia, nausea, and vomiting. Methotrexate commonly causes anorexia and vomiting 2 or 3 weeks after the start of therapy in dogs; these adverse effects are usually controlled with metoclopramide given at the dosage just described. If these problems persist, it may be necessary to discontinue methotrexate treatment. Cyclophosphamide tends to induce anorexia or vomiting in cats. Cyproheptadine (Periactin; Merck Sharp & Dohme, West Point, Pa) at a dosage of 1 to 2 mg (total dose) PO q8-12h is quite effective as an appetite stimulant and antinausea agent in cats.

Gastroenterocolitis is uncommon in animals receiving anticancer agents. Drugs that occasionally cause mucositis include methotrexate, 5-FU, actinomycin D, and doxorubicin. It occurs rarely in association with other alkylating agents, such as cyclophosphamide. Of the drugs mentioned in the previous paragraphs, only doxorubicin and methotrexate appear to be of clinical relevance. On the basis of our experience, Collies and Collie crosses, Old English

Sheepdogs, Cocker Spaniels, and West Highland White Terriers appear to be extremely susceptible to doxorubicininduced enterocolitis.

Doxorubicin-induced enterocolitis is characterized by the development of hemorrhagic diarrhea (with or without vomiting), primarily of the large bowel type, 3 to 7 days after the administration of the drug. Supportive fluid therapy (if necessary) and treatment with therapeutic doses of bismuth subsalicylate-containing products (Pepto-Bismol, 3 to 15 ml or 1-2 tabs PO q8-12h) are generally effective in controlling the clinical signs in dogs, which usually resolve in 3 to 5 days. The administration of Pepto-Bismol from days 1 to 7 of the treatment may alleviate or prevent these signs in dogs at risk for gastroenterocolitis (i.e., one of the breeds mentioned, an animal with a history of this toxicity). The use of bismuth subsalicylate should be avoided in cats. Gastroenteritis associated with the PO administration of methotrexate usually occurs a minimum of 2 weeks after the animal has been receiving this drug; the treatment is the same as that used for doxorubicin-induced enterocolitis.

#### HYPERSENSITIVITY REACTIONS

Acute type I hypersensitivity reactions occasionally occur in dogs receiving parenteral L-asparaginase or doxorubicin and are common in dogs treated with IV etoposide or taxol derivatives; in the latter two, there is a reaction to the solubilizing agent (Tween 80). The reaction to doxorubicin does not appear to be a true hypersensitivity reaction, however, because this agent can induce direct mast cell degranulation independently of immunoglobulin E (IgE) mediation. Etoposide can be safely administered to dogs PO. Hypersensitivity reactions to anticancer agents are extremely rare in cats and thus are not discussed.

Clinical signs in dogs with hypersensitivity reactions to anticancer agents are similar to those in dogs with other types of hypersensitivity reactions (i.e., they are primarily cutaneous and gastrointestinal). Typical signs appear during or shortly after administration of the agent and include head shaking (caused by ear pruritus), generalized urticaria and erythema, restlessness, occasionally vomiting or diarrhea, and rarely collapse caused by hypotension.

Most systemic anaphylactic reactions can be prevented by pretreating the patient with H<sub>1</sub> antihistamines (i.e., IM diphenhydramine, 1 to 2 mg/kg 20 to 30 minutes before administration of the drug) and by administering certain drugs (e.g., L-asparaginase) subcutaneously or intramuscularly rather than through an IV route. If the agent cannot be given by any other routes (i.e., doxorubicin), it should be diluted and administered by slow IV infusion.

The treatment of acute hypersensitivity reactions includes immediate discontinuation of the agent and the administration of H<sub>1</sub> antihistamines (i.e., diphenhydramine, 0.2 to 0.5 mg/kg by slow IV infusion), dexamethasone sodium phosphate (1 to 2 mg/kg IV), and fluids if necessary. If the systemic reaction is severe, epinephrine (0.1 to 0.3 ml of a 1:1000 solution IM or IV) should be used. Once the reaction subsides (and if it was mild), the administration of certain drugs, such as doxorubicin, may be continued. Injectable  $H_1$  antihistamines should be used with caution in cats (if at all), because they can cause acute central nervous system depression leading to apnea.

#### **DERMATOLOGIC TOXICITY**

It is rare for anticancer agents to cause dermatologic toxicity in small animals. However, three types of dermatologic toxicities can occur: local tissue necrosis (caused by extravasation), delayed hair growth and alopecia, and hyperpigmentation.

Local tissue necrosis resulting from the extravasation of vincristine, vinblastine, actinomycin D, or doxorubicin is occasionally seen in dogs receiving these drugs but is extremely rare in cats. Indeed, according to anecdotal reports, cats have accidentally received entire doses of doxorubicin perivascularly without developing tissue necrosis. The pathogenesis of this toxicity is poorly understood, but it is thought to be mediated by release of free radicals; however, some of these drugs are also directly caustic if given perivascularly, causing moderate to severe tissue necrosis. As a consequence, every effort should be made to ensure that these drugs are administered intravascularly. In addition to this complication, some retrievers (e.g., Labrador and Golden Retrievers) appear to experience pruritus or discomfort around the site of the IV injection even when the drug is known to have been administered intravascularly. This pain and discomfort frequently lead to licking and the development of a pyotraumatic dermatitis ("hot spot") within hours of the injection. In these dogs applying a bandage over the injection site or placing an Elizabethan collar prevents this type of reaction.

To prevent or minimize the probability of extravascular injection of caustic drugs, they should be administered through small-gauge (22- to 23-gauge), indwelling, IV, overthe-needle catheters or through 23- to 25-gauge butterfly catheters. We use the former to administer doxorubicin and the latter to administer the vinca alkaloids and actinomycin D. Caustic drugs should be properly diluted before administration (i.e., vincristine to a final concentration of 0.1 mg/ ml and doxorubicin to a concentration of 0.5 mg/ml) and the patency of the intravascular injection site ensured by intermittently aspirating until blood appears in the catheter. In our clinic, we do not administer doxorubicin by IV constant-rate infusion because such patients may be more likely to undergo extravasation. If the site is not patent, the catheter should be placed in another vein. Recommendations for the management of extravascular injections are listed in Box 78-1.

If, despite these precautions, a local tissue reaction occurs, it develops approximately 1 to 7 days after the perivascular injection of vinca alkaloids or actinomycin D and 7 to 15 days after doxorubicin extravasation. Tissue necrosis resulting from doxorubicin extravasation is far more severe than

Recommendations for the Management of Perivascular Injections of Caustic Anticancer Drugs in Cats and Dogs\*

- 1. Do not remove the IV catheter.
- Administer 10 to 50 ml of sterile saline solution through the catheter (in an attempt to dilute the agent).
- With a 25-gauge needle, administer 10 to 20 ml of sterile saline solution subcutaneously in the affected area.
- Inject 1 to 4 mg of dexamethasone sodium phosphate subcutaneously in the affected area (in an attempt to stabilize lysosomal and plasma membranes).
- Apply cold compresses or ice packs to the area for 48 to 72 hours (to cause vasoconstriction and prevent local dissemination of the drug and to decrease local tissue metabolism).

IV, Intravenous.

\* Please see text for additional information.

that associated with the extravasation of other agents because the drug is extremely caustic and persists in tissues for up to 16 weeks. If perivascular administration of doxorubicin has occurred (and the clinician has recognized it during or immediately after the administration), dexrazoxane (Zinecard, Pfizer) can be administered at 5 to 10 times the dose of doxorubicin given (i.e., for 30 mg of doxorubicin, 150-300 mg of dexrazoxane should be given). Dexrazoxane is rather expensive, so it is not routinely used in small animal patients.

We recently evaluated carvedilol (Coreg, Glaxo Smith Kline) in a limited number of dogs that received perivascular doxorubicin. In three dogs that received treatment immediately after drug extravasation (at a dosage of 0.1 to 0.4 mg/kg q12-24h), there were no visible signs of necrosis. In three dogs that developed necrosis after perivascular doxorubicin administration, carvedilol resulted in rapid healing of the area (i.e., within 2-3 weeks).

Clinical signs include pain, pruritus, erythema, moist dermatitis, and necrosis of the affected area; severe tissue sloughing may occur (Fig. 78-2).

If local tissue reactions develop, they can be treated as shown in Box 78-2.

In dogs and cats undergoing chemotherapy delayed hair growth is more common than alopecia. This is in contrast to the situation in human patients, in whom severe scalp alopecia is a predictable complication of therapy. Because most chemotherapeutic agents affect rapidly dividing tissues, cells in the anagen (growth) phase of the hair cycle are usually affected. Therefore hair is slow to regrow in areas that were clipped or shaved before or during chemotherapy. Excessive shedding is also common.

Alopecia occurs predominantly in woolly-haired (coarse-haired) dogs, such as Poodles, Schnauzers, and Kerry Blue Terriers (Fig. 78-3). It affects primarily the tactile hairs in

Tissue necrosis after extravascular injection of doxorubicin in a dog. Note the full-thickness sloughing of the area.

BOX 78-2

#### Treatment of Local Tissue Reactions

- 1. Apply an antibiotic ointment (with or without corticosteroids) to the affected area.
- Bandage the area (and replace bandages daily).
- 3. Prevent self-mutilation by placing an Elizabethan collar or a muzzle.
- 4. If there is no bacterial contamination (ruled out on the basis of negative bacterial cultures), 10 to 20 mg of methylprednisolone acetate (Depo-Medrol; Upjohn-Pharmacia, Kalamazoo, Mich.) can be injected subcutaneously in the affected area to alleviate pruritus and inflammation.
- 5. If severe necrosis or gangrene caused by anaerobic contamination occurs, the area should be surgically debrided.
- 6. In the event of severe doxorubicin-induced soft tissue necrosis, the affected limb may need to be amputated.

short-haired dogs and cats. Although the exact reason that chemotherapy-induced alopecia occurs in woolly-haired dogs is unknown, a prolonged anagen phase and synchronous hair growth, comparable to those occurring in human scalp hair, may make these dogs prone to this toxic effect. Drugs commonly associated with delayed hair growth and alopecia include cyclophosphamide, doxorubicin, 5-FU, 6thioguanine, and hydroxyurea (Hydrea; E.R. Squibb & Sons, Princeton, N.J.). Alopecia and delayed hair growth usually resolve shortly after discontinuation of the offending agent.

FIG 78-3 Alopecia in a 7-year-old Schnauzer undergoing doxorubicin and dacarbazine (ADIC) chemotherapy. Note the short and light-colored haircoat.

Hyperpigmentation is uncommon in dogs and extremely rare in cats receiving chemotherapy. Cutaneous hyperpigmentation affecting the face, ventral abdomen, and flanks is common in dogs receiving doxorubicin- and bleomycincontaining protocols.

#### **PANCREATITIS**

Pancreatitis is a well-recognized entity in human patients undergoing chemotherapy. Offending drugs in humans include corticosteroids, azathioprine, 6-mercaptopurine, L-asparaginase, cytosine arabinoside, and combination chemotherapy. Sporadic reports of pancreatitis in dogs (but not in cats) receiving chemotherapeutic and immunosuppressive agents have also appeared in the literature.

We have documented acute pancreatitis in several dogs receiving 1-asparaginase or combination chemotherapy. Dogs in the latter group were receiving COAP (cyclophosphamide, vincristine, cytosine arabinoside, prednisone), ADIC (doxorubicin, DTIC); or VAC (vincristine, doxorubicin, cyclophosphamide) chemotherapy. Clinical signs developed 1 to 5 days after the start of chemotherapy and consisted of anorexia, vomiting, and depression. Physical examination findings in these dogs were unremarkable, and abdominal pain was rare. Serum lipase and amylase activities were high in all the animals, and ultrasonographic evidence of pancreatitis was detected in approximately one half of the dogs. The animals were treated with IV fluids, and the clinical signs resolved within 3 to 10 days in most dogs.

It is difficult to prevent chemotherapy-induced pancreatitis because it is not a predictable complication. As a general precaution, we refrain from using L-asparaginase in dogs at high risk for pancreatitis (i.e., overweight middle-age to older female dogs). As a further precaution, dogs receiving drugs with the potential to cause pancreatitis should be fed a low-fat diet.

#### **CARDIOTOXICITY**

Cardiotoxicity is a relatively uncommon complication of doxorubicin therapy in dogs; it is extremely rare in cats. Two types of doxorubicin-induced cardiac toxicity are observed in dogs: an acute reaction occurring during or shortly after administration and a chronic cumulative toxicity. Acute doxorubicin toxicity is characterized by cardiac arrhythmias (mainly sinus tachycardia) that develop during or shortly after administration. This phenomenon is thought to stem from doxorubicin-induced, histamine-mediated catecholamine release because the sinus tachycardia and hypotension can be prevented by pretreatment with H1 and H2 antihistamines. Several weeks or months after repeated doxorubicin injections, persistent arrhythmias, including ventricular premature contractions, atrial premature contractions, paroxysmal ventricular tachycardia, second-degree atrioventricular blocks, and intraventricular conduction defects, develop. These rhythm disturbances are usually associated with the development of a dilated cardiomyopathy, similar to that which occurs spontaneously in Doberman Pinschers and Cocker Spaniels.

The hallmark of chronic doxorubicin toxicity is a dilated cardiomyopathy that develops after a total cumulative dose of approximately 240 mg/m² is exceeded in the dog. The histologic lesions seen in dogs with doxorubicin-induced cardiomyopathy consist of vacuolation of myocytes, with or without myofibril loss. Clinical signs of toxicity in dogs are those of congestive heart failure (usually left-sided). Therapy consists of discontinuation of the offending drug and the administration of cardiac drugs such as digitalis glycosides or nonglycoside inotropic agents. Once cardiomyopathy develops, the prognosis is poor because the myocardial lesions are irreversible.

It is critical to monitor patients receiving doxorubicin to prevent fatal cardiomyopathy. In this respect, dogs (and possibly) cats with underlying rhythm disturbances or impaired myocardial contractility, as shown by decreased fractional shortening on M-mode or Doppler echocardiograms, should not receive doxorubicin. It is also recommended that animals receiving doxorubicin undergo echocardiographic evaluation every three doxorubicin cycles (9 weeks) to assess myocardial contractility and that the drug be discontinued if decreased fractional shortening occurs. Endomyocardial biopsy specimens are commonly obtained in people receiving doxorubicin in an effort to detect submicroscopic lesions, but this is impractical in dogs. The value of serum cardiac troponin I concentrations to detect early myocardial damage from doxorubicin is currently being evaluated in dogs.

Several protocols have been devised in an attempt to minimize doxorubicin-induced cardiomyopathy in dogs. Unfortunately, only two have shown promise in minimizing or preventing cardiomyopathy. Of these, weekly low-dose doxorubicin therapy in humans has been found to be associated with a significantly lower frequency of histologic changes than the conventional 3-week schedule has been. I have been

able to administer total cumulative doses of 500 mg/m² to two dogs using a 10 mg/m² weekly protocol. However, recent reports describe a loss of antitumor activity when using weekly low-dose doxorubicin in dogs with lymphoma. A new compound, dexrazoxane (Zinacard, Upjohn-Pharmacia, Kalamazoo, Mich.), offers a promising means of reducing the chronic cardiotoxicity induced by doxorubicin; doses in excess of 500 mg/m² have been administered to dogs receiving the agent without causing significant cardiotoxicity. Recently, carvedilol (0.1-0.4 mg/kg, PO, q12-24h) has been used successfully to prevent or decrease the probability of developing doxorubicin-associated cardiomyopathy in people (Kalay et al, 2006); we have successfully used carvedilol in dogs with subclinical myocardial dysfunction that needed doxorubicin.

#### UROTOXICITY

The urinary tract in small animals is rarely affected by adverse reactions to anticancer agents. Only two specific complications are of clinical importance in pets with cancer: nephrotoxicity and sterile hemorrhagic cystitis. Transitional cell carcinomas of the urinary bladder associated with chronic cyclophosphamide therapy have also been reported in dogs.

Nephrotoxicity is rarely observed in dogs and cats undergoing chemotherapy. Although several potentially nephrotoxic drugs are commonly used in these species, only doxorubicin (primarily in cats), cisplatin (in dogs), and intermediate to high doses of methotrexate (in dogs) are of concern to clinicians. In our clinic we do not use cisplatin frequently on account of its potential to induce nephrotoxicity.

Doxorubicin may be a nephrotoxin in cats, and the limiting cumulative toxicity in this species may be renal rather than cardiac. Doxorubicin may cause nephrotoxicosis in dogs with preexisting renal disease and in those concomitantly receiving other nephrotoxins, such as aminoglycoside antibiotics or cisplatin. The administration of cisplatin using forced diuresis protocols minimizes the prevalence of nephrotoxicity in dogs.

Sterile hemorrhagic cystitis is a relatively common complication of long-term cyclophosphamide therapy in dogs; rarely, it may also occur acutely after a single dose of cyclophosphamide. This toxicity is not clinically relevant in cats. Acute clinical signs and urinalysis changes compatible with sterile hemorrhagic cystitis developed after the first injection in three dogs treated at our clinic with IV cyclophosphamide, 100 mg/m², and four dogs receiving PO cyclophosphamide, 300 mg/m². Sterile cystitis results from the irritating effects of one of the cyclophosphamide metabolites (acrolein). It develops in approximately 5% to 25% of dogs and 1% to 3% of cats treated with cyclophosphamide, usually after an average of 18 weeks of therapy. Furosemide or prednisone administered concomitantly with cyclophosphamide appears to decrease the prevalence of cystitis.

Forced diuresis appears to minimize the severity of this complication or prevent it. I usually recommend administering the cyclophosphamide in the morning, allowing the pet to urinate frequently (if it is an indoor dog), salting the food, and administering prednisone on the same day that the animal receives the cyclophosphamide (if the protocol calls for prednisone administration).

Clinical signs of sterile hemorrhagic cystitis are similar to those of other lower urinary tract disorders and include pollakiuria, hematuria, and dysuria. Urinalysis typically reveals blood and mildly to moderately increased numbers of white blood cells but no bacteria. Treatment of this complication consists of discontinuing the cyclophosphamide, forcing diuresis, diminishing the inflammation of the bladder wall, and preventing secondary bacterial infections. The cystitis resolves in most dogs within 1 to 4 months after the cyclophosphamide is discontinued. I administer furosemide (Lasix) at a dosage of 2 mg/kg PO every 12 hours for its diuretic effects, prednisone at a dosage of 0.5 to 1 mg/kg PO every 24 hours for its antiinflammatory (and diuretic) effect, and an ST combination at a dose of 13 to 15 mg/kg PO every 12 hours to prevent secondary bacterial contamination. If the clinical signs worsen despite this approach, the instillation of 1% formalin solution in water into the bladder can be attempted. Gross hematuria resolved within 24 hours and did not recur in two dogs thus treated. The intravesical infusion of a 25% to 50% dimethylsulfoxide solution may also alleviate the signs of cystitis in dogs.

#### HEPATOTOXICITY

Chemotherapy-induced hepatotoxicity is extremely rare in dogs and cats. With the exception of the hepatic changes induced by corticosteroids in dogs, to my knowledge only methotrexate, cyclophosphamide, lomustine, and azathioprine (Imuran; Burroughs Wellcome, Research Triangle Park, N.C.) have been implicated as or confirmed to be hepatotoxins in dogs. In my experience, the hepatotoxicity caused by anticancer drugs in small animals is of little or no clinical relevance, with the exception of lomustine.

A recent report describes a low prevalence of hepatotoxicity (<10%) in dogs receiving lomustine (CCNU) for lymphoma or mast cell tumors. In our clinic we have documented marked increases in alanine transaminase (ALT) activities (>1000 IU/L) and mild increases in alkaline phosphatase (ALP) activities (<500 IU/L) within 3 weeks of starting lomustine therapy in several dogs with mast cell tumors or granulomatous meningoencephalitis. Most dogs had decreases in the ALT and ALP concentrations after lengthening the dosing interval, decreasing the individual dosage, or both. In my experience, hepatoprotectors appear to be of no benefit in preventing CCNU-induced hepatotoxicity.

Dogs with immune-mediated disorders receiving chronic azathioprine therapy rarely develop increases in liver enzyme activities that respond to discontinuation of the drug.

# **NEUROTOXICITY**

Anticancer agent-induced neurotoxicity is also extremely rare in dogs and cats. Neurotoxicosis occurs infrequently in dogs receiving 5-FU, although it is common in cats (for this reason, this drug should not be used in cats). Neurotoxicity can also occur in dogs and cats that ingest 5-FU intended for human use (i.e., prescribed for the owners). Clinical signs occur shortly (3 to 12 hours) after ingestion of the drug and consist primarily of excitation and cerebellar ataxia, resulting in death in approximately one third of the dogs and in most cats. Neurotoxicity was also documented in 25% of dogs receiving a combination of actinomycin D, 5-FU, and cyclophosphamide (the CDF protocol) for the management of metastatic or nonresectable carcinomas at our clinic. This prevalence is considerably higher than that seen in association with the use of 5-FU in combination with other drugs and may be a result of drug interactions.

# **PULMONARY TOXICITY**

Pulmonary toxicity is extremely rare in dogs and cats receiving chemotherapy. To my knowledge, only cisplatin has been documented as a cause of pulmonary toxicity in cats. Acute signs of dyspnea leading to death occur within 48 to 96 hours of the administration of cisplatin in this species. Necropsy findings consist of pulmonary and mediastinal edema and microangiopathic changes in the pulmonary vasculature. Because of the risk of this serious toxicity, cisplatin should not be used in cats; carboplatin, a cisplatin derivative, does not cause pulmonary toxicity in this species.

# **ACUTE TUMOR LYSIS SYNDROME**

In human patients the rapid lysis of certain tumor cells (e.g., lymphoma cells) shortly after chemotherapy may lead to a syndrome of hyperuricemia, hyperphosphatemia, and hyperkalemia, either singly or in combination. This clinical entity is referred to as *acute tumor lysis syndrome* and is thought to be secondary to the release of high quantities of intracellular phosphate, uric acid, and nucleic acid metabolites. The intracellular concentration of phosphorus in human lymphoma and leukemic cells is four to six times higher than that in normal lymphocytes, and the same appears to be true for dogs.

In dogs ATLS has been reported to occur only in association with lymphomas treated with chemotherapy, radiation therapy, or both and is characterized by hyperphosphatemia, with or without azotemia, hyperkalemia, hypocalcemia, metabolic acidosis, and hyperuricemia. It is rare in cats. Clinical signs include depression, vomiting, and diarrhea and occur within hours of the start of chemotherapy.

We have documented clinically evident ATLS after chemotherapy in 10 dogs with lymphoma, during a period in

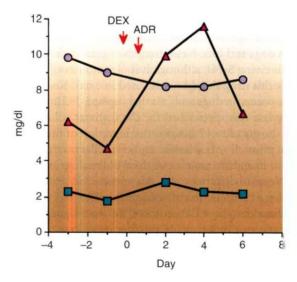

FIG 78-4

Serum phosphorus ( ), calcium ( ), and creatinine ( ) concentrations in a dog with acute tumor lysis syndrome after chemotherapy for a primary pulmonary lymphoma. Note the increase in the serum phosphorus concentrations, with a mild decrease in the calcium concentrations and minor increases in the serum creatinine concentrations. DEX, Dexamethasone; ADR, doxorubicin. (From Couto CG: Management of complications of cancer chemotherapy, Vet Clin North Am 20:1037, 1990.)

which approximately 2000 dogs with lymphoma were treated with chemotherapy. In most dogs the pretreatment serum creatinine concentrations or the tumor burden was high; one of the dogs had high liver enzyme activities. Within 1 to 7 days of the start of chemotherapy, lethargy, vomiting, and

bloody diarrhea developed in affected dogs and the serum phosphorus concentrations increased markedly (Fig. 78-4). Aggressive fluid therapy and the correction of acid-base and electrolyte disturbances resulted in resolution of the clinical signs within 3 days in six dogs; the remaining two dogs died as a result of ATLS.

# CHAPTER Approach to the Patient with a Mass

# CHAPTER OUTLINE

APPROACH TO THE CAT OR DOG WITH A SOLITARY MASS

APPROACH TO THE CAT OR DOG WITH A METASTATIC LESION

APPROACH TO THE CAT OR DOG WITH A MEDIASTINAL MASS

# APPROACH TO THE CAT OR DOG WITH A SOLITARY MASS

It is common for the practicing veterinarian to evaluate a clinically healthy cat or dog in which a single mass is found during a routine physical examination or in which the owner has detected a mass and is concerned about it. The mass can be superficial (e.g., enlarged prescapular lymph node, subcutaneous mass) or deep (e.g., splenic mass, enlarged mesenteric lymph node), and often the clinician wonders how to proceed and what to recommend to the owner.

In this situation there are several possible approaches:

- 1. Do nothing and see if the mass "goes away."
- 2. Evaluate the mass cytologically.
- 3. Evaluate the mass histopathologically.
- 4. Do a complete workup, including complete blood count (CBC), serum biochemistry profile, radiography, abdominal ultrasonography, and urinalysis.

The first option (i.e., do nothing and see if the mass goes away) is not really an option because the presence of any mass is abnormal, and it should therefore be evaluated. As a general rule, most masses, with the notable exception of inflammatory lesions, histiocytomas in young dogs, and transmissible venereal tumors, do not regress spontaneously.

At our clinic the typical first step in evaluating a solitary mass is to perform fine-needle aspiration (FNA) to obtain material for cytologic evaluation (see Chapter 75). Using this simple, relatively atraumatic, quick, and inexpensive procedure, the clinician can arrive at a highly presumptive or definitive diagnosis in the vast majority of animals. After identifying the nature of the mass (i.e., benign neoplastic, malignant neoplastic, inflammatory, or hyperplastic), the clinician can recommend additional tests to the owner.

Performing a biopsy for histopathology constitutes another valid alternative. However, the cost, the trauma to the patient, and the time it takes for the pathologist's report to become available make this a less attractive option than FNA. An intensive workup of a cat or dog with a solitary mass (i.e., option 4) may not be warranted because additional diagnostic information regarding the mass is rarely gained from these procedures. However, the presence of metastatic lesions on thoracic radiographs may suggest that the mass in question is a malignant tumor.

If a cytologic diagnosis of a benign neoplasm is made (e.g., lipoma), the clinician faces two options: to do nothing and observe the mass or to surgically excise it. Because benign neoplasms in cats and dogs are rarely premalignant (with the notable exception of solar dermatitis/carcinoma in situ preceding the development of squamous cell carcinomas in cats), if a benign neoplasm is definitively diagnosed, a sound approach is to recommend a wait-and-see attitude. If the mass enlarges, becomes inflamed, or ulcerates, then surgical excision is recommended. However, the clinician should keep in mind that most benign neoplasms are more easily excised when they are small (i.e., it is not advisable to wait until the mass becomes quite large). To some owners the option of surgically excising the mass shortly after diagnosis is more appealing.

If a cytologic diagnosis of malignancy is obtained (or if the findings are suggestive of or compatible with malignancy), additional evaluation is warranted. Different approaches are indicated, depending on the cytologic diagnosis (i.e., carcinoma versus sarcoma versus round cell tumor). However, with the exception of mast cell tumors (i.e., pulmonary metastases are extremely rare in dogs and cats with this tumor type), thoracic radiographs should be obtained to search for metastatic disease in dogs and cats with most types of malignant neoplasms. Two lateral views

and a ventrodorsal (or dorsoventral) view are recommended to increase the likelihood of detecting metastatic lesions. If available, a computed tomography (CT) scan may be obtained because it can detect masses smaller than those detectable on plain radiography. Plain radiographs of the affected area may also be indicated to look for soft tissue and bone involvement. Abdominal ultrasonography (or radiography) may be indicated for further staging in animals with certain neoplasms (e.g., hemangiosarcoma, intestinal neoplasms, mast cell tumors). A CBC, serum biochemistry profile, and urinalysis may provide additional clinical information (e.g., paraneoplastic syndromes, concurrent organ failure).

If the mass is malignant and there is no evidence of metastatic disease, surgical excision is usually recommended. If there are metastatic lesions, the pathologist feels comfortable with the cytologic diagnosis, and the tumor is likely to respond to chemotherapy (e.g., lymphoma, hemangiosarcoma), chemotherapy constitutes the best viable option (see Chapter 76). However, as discussed in Chapter 76, surgical resection of the primary mass (e.g., mammary carcinoma) in a patient with metastatic lesions may provide considerable palliation and prolong good-quality survival. If an assertive diagnosis cannot be made on the basis of the cytologic findings, an incisional or excisional biopsy of the mass is advisable. In our clinic we typically do not recommend euthanasia in dogs and cats with metastatic lesions and good quality of life because survival times in excess of 6 months (without chemotherapy) are common in animals with most metastatic neoplasms.

# APPROACH TO THE CAT OR DOG WITH A METASTATIC LESION

Radiographic or ultrasonographic evidence of metastatic cancer is often found during the routine evaluation of an animal with a suspected or confirmed malignancy or during the evaluation of a cat or dog with obscure clinical signs. In such instances the clinician should be familiar with both the biologic behavior of the common neoplasms and with their characteristic radiographic and ultrasonographic patterns (Table 79-1). Suter et al. (1974) have described the typical radiographic appearances of various metastatic malignancies. In addition, the owner should be questioned regarding any prior surgeries in the pet (e.g., excision of a mass that was thought to be benign but may have been the primary malignancy).

If a cytologic or histopathologic diagnosis of malignancy has already been made and the metastatic lesions are detected while staging the animal, treatments can be recommended to the owner at this point (assuming that the metastatic lesions have arisen from the previously diagnosed primary tumor). As a general rule, cytologic or histopathologic evaluation of one or more of these lesions should be performed so that the clinician can best advise the owner as to the appropriate course of action.

A cytologic diagnosis of metastatic lung lesions can usually be obtained through blind or ultrasonography-, fluoroscopy-, or CT-guided percutaneous FNA of the lungs. To do this, the area to be aspirated (i.e., the one with the highest density of lesions radiographically or the identified lesions) is clipped and aseptically prepared. For blind percutaneous lung aspirates the animal should be in sternal recumbency or standing; a 25-gauge, 2- to 3-inch (5- to 7.5-cm) needle (depending on the size of the animal) coupled to a 12- to 20-ml syringe is rapidly advanced through an intercostal space along the cranial border of the rib to the depth required (previously determined on the basis of the radiographs), and suction is applied two or three times and then released; the needle is then withdrawn. Smears are made as described in Chapter 75. When aspirating lungs, the clinician is likely to obtain a fair amount of air or blood (or both) in the syringe. Rare complications associated with this technique include pneumothorax (animals should be closely observed for 2 to 6 hours after the procedure and dealt with accordingly if pneumothorax

晶

TABLE 79-1

Metastatic Behavior of Some Common Neoplasms in Dogs and Cats

NEOPLASM	SPECIES	COMMON METASTATIC SITES

MEL—oral	D	Lymph nodes, lungs
MCT	D	Lymph nodes, liver, spleen
MCT	С	Spleen, liver, bone marrow

develops) and bleeding. As a general rule, FNA of the lungs should not be performed in cats or dogs with coagulopathies.

If an FNA of the lungs fails to yield a diagnostic sample, a lung biopsy performed with a biopsy needle (under ultrasonographic, fluoroscopic, or CT guidance) or through a thoracotomy should be contemplated. This procedure is associated with an extremely low morbidity and should be recommended if owners are considering treatment.

Metastatic lesions in other organs or tissues (e.g., liver, bone) can also be diagnosed on the basis of FNA findings. The clinician should remember that nodular lesions of the liver or spleen in dogs with a primary malignancy should not necessarily be considered metastatic. FNA or biopsies of such lesions frequently reveal normal hepatocytes (i.e., regenerative hepatic nodule) or extramedullary hematopoiesis/lymphoreticular hyperplasia, respectively. In the case of bone metastases, an aspirate can be obtained using a hypodermic needle (20-22G) that is inserted blindly or under ultrasonographic guidance; if this fail to yield cells, a 16 or 18 gauge bone marrow aspiration needle can be used. If a cytologic diagnosis cannot be made, a core (needle) biopsy can be performed.

As discussed in Chapter 76, cats and dogs with metastatic neoplasms can now be treated fairly successfully using chemotherapy. To do this, however, it is necessary to know the histologic (or cytologic) tumor type. The clinician should always bear in mind that euthanasia is a viable option for some owners.

# APPROACH TO THE CAT OR DOG WITH A MEDIASTINAL MASS

Several lesions are found as anterior mediastinal masses (AMMs) during physical examination or plain thoracic radiography (Table 79-2). Some of these lesions are malignant neoplasms; therefore diagnosis and treatment should be approached aggressively in such animals.

# Clinicopathologic Features and Diagnosis

When evaluating a cat or dog with an AMM, the clinician should consider several issues before recommending a

specific treatment. As discussed previously (see Chapter 76), the treatment prescribed depends on the specific tumor type (i.e., surgical excision may be curative for dogs and cats with thymomas, whereas chemotherapy is indicated for those with lymphoma). Because lymphomas and thymomas are the most common AMMs in small animals, the ensuing discussion is limited to these two neoplasms. Other neoplasms that originate in anterior mediastinal structures include chemodectomas (heartbase tumors), ectopic thyroid carcinomas, and lipomas, among others. Nonneoplastic lesions of the mediastinum include mainly thymic or mediastinal hematomas and ultimobranchial cysts.

Paraneoplastic syndromes, such as generalized or focal myasthenia gravis, polymyositis, exfoliative dermatitis, and second neoplasms, have been well characterized in cats and dogs with thymoma. Aplastic anemia, a paraneoplastic syndrome common in humans with thymoma, has not been recognized in small animals with this tumor type. Hypercalcemia is a common finding in dogs with mediastinal lymphoma, but it can also occur in dogs with thymoma.

In cats the age at the time of presentation points to a specific diagnosis. In other words, anterior mediastinal lymphomas are more common in young cats (1 to 3 years old), whereas thymomas are more common in older cats (8 to 10 years old). It is also important to know the feline leukemia virus (FeLV) status in this species because most cats with mediastinal lymphomas are viremic (i.e., FeLV-positive), whereas most cats with thymoma are not. We occasionally see FeLV-negative mediastinal lymphomas in young to middle-age Siamese cats.

In dogs most AMMs are diagnosed in older animals (older than 5 to 6 years of age); therefore age cannot be used as a means of distinguishing between lymphomas and thymomas. However, a large proportion of dogs with mediastinal lymphomas are hypercalcemic, whereas most dogs with thymoma are not (although hypercalcemia can also occur in dogs with this neoplasm). Peripheral lymphocytosis can be present in dogs and cats with either lymphoma or thymoma. The presence of neuromuscular signs in a dog or cat with an AMM suggests the existence of a thymoma.

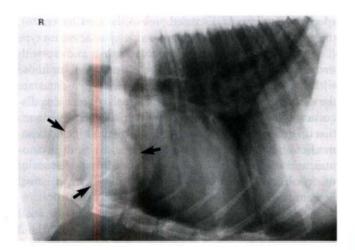

**TABLE 79-2** 

Anterior Mediastinal Masses in Cats and Dogs

LESION	CAT	DOG	COMMENTS
Thymoma	Common	Common	See text
Lymphoma	Common	Common	See text
Thyroid adenocarcinoma	Rare	Rare	
Lipoma	Rare	Rare	Low radiographic density
Branchial cysts	Rare	Rare	Cystic on ultrasound
Thymic hematomas	ŝ	Rare	Traumatic, rodenticides?
Heartbase tumors	ŝ	Rare	Brachiocephalic breeds

<sup>?,</sup> Questionable.

Typical radiographic features of thymoma (arrows) in a dog. The mass originates in the ventral mediastinum, unlike most lymphomas, which usually originate in the dorsal mediastinal region. Percutaneous fine-needle aspiration of this mass yielded findings diagnostic for thymoma, and the

mediastinal region. Percutaneous tine-needle aspiration of this mass yielded findings diagnostic for thymoma, and the dog underwent a thoracotomy with complete resection of the mass.

Thoracic radiographs are of little help in differentiating thymomas from lymphomas. The two neoplasms are similar in appearance, although lymphomas appear to originate more frequently in the dorsal anterior mediastinum, whereas thymomas originate more often in the ventral mediastinum (Fig. 79-1). The prevalence of pleural effusion in dogs and cats with either thymomas or lymphomas appears to be similar; thus the finding cannot be used as a means to distinguish between these two tumor types.

Ultrasonographic evaluation of the AMM should be attempted before more invasive diagnostic techniques are used. Ultrasonographically, most thymomas have a mixed echogenicity, with discrete hypoechoic to anechoic areas that correspond to true cysts on cross section. The lack of a supporting stroma in lymphomas usually confers a hypoechoic to anechoic density to the mass, which therefore may look diffusely cystic. In addition to aiding in the presumptive diagnosis of a given tumor type, ultrasonography may provide information regarding the resectability of the mass and assists in obtaining a specimen for cytologic evaluation (see next paragraph). In patients with thymoma a thoracic CT scan may help in planning surgery.

Transthoracic FNA of AMMs constitutes a relatively safe and reliable evaluation technique. After sterile preparation of the thoracic wall overlying the mass (see Chapter 75), a 2- to 3-inch (5- to 7.5-cm), 25-gauge needle coupled to a syringe is used to aspirate the mass. This can be done blindly (if the mass is so large that it is pressing against the interior thoracic wall) or guided by radiography (using three views to establish a three-dimensional location), fluoroscopy, ultrasonography, or CT. Despite the fact that there are large vessels within the anterior mediastinum, postaspiration bleeding is extremely rare if the animal remains motionless

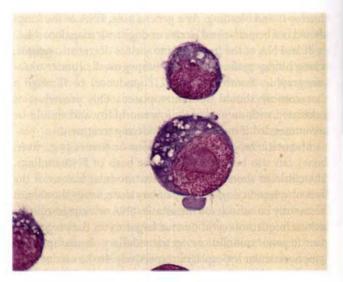

FIG 79-2 Cytologic characteristics of feline mediastinal lymphoma. Note the dark cytoplasm with abundant vacuoles typical of this neoplasm in cats. (×1000.)

during the procedure. Alternatively, if the mass is large enough to be in close contact with the internal thoracic wall, a transthoracic needle biopsy can be performed to allow histopathologic evaluation.

Cytologically, mediastinal lymphomas are composed of a monomorphic population of lymphoid cells that are mostly immature (i.e., low nuclear-to-cytoplasmic ratio, dark blue cytoplasm, clumped chromatin pattern, and nucleoli); in cats most cells in anterior mediastinal lymphomas are heavily vacuolated and resemble human Burkitt's lymphoma cells (Fig. 79-2). Thymomas are cytologically heterogeneous and composed primarily of a population of small lymphocytes (although large blasts are sometimes present), and occasionally a distinct population of epithelial-like cells that are usually polygonal or spindle shaped and can be identified either as individual cells or in sheets. Hassall's corpuscles are rarely seen in Wright's-stained cytologic preparations. Plasma cells, eosinophils, neutrophils, mast cells, macrophages, and melanocytes are all occasionally seen.

#### **Treatment**

As discussed in preceding paragraphs, anterior mediastinal lymphomas are best treated with chemotherapy (see Chapter 80). Radiotherapy can also be used in conjunction with chemotherapy to induce a more rapid remission. However, in my experience, the combination of radiotherapy and chemotherapy does not offer any advantages over chemotherapy alone, and it may indeed be detrimental to the animal, given that many cats and dogs with anterior mediastinal lymphoma have severe respiratory compromise at the time of presentation. Chemical restraint of these animals for radiotherapy may further compound this problem.

Because most thymomas are benign, surgical excision is usually curative. Although in some reports the perioperative

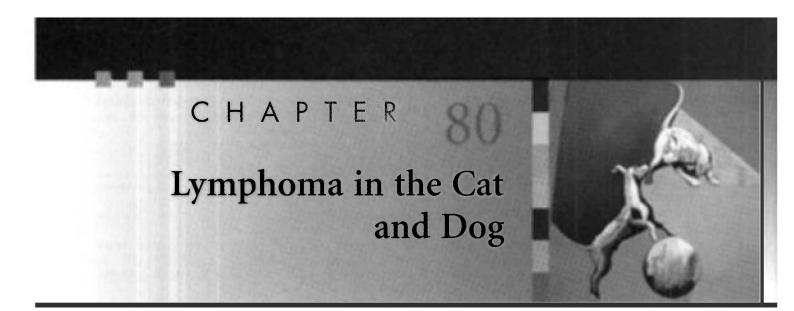

morbidity and mortality of this procedure are high (Atwater et al., 1994), in our experience, most patients that undergo thoracotomies for removal of a thymoma do well and are released from the hospital in 3 to 4 days. We recently reviewed the surgical outcome in 9 cats and 11 dogs with thymomas (Zitz et al., 2008); eight out of nine cats and eight out of eleven dogs survived the immediate postoperative period and had median survival times of 30 and 18.5 months, respectively. Two cats and one dog had late recurrences.

Radiotherapy can successfully induce remission in patients with thymoma, although complete, long-lasting remission is rarely achieved. This may be because the radiotherapy eliminates only the lymphoid component of the neoplasm but the epithelial component remains unchanged. Chemotherapy may be beneficial in selected cats and dogs with nonresectable thymomas or in those in which repeated anesthetic episodes or a major surgical procedure poses a severe risk. We have used combination chemotherapy protocols commonly used for dogs and cats with lymphoma (i.e., cyclophosphamide, vincristine, cytosine arabinoside, and prednisone [COAP]; cyclophosphamide, vincristine, and prednisone [COP]; and cyclophosphamide, doxorubicin, vincristine, and prednisone [CHOP]; see Chapter 80) in a limited number of cats and dogs with cytologically diagnosed thymomas. As with radiotherapy, however, chemotherapy may only eliminate the lymphoid cell population, thus rarely resulting in complete or long-lasting remissions.

If a definitive diagnosis of thymoma or lymphoma cannot be obtained preoperatively, the clinician has two therapeutic options: (1) to perform a thoracotomy and excise the mass or (2) to initiate chemotherapy for lymphoma (COP, COAP, or CHOP). In the latter case, if no remission (or only a partial remission) is observed 10 to 14 days after the start of chemotherapy, the mass is most likely a thymoma and surgical resection should be considered.

# CHAPTER OUTLINE

Etiology and Epidemiology Clinical Features Diagnosis Treatment

Lymphoma (i.e., malignant lymphoma, lymphosarcoma) is a lymphoid malignancy that originates from solid organs (e.g., lymph nodes, liver, spleen); this distinguishes lymphomas from lymphoid leukemias, which originate in the bone marrow (see Chapter 81).

# **Etiology and Epidemiology**

Early reports stated that approximately 70% of cats with lymphoma have feline leukemia virus (FeLV) infection (Table 80-1). Although the prevalence of viremia in cats with lymphoma varies with the anatomic form of presentation (see later discussion), young cats with lymphoma generally are FeLV-positive, whereas older cats are FeLV-negative. Over the past few years, the prevalence of FeLV infection in cats with lymphoma seen at our clinic has been decreasing. Feline immunodeficiency virus (FIV) infection increases the risk of developing lymphoma in cats; cats infected with FIV are almost six times more likely to develop lymphoma than noninfected cats, whereas cats coinfected with FeLV and FIV are more than 75 times more likely to develop lymphoma than noninfected cats (Shelton et al., 1990). Recently, Louwerens et al. (2005) reported an increase in the prevalence of feline lymphoma, despite the decrease in the prevalence of FeLV infection; this increase was associated with a high prevalence of the gastrointestinal form, extranodal or atypical forms, and FeLV-negative mediastinal forms in young to middle-aged Siamese and oriental breeds.

In dogs the etiology of lymphomas is considered multifactorial because no single etiologic agent has been identified. However, a genetic component is evident, in that the neoplasm is highly prevalent in certain breeds and bloodlines (Modiano et al., 2005). There is also a distinct breedrelated predisposition to lymphoma in dogs, with some breeds, such as the Boxer, Basset Hound, Rottweiler, Cocker Spaniel, Saint Bernard, Scottish Terrier, Airedale Terrier, English Bulldog, and Golden Retriever, being at high risk. At our clinic the breeds most commonly affected are Golden Retrievers, Cocker Spaniels, and Rottweilers.

The age of cats with lymphoma at the time of presentation is bimodal, with the first peak occurring in cats that are approximately 2 years of age and the second one occurring in cats that are approximately 10 to 12 years of age. The cats that make up the first peak are mainly FeLV-positive, whereas those that make up the second peak are predominantly FeLV-negative. As mentioned before, the prevalence of FeLV-positive cats with lymphoma continues to decrease at our clinic. The mean age of FeLV-positive cats with lymphoma when first seen is 3 years, whereas the mean age of FeLV-negative cats with lymphoma is 7 to 8 years. Most dogs with lymphoma are middle-age or older (6 to 12 years of age).

#### **Clinical Features**

There are four anatomic forms of presentation in cats and dogs with lymphoma:

- 1. *Multicentric*, characterized by generalized lymphadenopathy; hepatic, splenic, or bone marrow involvement; or a combination of these
- 2. *Mediastinal*, characterized by mediastinal lymphadenopathy, with or without bone marrow infiltration
- 3. Alimentary, characterized by solitary, diffuse, or multifocal gastrointestinal tract infiltration, with or without intraabdominal lymphadenopathy
- 4. *Extranodal*, affecting any organ or tissue (e.g., renal, neural, ocular, cutaneous)

The distribution of the different anatomic forms differs between cats and dogs. The multicentric form is the most common in dogs, accounting for more than 80% of all the lymphomas in this species. In cats the alimentary form is the most common. At our clinic, alimentary lymphoma is found in more than 70% of the cats with this neoplasm.

The clinical findings in cats and dogs with lymphoma are related to the anatomic form of the presentation. Animals with the generalized or multicentric form are evaluated because of vague, nonspecific clinical signs; frequently, the owners detect one or more subcutaneous masses (i.e., enlarged lymph nodes) during grooming in an otherwise healthy pet, and this prompts them to seek veterinary care. Occasionally, dogs and cats with lymphoma are evaluated because of nonspecific clinical signs, such as weight loss, anorexia, and lethargy. If the enlarged lymph nodes mechanically obstruct lymphatic drainage, edema occurs; if they compress the airway, coughing is the main presenting complaint.

Physical examination of cats and dogs with multicentric lymphoma usually reveals massive generalized lymphade-nopathy, with or without hepatomegaly, splenomegaly, or extranodal lesions (e.g., ocular, cutaneous, renal, neural). The affected lymph nodes are markedly enlarged (5 to 15 times their normal size), painless, and freely movable. A syndrome of reactive (hyperplastic) lymphadenopathy that occurs in cats can mimic the clinicopathologic features of multicentric lymphoma.

Cats and dogs with mediastinal lymphoma are usually evaluated because of dyspnea, coughing, or regurgitation (the latter is more common in cats) of recent onset. Polyuria and polydipsia are common presenting complaints in dogs with mediastinal lymphoma and hypercalcemia; tumorassociated hypercalcemia is extremely rare in cats with lymphoma. The respiratory and upper digestive tract signs are

TABLE 80-1

Prevalence of Feline Leukemia Virus Infection in Cats with Lymphoma

ANATOMIC FORM	FeLV POSITIVE (%)
Alimentary	30
Mediastinal	90
Multicentric	80
Cutaneous	0

caused by compression from enlarged anterior mediastinal lymph nodes, although malignant pleural effusion can contribute to the severity of the respiratory tract signs. On physical examination the abnormalities are usually confined to the thoracic cavity and consist of decreased bronchovesicular sounds, normal pulmonary sounds displaced to the dorsocaudal thoracic cavity, a dull sound heard on percussion of the ventral thoracic cavity, and a noncompressible anterior mediastinum (in cats). Unilateral or bilateral Horner's syndrome may occur in cats (and occasionally dogs) with mediastinal lymphoma. Some dogs with mediastinal lymphoma have marked head and neck edema caused by compression from enlarged lymph nodes (anterior vena cava syndrome).

Cats and dogs with an alimentary lymphoma usually display gastrointestinal tract signs, such as vomiting, anorexia, diarrhea, and weight loss. Occasionally, signs compatible with an intestinal obstruction or peritonitis (caused by rupture of a lymphomatous mass) occur. Physical examination typically reveals an intraabdominal mass or masses (e.g., enlarged mesenteric or ileocecocolic lymph nodes or intestinal masses) and thickened bowel loops (in patients with diffuse small intestinal lymphoma). Rarely, polypoid lymphomatoid masses can protrude through the anus in dogs with colorectal lymphoma.

The clinical signs and physical examination findings in cats and dogs with extranodal lymphomas are extremely variable and depend on the location of the mass or masses. In general, the clinical signs stem from the compression or displacement of normal parenchymal cells in the affected organ (e.g., azotemia in renal lymphoma, variable neurologic signs in central nervous system [CNS] lymphoma). The typical clinical signs and physical examination findings in cats and dogs with extranodal lymphomas are summarized in Table 80-2. Common extranodal forms in dogs include cutaneous and ocular lymphomas; in cats they include nasopharyngeal, ocular, renal, and neural lymphomas.

Cutaneous lymphoma is one of the most common extranodal forms of lymphoma in dogs; it is the most common extranodal lymphoma in dogs at our clinic, but it is rare in cats. The clinical signs and characteristics of the lesions are extremely variable, and they can mimic any primary or

TABLE 80-2

Clinical Signs and Physical Examination Findings in Dogs and Cats with Extranodal Lymphomas

ORGAN INVOLVED	CLINICAL PRESENTATION	PHYSICAL FINDING(S)
CNS	Solitary or multifocal CNS signs	Any neurologic finding

PIG 80-1
Diffuse desquamative dermatopathy in a 13-year-old female spayed dog with mycosis fungoides (a specific type of epidermotropic cutaneous T-cell lymphoma). Clinical signs and lesions were present for almost 2 years.

FIG 80-2 Typical doughnut-shaped lesion in a Rottweiler with cutaneous T-cell lymphoma.

secondary skin lesion. Dogs with mycosis fungoides (an epidermotropic T-cell lymphoma) are usually first evaluated because of chronic alopecia, desquamation, pruritus, and erythema, eventually leading to plaque and tumor formation (Fig. 80-1). Mucocutaneous and mucosal lesions are relatively common, but generalized lymph node involvement may not be seen initially. A characteristic lesion in dogs with this form of lymphoma is a circular, raised, erythematous, donut-shaped, dermoepidermal mass that contains normal skin in the center (Fig. 80-2). Most of the cats with cutaneous lymphoma reported in the literature have been negative for FeLV viremia.

Ocular lymphoma occurs in both dogs and cats. Ocular involvement in dogs is commonly associated with the multicentric form, whereas both primary ocular involvement and ocular involvement associated with the multicentric form are common in cats. A variety of signs and lesions may be present in these animals, including photophobia, blepharospasm, epiphora, hyphema, hypopyon, ocular masses, third eyelid infiltration, anterior uveitis, chorioretinal involvement, and retinal detachment.

Nasopharyngeal lymphoma is relatively common in cats but is extremely rare in dogs. Clinical signs are similar to those seen in cats with any upper respiratory tract disorder and include sneezing, unilateral or bilateral nasal discharge (ranging from mucopurulent to frankly hemorrhagic), stertorous breathing, exophthalmos, and facial deformity; this is one of the most common forms of presentation of extranodal lymphoma seen in cats at our clinic.

Renal lymphoma is relatively common in cats but rare in dogs. Cats with this anatomic form are first evaluated because of vague clinical signs, usually secondary to chronic renal failure. On physical examination the cat is emaciated and usually anemic and has large, irregular, and firm kidneys; both kidneys are commonly affected. There is a purported association between renal and CNS lymphoma in cats, so some oncologists recommend using antineoplastic drugs that achieve high CNS concentrations (i.e., cytosine arabinoside, lomustine) in the treatment of cats with renal involvement in an attempt to prevent secondary CNS dissemination. This association has not been recognized at our clinic.

Cats and dogs with neural lymphoma are evaluated because of a variety of neurologic signs that reflect the location and extent of the neoplasms. Although CNS signs are most common, peripheral nerve involvement may occur occasionally in cats. Three forms of presentation are clinically recognized: solitary epidural lymphoma, neuropil (intracranial or intraspinal) lymphoma (also called true CNS lymphoma), and peripheral nerve lymphoma. The solitary epidural lymphoma is common in young FeLV-positive cats. Neural lymphomas can be primary (e.g., epidural lymphoma), or they may be secondary to the multicentric form; as discussed earlier, secondary CNS lymphoma may ocur in cats with the renal form. A relatively common presentation is that of a CNS relapse in dogs that have been receiving chemotherapy for multicentric lymphoma for months to years; these patients develop acute onset of neurologic signs, typically while the multicentric neoplasm is still in remission. This late CNS relapse is likely related to the fact that most drugs used to treat lymphoma do not cross the bloodbrain barrier when used at standard doses; thus the CNS becomes a sanctuary for tumor cells.

A variety of differential diagnoses should be considered in a cat or dog with suspected lymphoma. The clinician should always bear in mind that lymphomas are great imitators; they can mimic numerous different neoplastic and nonneoplastic disorders. The differential diagnoses in cats and dogs with lymphoma are similar to those in patients with leukemia (see Chapter 81).

Occasionally, dogs with lymphoma are evaluated because of clinical signs secondary to a paraneoplastic syndrome (i.e., molecularly mediated distant effects of the neoplasm). Paraneoplastic syndromes that have been encountered in dogs with lymphoma include hypercalcemia, monoclonal and polyclonal gammopathies, immune cytopenias, polyneuropathy, and hypoglycemia. Only hypercalcemia and gammopathies have been documented in cats with this neoplasm, although they are considerably less frequent than in dogs. Of all these syndromes, only humoral hypercalcemia of malignancy in dogs is of clinical relevance.

Hematologic and serum biochemical features. A variety of nonspecific hematologic and serum biochemical abnormalities can be detected in cats and dogs with lymphoma. The hematologic abnormalities result from the infiltration of bone marrow with neoplastic cells, splenic hypofunction or hyperfunction (caused by neoplastic infiltrates), chronic disease, or paraneoplastic immune-mediated abnormalities (i.e., immune hemolytic anemia or thrombocytopenia, both of which are extremely rare). Certain hematologicabnormalities (i.e., monocytosis, leukemoid reactions) may result from the local or systemic production of bioactive substances by the tumor cells (e.g., hematopoietic growth factors, interleukins). The serum biochemical abnormalities result either from the production of bioactive substances by the tumor cells (i.e., paraneoplasia) or from organ failure secondary to neoplastic infiltration. In general, the complete blood count (CBC) and biochemical profile are not diagnostic in cats and dogs with lymphoma.

Common hematologic abnormalities include nonregenerative anemia, leukocytosis, neutrophilia (with or without a left shift), monocytosis, abnormal lymphoid cells in peripheral blood (i.e., lymphosarcoma cell leukemia), thrombocytopenia, isolated or combined cytopenias, and leukoerythroblastic reactions, among others. Lymphocytosis is rare in dogs and cats with lymphoma; when present, it is usually of low magnitude (i.e., <10,000 to 12,000/µl).

Serum biochemical abnormalities are more common in dogs than in cats with lymphoma and consist mainly of hypercalcemia and gammopathies. Hypercalcemia is one of the most common paraneoplastic abnormalities in dogs with lymphoma, occurring in approximately 20% to 40% of the patients; it is extremely rare in cats, and it is more prevalent in dogs with mediastinal lymphoma than in those with the multicentric, alimentary, or extranodal forms. In most dogs with lymphoma and hypercalcemia, the tumor is of T-cell origin.

There are numerous molecular mechanism underlying hypercalcemia in dogs with lymphoma, but in most cases hypercalcemia is thought to occur as a result of the production of a parathormone-like protein, called PTHrp (PTHrelated protein), by the neoplastic cells. Markedly increased serum concentrations of 1,25-vitamin D have been documented in human patients with lymphoma and hypercalcemia. We have recently recognized a similar condition in dogs with lymphoma and hypercalcemia (most of the dogs were Boxers with mediastinal T-cell lymphoma).

Hyperproteinemia is another paraneoplastic abnormality that rarely occurs in cats and dogs with lymphoma. It may be secondary to the production of a monoclonal protein by the lymphoma cells and can result in the development of hyperviscosity syndromes. Polyclonal gammopathies may also be present in cats and dogs with lymphoma.

Imaging. Radiographic abnormalities in cats and dogs with lymphoma vary with the different anatomic forms but in general are secondary to lymphadenopathy or organomegaly (i.e., hepatomegaly, splenomegaly, renomegaly); occasionally, the infiltration of other organs (e.g., lungs) may

lead to the appearance of additional radiographic abnor-

Radiographic changes in cats and dogs with multicentric lymphoma include sternal or tracheobronchial lymphadenopathy or both; interstitial, bronchoalveolar, or mixed pulmonary infiltrates; pleural effusion (rare); intraabdominal lymphadenopathy (e.g., mesenteric or iliac); hepatomegaly; splenomegaly; renomegaly; or intraabdominal masses. Rarely, lytic or proliferative bone lesions are identified on plain abdominal or thoracic radiographs.

In cats and dogs with mediastinal lymphoma, radiographic changes are usually limited to the finding of an anterior (or, more rarely, posterior) mediastinal mass, with or without pleural effusion. In cats and dogs with alimentary lymphoma, abnormalities are rarely detected on plain abdominal radiographs (<50%). When present, they vary in nature but include mainly hepatomegaly, splenomegaly, and midabdominal masses. Positive contrast-enhanced radiography of the upper gastrointestinal tract usually reveals abnormalities in most animals. In a series of dogs with alimentary lymphoma evaluated at our clinic, abnormalities were found in all dogs that underwent positive contrastenhanced radiography of the upper gastrointestinal tract and included mucosal irregularities, luminal filling defects, and irregular thickening of the wall, suggestive of infiltrative mural disease.

Ultrasonography constitutes an invaluable tool for evaluating cats or dogs with suspected or confirmed intraabdominal lymphoma. The technique is also helpful in the evaluation of mediastinal masses in both species (see Chapter 79). Changes in the echogenicity of parenchymal organs (i.e., liver, spleen, kidneys) detected by this technique usually reflect changes in organ texture secondary to neoplastic infiltration. In addition, enlarged lymphoid structures or organs can easily be identified using this technique. Several abnormalities are commonly detected ultrasonographically in cats and dogs with intraabdominal lymphoma; these include hepatomegaly, splenomegaly, changes in the echogenicity of liver or spleen (mixed echogenicity or multiple hypoechoic areas), intestinal thickening, lymphadenopathy (Fig. 80-3), splenic masses, and effusion. In a study of 11 cats with alimentary lymphoma evaluated ultrasonographically at our clinic, we found hypoechoic masses of the gastric or intestinal wall, focal or diffuse gastric wall thickening, a symmetrical thickening of the intestinal wall, loss of the normal layered appearance of the gastrointestinal wall, and abdominal lymphadenopathy (Grooters et al., 1994). Fine-needle aspiration (FNA) and needle biopsy can also be easily performed using this technique to guide the placement of the needle.

# **Diagnosis**

The clinical signs and physical examination findings described in preceding paragraphs are usually suggestive of lymphoma. However, before instituting therapy, the clinician must confirm the diagnosis cytologically, histopathologically, or molecularly. In addition, a minimum database con-

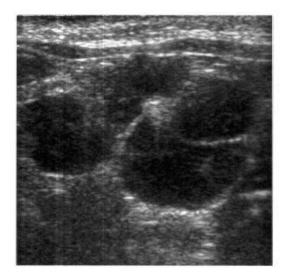

FIG 80-3 Mesenteric lymphadenopathy in a 12-year-old cat with diarrhea associated with an intestinal small cell lymphoma. Note the marked enlargement of the affected lymph node  $(3 \times 5 \text{ cm})$ .

sisting of a CBC, serum biochemistry profile, and urinalysis should be obtained if the owners are contemplating treatment.

In most cats and dogs with multicentric, superficial extranodal, mediastinal, or alimentary lymphoma, a diagnosis can easily be obtained by FNA cytologic studies of the affected organs or lymph nodes. The techniques for FNA and the cytologic features of lymphoma are described in detail in Chapter 75.

In our practice lymphomas can be diagnosed cytologically in approximately 90% of dogs and 70% to 75% of cats evaluated (i.e., usually in only 10% of the dogs and 25% to 30% of the cats is it necessary to perform a histopathologic, flow cytoemetric, or molecular evaluation of a lymph node or mass to establish a diagnosis). Until there is conclusive evidence that the histopathologic classification of canine and feline lymphomas offers prognostic information, the surgical removal of a lymph node or extranodal mass for histopathologic evaluation in an animal with a cytologic diagnosis of lymphoma is not necessarily indicated. A diagnosis based on cytologic findings rather than histopathologic findings yielded by an excisional lymph node biopsy also offers two major benefits: (1) It is associated with minimal or no morbidity, and (2) it is financially acceptable to most owners (i.e., approximate cost of a lymph node aspirate is \$70 to \$100; the cost for biopsy and histopathologic evaluation is \$300 to \$400).

New diagnostic methodologies commonly used in patients with lymphoma in our clinic include immunophenotyping by flow cytometry and clonal analysis by polymerase chain reaction (PCR). In the former, a sample of the affected organ/tissue is obtained by FNA and placed in an appropriate transport media. In the laboratory these cells are incubated with specific antibodies that recognize epitopes specific

# **TABLE 80-3**

TNM Staging System for Dogs and Cats with Lymphoma

CLINICAL FEATURES		
Solitary lymph node involvement		
More than one lymph node enlarged but on one side of the diaphragm (i.e., cranial or caudal)		
Generalized lymph node involvement		
Stage III findings, plus hepatomegaly and/or splenomegaly		
Any of the above, plus bone marrow or extranodal involvement substage a: asymptomatic substage b: sick		

TNM, Tumor, node, metastasis.

for T- or B-cells. Flow cytometric evaluation of the sample allows to immunophenotype the cell population. Clonal analysis by PCR also requires an FNA or a small biopsy specimen. Specific laboratories will evaluate the population of cells in question by PCR to determine if they are B- or T-cell in origin and if they are monoclonal or poyclonal. This technique has high sensitivity and specificity for distinguishing reactive lymphadenopathy from lymphoma (Lana et al., 2006).

After a diagnosis of lymphoma is confirmed, it is customary to stage the disease to obtain a prognosis. A staging system devised by the World Health Organization has been used for the past two decades for the staging of cats and dogs with lymphoma (Table 80-3). In this system, derived from the TNM (tumor, node, metastasis) staging system for neoplasms in humans, clinical and clinicopathologic information from the patient is used in an attempt to determine the extent of disease and correlate it with the prognosis. Unfortunately, it cannot be used prognostically (i.e., animals with stage I disease have survival times similar to those of animals with stage IV disease). The only prognostic information of clinical relevance in this system is the fact that asymptomatic (i.e., substage a) dogs with lymphoma have better prognosis than "sick" (i.e., substage b) dogs. A staging system that takes into account tumor bulk and FeLV status in cats with lymphoma provides some prognostic information when cats are treated with a specific chemotherapy protocol (Mooney et al., 1989). Until a new system is devised, it is advisable to determine the prognosis on the basis of the patient's overall clinical condition, the FeLV status (in cats), and any constitutional signs or severe hematologic and biochemical abnormalities the patient may have. Another important issue is that even though a specific staging protocol may be of some prognostic value in patients treated with a given chemotherapy protocol, it may not be so when a different drug combination is used. Moreover, at this time the effectiveness of more aggressive protocols in dogs and cats with advancedstage lymphoma is unknown.

At least a CBC, a serum biochemistry profile, and a urinalysis should be performed in all cats and dogs with lymphoma whose owners are contemplating therapy. In addition, FeLV and FIV tests should be performed in cats. The resulting minimum database can provide a wealth of information that can help the owner (and the clinician) decide whether to treat the patient. In addition, once a decision to treat the pet has been made, the nature of any clinicopathologic abnormalities usually dictates the treatment or treatments used. For example, in a dog with pronounced cytopenias caused by lymphomatous infiltration of the bone marrow, a highly myelosuppressive chemotherapy combination almost certainly will result in severe neutropenia and sepsis; it should therefore be avoided.

In cats and dogs with suspected CNS lymphoma, it is advisable to perform cerebrospinal fluid (CSF) analysis and advanced imaging (i.e., computed tomography [CT] scan or magnetic resonance imaging [MRI]). The finding of high numbers of neoplastic lymphoid cells and an increased protein concentration in a CSF sample is diagnostic for lymphoma. Because of their poor accessibility, the diagnosis of extradural masses usually requires the collection of a surgical specimen for cytologic or histopathologic evaluation.

As previously discussed, immunophenotyping of canine and feline lymphoma has become routine for most oncologists. This can be done by immunocytochemistry, immunohistochemistry, flow cytometry, or PCR for clonality. Published reports suggest that dogs with T-cell lymphoma treated with standard combination chemotherapy have a worse prognosis for remission and survival than dogs with B-cell tumors; however, in our experience, this is not the case. In a recent study we demonstrated that T-cell phenotype was not a negative prognostic factor in dogs with lymphoma treated with COP- or CHOP-based protocols (Hosoya et al., 2007). This is likely because most dogs with T-cell lymphoma received lomustine (CCNU), a drug that in our experience is effective in patients with T-cell phenotype.

#### Treatment

Once a diagnosis of lymphoma is established, the prognosis and potential therapeutic options should be discussed with the pet's owner. Remission rates in cats and dogs with lymphoma treated with various chemotherapy protocols are approximately 65% to 75% and 80% to 90%, respectively. Most cats with lymphoma treated with multiple-agent chemotherapy protocols are expected to live 6 to 9 months; approximately 20% of the cats live more than 1 year. Most dogs with lymphoma treated in a similar fashion are expected to live 12 to 16 months; approximately 20% to 30% of the dogs are alive 2 years after diagnosis. The approximate survival time in untreated cats and dogs with lymphoma is 4 to 8 weeks. Probably the most important reason for the shorter survival times in cats than in dogs with lymphoma is that remissions appear to be difficult to reinduce once the tumor has relapsed. In addition, the retrovirus-associated nonlymphomatous disorders that affect cats with lymphoma lead to shortened survival times (i.e., FeLV infection is a negative prognostic factor in cats with lymphoma).

In my experience, even if an animal has stage I nodal or extranodal lymphoma at the time of presentation, systemic dissemination of the disease usually occurs within weeks to months of diagnosis. However, occasionally solitary oral or cutaneous lymphomas may behave as true stage I diseases (i.e., there is no systemic dissemination). Therefore the mainstay of treatment for animals with lymphoma is chemotherapy, given the fact that lymphomas are (or will become) systemic neoplasms. Surgery, radiotherapy, or both can be used to treat localized lymphomas before or during chemotherapy. Half-body irradiation or chemotherapy and bone marrow transplantation have also been recently used to treat dogs with lymphoma (see Suggested Readings). General guidelines for the management of patients with lymphoma are presented here. The protocols recommended in this chapter have been used at our clinic with a success rate comparable to those of other treatments published in the literature.

There are two main chemotherapeutic approaches in dogs and cats with lymphoma: induction chemotherapy, followed by maintenance (and reinduction) or more aggressive chemotherapy for a finite period of time, at the end of which no maintenance chemotherapy is used. The former is usually done with a less aggressive COP (cyclophosphamide, vincristine, and prednisone)-based protocol, whereas the latter is usually based on CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone)-type protocols. An example of the latter is one of several University of Wisconsin (UW) protocols. CHOP-based protocols are similar to those used in people with high-grade lymphomas.

# **COP-Based Protocols**

When using COP-based protocols, the treatment of cats and dogs with lymphoma is divided into several phases, or strategies: induction of remission, intensification, maintenance, and reinduction of remission or "rescue" (Box 80-1). Immediately after diagnosis, a relatively nonaggressive multipleagent COP-based chemotherapy protocol is used to induce remission; in our clinic we frequently use the COAP protocol, with the addition of cytosine arabinoside to the COP protocol. During this phase, which lasts 6 to 8 weeks, patients are evaluated weekly by a veterinarian, at which time they receive an intravenous (IV) injection of an antimitotic agent (vincristine) in addition to undergoing a routine physical examination (with or without a CBC). If at the end of this phase the patient is considered to be in complete remission (CR; i.e., all neoplastic masses have completely disappeared), the maintenance phase is initiated. During this phase, a multipleagent chemotherapy protocol consisting of three drugs (chlorambucil [Leukeran], methotrexate, prednisone [LMP]) administered orally is used, so that the patient requires less intensive monitoring (once every 6 to 8 weeks). In my experience, maintenance chemotherapy is necessary when using COP-based protocols. Over the past few years, we have instructed the owners of pets with multicentric lymphoma

Chemotherapy Protocols Used to Treat Dogs and Cats\* with Lymphoma at the Ohio State University Veterinary Teaching Hospital

#### 1. Induction of Remission

#### a. COAP protocol†

Cyclophosphamide: 50 mg/m<sup>2</sup> PO q48h in dogs or 200-300 mg/m<sup>2</sup> PO q3 weeks in cats

Vincristine: 0.5 mg/m<sup>2</sup> IV weekly

Cytosine arabinoside: 100 mg/m² daily as an IV drip or SC for only 2 days in cats and 4 days in dogs

Prednisone: 50 mg/m<sup>2</sup> PO q24h for 1 week, then 20 mg/m<sup>2</sup> PO q48h

# b. COP protocol

Cyclophosphamide (Cytoxan®): 50 mg/m² BSA, PO, q48h; or 300 mg/m² BSA, PO, every 3 weeks (dogs or cats) Vincristine (Oncovin®): 0.5 mg/m² BSA, IV, once a week Prednisone: 40-50 mg/m² BSA, PO, q24h for a week; then 20-25 mg/m<sup>2</sup> BSA, PO, every other day.

#### c. UW-19 protocol (This protocol uses no maintenance chemotherapy-for additional information see text)

Week 1: Vincristine 0.5-0.75 mg/m<sup>2</sup>, IV Asparaginase 400 IU/KG IM or SC Prednisone 2 mg/kg PO q24h

Cyclophosphamide 200-250 mg/m², IV Prednisone 1.5 mg/kg PO q24h Week 2:

Week 3: Vincristine 0.5-0.75 mg/m<sup>2</sup>, IV Prednisone 1 mg/kg PO q24h

Doxorubicin 30 mg/m² (or 1 mg/kg if <10 kg) IV Week 4: Prednisone 0.5 mg/kg PO q24h

Week 5: No treatment

Week 6: Vincristine 0.5-0.75 mg/m<sup>2</sup>, IV

Week 7: Cyclophosphamide 200-250 mg/m<sup>2</sup>, IV

Vincristine 0.5-0.75 mg/m<sup>2</sup>, IV Week 8:

Week 9: Doxorubicin 30 mg/m² (or 1 mg/kg if <10 kg) IV

Week 10: No treatment

Week 11: Vincristine 0.5-0.75 mg/m², IV Week 12: Cyclophosphamide 200-250 mg/m², IV

Week 13: Vincristine 0.5-0.75 mg/m<sup>2</sup>, IV

Week 14: Doxorubicin 30 mg/m² (or 1 mg/kg if <10 kg) IV

Week 15: No treatment

Week 16: Vincristine 0.5-0.75 mg/m<sup>2</sup>, IV

Week 17: Cyclophosphamide 200-250 mg/m², IV Week 18: Vincristine 0.5-0.75 mg/m², IV

Week 19: Doxorubicin 30 mg/m<sup>2</sup> (or 1 mg/kg if <10 kg) IV

# 2. Intensification

# Dogs

L-Asparaginase (Elspar): 10,000-20,000 IU/m<sup>2</sup> IM (one or two doses

Vincristine (Oncovin): 0.5-0.75 mg/m<sup>2</sup> IV q1-2 weeks

#### Cats

Doxorubicin (Adriamycin): 1 mg/kg IV q3 weeks

Mitoxantrone (Novantrone): 4-6 mg/m<sup>2</sup> IV q3 weeks

# 3. Maintenance1

a. LMP protocol

Chlorambucil:  $20 \text{ mg/m}^2 \text{ PO q2}$  weeks Methotrexate:  $2.5 \text{ mg/m}^2 \text{ PO two}$  or three times per week

Prednisone: 20 mg/m<sup>2</sup> PO q48h

#### b. COAP protocol

Use as above every other week for six treatments, then every third week for six additional treatments, then try to maintain the animal on one treatment every fourth week. Maintenance therapy is continued until the tumor relapses.

#### 4. Rescue

#### Dogs

a. D-MAC protocol (14-day cycle)

Dexamethasone: 0.5 mg/lb (0.23 mg/kg) PO or SC on days 1 and 8

Actinomycin D: 0.75 mg/m² as IV push on day 1

Cytosine arabinoside: 200-300 mg/m² as IV drip over 4 hours or SC on day 1

Melphalan: 20 mg/m² PO on day 8§

b. AC protocol (21-day cycle)

Doxorubicin (Adriamycin): 30 mg/m² (or 1 mg/kg for dogs under 10 kg) IV on day 1

Cyclophosphamide (Cytoxan): 100-150 mg/m<sup>2</sup> PO on days 15 and 16

c. CHOP protocol (21-day cycle)

Cyclophosphamide (Cytoxan): 200-300 mg/m² PO on day 10 Doxorubicin (Adriamycin): 30 mg/m² (or 1 mg/kg for dogs under 10 kg) IV on day 1

Vincristine (Oncovin): 0.75 mg/m² IV on days 8 and 15 Prednisone: 20-25 mg/m<sup>2</sup> PO q48h

#### Cats

a. AC protocol (21-day cycle)

Doxorubicin (Adriamycin): 1 mg/kg IV on day 1

Cyclophosphamide (Cytoxan): 200-300 mg/m² PO on day 10 or 11

Dexamethasone (4 mg/cat q1-2 weeks can be added to this protocol)

b. MiC protocol (21-day cycle)

Mitoxantrone (Novantrone): 4-6 mg/m² as IV drip over 4-6 hours on day 1

Cyclophosphamide (Cytoxan): 200-300 mg/m² PO on day 10 or 11

Dexamethasone (4 mg/cat q1-2 weeks can be added to this protocol)

c. MiCA protocol (21-day cycle)

Mitoxantrone (Novantrone): 4-6 mg/m<sup>2</sup> in IV drip over 4-6 hours on day 1

Cyclophosphamide (Cytoxan): 200-300 mg/m<sup>2</sup> PO on day 10 or 11

Cytosine arabinoside (Cytosar-U): 200 mg/m<sup>2</sup> in IV drip over 4-6 hours (mixed in the same bag with mitoxantrone) on day 1

Dexamethasone (4 mg/cat a 1-2 wks can be added to this protocol)

#### 5. "Low-Budget" Protocols

Prednisone: 50 mg/m<sup>2</sup> PO q24h for 1 week; then 25 mg/m<sup>2</sup> PO q48h

Chlorambucil: 20 mg/m² PO q2 weeks

Lomustine (CCNU; Ceenu): 60 mg/m<sup>2</sup> PO q3 weeks in dogs; 10 mg (total dose) q3 weeks in cats

Prednisone and chlorambucil: doses as above Prednisone and lomustine: doses as above

PO, By mouth; IV, intravenous; SC, subcutaneous; BSA, body surface area; IM, intramuscular.

\* Unless otherwise specified, protocols can be used in both dogs and cats.

† Use for 6-10 weeks, then use LMP.

‡Use until relapse occurs, then go to "rescue." § After four doses, substitute Leukeran (20 mg/m² PO q2 weeks) for Alkeran.

The duration of chemotherapy using this protocol is variable.

to closely monitor the size of the lymph nodes in their pets; when the nodes start enlarging (i.e., relapse), we add a fourth drug to the LMP protocol (usually vincristine, at a dosage of 0.5-0.75 mg/m<sup>2</sup>, IV, q1-2 weeks). This usually suffices to reinduce remission and maintain it for several weeks or months.

The maintenance or modified maintenance phase continues until the tumor relapses (i.e., is out of remission), at which time the reinduction phase begins. This phase is similar to the induction phase in that intensive treatments are used. Once remission is obtained, the patient is started again on a modified maintenance protocol. If at the end of the induction phase the patient is not in CR, we recommend that intensification with L-asparaginase be done before the maintenance phase is initiated. In addition to the chemotherapeutic approach discussed in this section, a variety of protocols have been used successfully in the treatment of cats and dogs with lymphoma. (See Suggested Readings for additional information.)

Induction of remission. As previously discussed, my protocol of choice for the induction of remission is COAP. The agents in this protocol consist of cyclophosphamide, vincristine, cytosine arabinoside, and prednisone; these four drugs are currently available as generic products. The dosages are specified in Box 80-1. These drugs belong to four different categories, have different mechanisms of action, and do not have superimposed toxicities (with the exception of cyclophosphamide and cytosine arabinoside, both of which are myelosuppressive; however, the latter is used only for a short period); thus they fulfill the basic criteria of multipleagent chemotherapy described in Chapter 77. The cytosine arabinoside is usually administered by the subcutaneous (SC) route because, given its short half-life and S-phasespecific mechanism of action, an IV bolus injection results in minimal cell kill; SC administration of this drug is painful in cats (and in some dogs). IV infusion of the agent is also associated with myelosuppression. The induction phase lasts 6 to 8 weeks, and weekly visits to the veterinarian are necessary during this time.

During the induction phase toxicity is minimal (<15%) and client compliance is high because most of the toxic signs are hematologic (i.e., cytopenias) and usually do not result in clinical signs that can be detected by the owners. The dose-limiting toxicity of this induction protocol is hematologic (i.e., myelosuppression leading to neutropenia); the neutrophil nadir usually occurs around day 7 or 8 because two myelosuppressive agents (i.e., cyclophosphamide and cytosine arabinoside) are given during the initial 2 to 4 days of treatment. In most cases the neutropenia is mild (2000 to 3500 cells/μl). The neutropenia is severe if the animals have neoplastic bone marrow infiltration before the initiation of treatment, have FeLV- or FIV-associated myelodysplasia or other retrovirus-associated bone marrow disorders, or receive the cytosine arabinoside by constant-rate IV infusion rather than by the SC route. Also, anecdotally, neutropenia appears to be common in Cocker Spaniels receiving this protocol. Dosage adjustments in cats and dogs that develop neutropenia are described in Chapter 78. Gastrointestinal toxicity is minimal to nonexistent; however, cats receiving cyclophosphamide occasionally become anorectic. Consequently, this drug should be administered once every 3 weeks in cats (as opposed to every other day in dogs; see Box 80-1). If anorexia develops, treatment with cyproheptadine (Periactin; Merck Sharp & Dohme, West Point, Pa.), an antiserotonin compound, at a dosage of 1 to 2 mg per cat PO q8-12 hours is indicated. Hair loss is also minimal, and it occurs primarily in woolly-haired dogs (e.g., Poodle, Bichon Frise); cats (and some dogs) may shed their tactile hairs during treatment.

During this phase, owners are instructed to monitor their pet's appetite and activity level, measure their lymph nodes (if superficial lymphadenopathy was present initially), and take their pet's rectal temperature daily (pyrexia is usually secondary to neutropenia and bacteremia or sepsis). If pyrexia develops, owners are instructed to contact their veterinarian immediately so that their pet can undergo a complete physical examination and CBC (for additional information, see Chapter 78). Treatment with COAP results in CR within 1 to 14 days of the start of therapy in most animals (>85% in dogs, >70% in cats). This remission is usually maintained throughout the induction phase.

In dogs with diffuse alimentary lymphoma we use a more aggressive doxorubicin-containing protocol (CHOP; see Box 80-1) because, in my experience, the response rate to COAP is low. This protocol is more expensive and more likely to cause adverse effects than the COAP protocol. We typically use lomustine (CCNU) in dogs with epidermotropic T-cell lymphoma (see Box 80-1).

In dogs and cats with multicentric (or any other anatomic form of) lymphoma coexisting with neurologic signs, we usually use the COAP protocol but administer the cytosine arabinoside as a continuous IV infusion (200-400 mg/m<sup>2</sup> as an IV infusion over 24 hours for 1 to 4 days) in order to attain high concentrations of this drug in the CNS. This protocol tends to cause marked myelosuppression in cats, so we typically administer cytosine arabinoside as a 12- to 24-hour infusion (200 mg/m<sup>2</sup>) in this species. More information on the treatment of dogs and cats with suspected or confirmed CNS lymphoma is given later in this chapter.

Maintenance. The protocol recommended for the maintenance phase of treatment is LMP ("lump"), which consists of chlorambucil, methotrexate, and prednisone (see Box 80-1). These three drugs also act by three different mechanisms of action and have different toxicities. The advantages of this protocol include its reduced cost compared with the cost of the induction phase; its ease of administration (all the drugs are administered orally by the owners); its minimal toxicity; and the fact that intensive monitoring by a veterinarian is not necessary.

The toxicities associated with LMP maintenance chemotherapy are minimal. Of the three drugs in this protocol, methotrexate is the only one that is associated with moderate to severe toxicity. In approximately 25% of dogs and cats receiving methotrexate, gastrointestinal tract signs consisting of anorexia, vomiting, or diarrhea develop. Anorexia and vomiting are more common than diarrhea and usually occur after the patient has been receiving the drug for more than 2 weeks. In these cases treatment with an antiemetic, such as metoclopramide, on the days the animal receives the methotrexate, at a dosage of 0.1 to 0.3 mg/kg PO every 8 hours, alleviates or eliminates the upper gastrointestinal tract signs. We have recently used maropitant (Cerenia, Pfizer Animal Health, Kalamazoo, Mich.) at a dosage of 2 mg/kg PO every 24 hours to prevent chemotherapy-associated nausea and vomiting. Gastroprotectants, such as famotidine (0.5 mg/kg PO q24h) may also be effective in preventing or minimizing this adverse effect. In cases of methotrexate-associated diarrhea, treatment with a bismuth subsalicylate-containing product (Pepto-Bismol) may also alleviate or eliminate the signs; however, it may be necessary to discontinue the drug. Hematologic toxicity associated with LMP therapy is minimal to nonexistent. In a very small proportion of cats (i.e., <5%) receiving chlorambucil for weeks to months, serum biochemical abnormalities consistent with cholestasis that resolve on discontinuation of the drug may develop. Recently, tonic or tonic-clonic convulsions have been decribed in cats receiving chlorambucil.

During this phase the patient is examined every 6 to 8 weeks, at which time a complete physical examination and a CBC are performed. As with the induction protocols, owners are instructed to monitor their pet's activity, appetite, behavior, rectal temperature, and lymph node size. As previously discussed, over the past few years we have been instructing the owners of pets with multicentric lymphoma to closely monitor the size of the lymph nodes in their pets; when the nodes start enlarging (i.e., relapse), a fourth drug is added to the LMP protocol (usually vincristine, at a dosage of 0.5-0.75 mg/m², IV, q1-2 weeks). This usually suffices to reinduce remission and maintain it for several weeks or months.

Most animals treated with this protocol remain in remission for approximately 3 to 6 months. If a relapse occurs, reinduction of remission (as discussed next) is instituted. After remission is reinduced, animals can be treated with a modified maintenance protocol, as described in previous paragraphs.

Reinduction of remission or rescue. Virtually every dog and cat with lymphoma treated with induction followed by maintenance chemotherapy eventually relapses; this generally occurs 3 to 6 months after the start of induction therapy (median: approximately 4 months), but it can occur within weeks of starting the maintenance phase or years after the original diagnosis was made. At this time, reinduction of remission is indicated. In my experience, remission can be reinduced one to four additional times in most dogs with relapsing lymphoma. Reinduction of remission is usually not as successful in cats as in dogs (i.e., remission cannot be reinduced in most cats with relapsing lymphoma). Therefore the following discussion on "rescue" pertains mostly to dogs with lymphoma.

There are numerous "rescue" protocols described in the literature, and as a general rule, the practitioner may have difficulty deciding what protocol to choose. We currently use

the D-MAC protocol (see Box 80-1), which consists of dexamethasone, melphalan (Alkeran; Burroughs Wellcome, Research Triangle Park, N.C.), cytosine arabinoside (Cytosar-U), and actinomycin D (Cosmegen; Merck Sharp & Dohme, West Point, Pa.) as our trump card for rescue (Alvarez et al., 2006). This protocol results in an over 70% remission rate in dogs with relapsing lymphoma; it has a relatively low toxicity compared with that of doxorubicin-containing protocols, and it is necessary for the owner to go the veterinarian only once every 2 weeks (instead of every week). The median duration of remission using the D-MAC protocol was 61 days (range 2 to 467+ days). Previous use of doxorubicin and failure to induce remission with the induction protocol were negative prognostic factors for response to this protocol. Thrombocytopenia occurred in 56% of the dogs, neutropenia in 17%, and gastrointestinal toxicity in 22%; three of the 56 dogs required hospitalization because of toxicity. Because the long-term use of melphalan is associated with severe chronic thrombocytopenia, chlorambucil (Leukeran), 20 mg/m<sup>2</sup>, is substituted for melphalan after four cycles. If complete or partial remissions are achieved after the administration of four to six cycles of D-MAC, the patient can be started on a maintenance protocol again.

If the response to D-MAC is poor (i.e., the disease progresses), the CHOP protocol is recommended (see Box 80-1). Our protocol calls for two or three cycles of CHOP once the tumor has relapsed; if CR is obtained, the patient is started on maintenance chemotherapy at the end of the second or third CHOP cycle. The maintenance protocol in these animals also includes LMP, with the possible addition of vincristine (0.5 to 0.75 mg/m² IV once weekly to every other week, alternating weeks with the chlorambucil) or cytosine arabinoside (200 to 400 mg/m² subcutaneously every other week, alternating weeks with the chlorambucil).

After a second relapse occurs, D-MAC or CHOP is administered for two additional cycles, as described in the preceding paragraph. In our experience, after the second and third relapses, the percentage of animals in which remission can be easily reinduced decreases with each subsequent cycle. This likely stems from the development of multiple-drug resistance by the tumor cells. Other protocols that have been successful in reinducing remission in dogs with lymphoma are listed in Box 80-1. Although the probability of reinducing remission is considerably lower in cats than in dogs, one of the protocols listed in Box 80-1 can be used for this purpose.

In cats doxorubicin- or mitoxantrone-containing protocols have been used with some degree of success (see Box 80-1); asparaginase-containing protocols may also be used but generally are not as effective as in dogs.

Intensification. If a dog is undergoing induction therapy but only partial remission (PR) is obtained, intensification with one or two doses of L-asparaginase (Elspar; 10,000 to 20,000 IU/m² IM, repeated once at a 2- to 3-week interval) may be indicated. This drug can rapidly induce CR in most dogs with lymphoma that have shown only PR while receiving COP-based protocols. Asparaginase should not be used

in dogs with a history of pancreatitis or in those that are at high risk for acute pancreatitis (i.e., obese, middle-age female dogs). In my experience, L-asparaginase appears to be less effective in cats than in dogs; doxorubicin (1 mg/kg IV q3 weeks) or mitoxantrone (4 to 6 mg/m² IV q3 weeks; Novantrone; Lederle, Wayne, N.J.) can be used as intensifying agents in cats. In a recent study only two of thirteen (15%) cats with lymphoma treated with L-asparaginase underwent CR, and two of thirteen (15%) underwent PR; these response rates are quite a bit lower than those reported in dogs (i.e., >70%) (LeBlanc et al., 2007).

#### **CHOP-Based Protocols**

Although I do not personally use CHOP-based protocols, such as the UW-19 or UW-25, to treat dogs with multicentric lymphoma, I occasionally use them in dogs with diffuse small intestinal lymphoma. However, numerous articles on CHOP-based protocols in dogs with lymphoma have appeared in the literature in the last two decades. The most attractive aspect of using CHOP-based protocols is that the patient is under treatment for a finite period of time (i.e., 19 weeks for the UW-19 and 25 weeks for the UW-25); when the protocol ends, the patient is closely monitored but does not receive additional chemotherapy (i.e., no maintenance). This feature is extremely important in humans undergoing chemotherapy, in whom the prevalence of adverse effects is extremely high and the patient is looking forward to a life without chemotherapy. However, people considering chemotherapy for their pets may not share this sentiment. As a general rule, the probability and severity of toxicity with CHOP-based protocols are higher than with COP-based protocols. Box 80-1 lists the UW-19 protocol, commonly used by numerous oncologists.

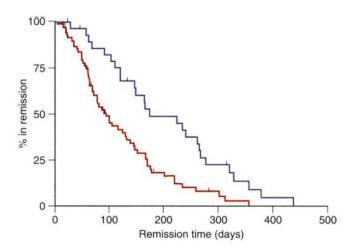

# Should You Use COP-Based or CHOP-Based Protocols?

Clinicians have been debating the relative merits of COPand CHOP-based protocols for several years. However, because most institutions or clinicians prefer one protocol over the other, because most of the reports on COP-based protocols are 10 to 20 years old, and because in most reports of COP- or CHOP-based chemotherapy studies the endpoint has been remission times, rather than survival times, a definitive answer is not readily available.

However, in our clinic we have a similar number of patients treated with COP- and CHOP-based (UW-19) protocols; these patients are cared for by the same group of clinicians and technicians. We recently published the results of a retrospective study of 101 dogs with multicentric lymphoma treated with either COP-based protocols with maintenance chemotherapy (n = 71) or CHOP-based protocol (UW-19, n = 30) in our clinic (Hosoya et al., 2007). The probability of achieving CR or PR was similar for both protocols (92% for dogs treated with COP versus 100% for dogs treated with CHOP). Although the median duration of remission was significantly longer in dogs treated with CHOP than in those treated with COP (174 versus 94 days),

the median survival times (MST) were not statistically different between groups (Figs. 80-4 and 80-5). The MST in dogs receiving COP was 309 days, compared with 275 days in dogs receiving the UW-19 protocol. The MST was similar for dogs with B- or T-cell lymphoma treated with the COP-based protocols (321 versus 378 days, respectively); there were not enough dogs with T-cell phenotype treated with the UW-19 to perform statistical analysis.

The prevalence of severe myelosuppression and adverse gastrointestinal effects was significantly higher in dogs receiving CHOP chemotherapy. The cost of treatment using both protocols was similar. Therefore there is no advantage of one protocol over the other one, and the clinician must

**FIG 80-4** Kaplan Meier curves for duration of first remission in dogs with multicentric lymphoma treated with COAP (red line) or CHOP (blue line). The median duration of remission was significantly longer in dogs treated with CHOP chemotherapy (p < 0.01). (From Hosoya et al., 2008.)

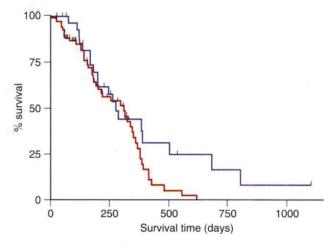

FIG 80-5

make a decision based on a variety of factors (e.g., the owner's perception, the patient's clinical signs and other concurrent illnesses, cost).

Management of solitary and extranodal lymphomas. The clinician faces a dilemma when confronted with a dog or cat with a solitary lymphoma, regardless of whether it is nodal (i.e., stage la disease) or extranodal (i.e., a solitary cutaneous or oral mass). Should the mass (or lymph node) be treated in the same manner as other solitary malignancies (i.e., by wide surgical excision)? Should the patient be treated primarily with chemotherapy? Should the patient be treated with a combination of surgery, irradiation, and chemotherapy? Unfortunately, there are no correct answers to these questions.

In my experience, seemingly solitary lymphomas become (or already are) systemic in most animals. Exceptions include some oral and some cutaneous solitary T-cell lymphomas. Although cures have been achieved through the surgical excision or irradiation of solitary lymphomas, they are extremely rare. Therefore it is important not to underestimate the malignant behavior of this neoplasm by treating the patient only with a local treatment modality, such as surgery or radiotherapy. The following guidelines can be used in this subset of patients:

- 1. If the tumor is easily resectable (e.g., cutaneous mass, superficial lymph node, intraocular mass) and the surgical procedure does not pose a considerable risk to the patient, the mass should be resected and the animal treated with chemotherapy.
- 2. If the mass is difficult or impossible to resect or if a major surgical procedure would pose an undue risk for the animal, an FNA or a needle biopsy specimen of the mass should be obtained and the animal treated with chemotherapy (with or without radiotherapy of the primary lesion).

Radiotherapy constitutes an excellent treatment modality for dogs and cats with solitary lymphomas because lymphoma cells are extremely radiosensitive. Marked responses (CR or PR) are seen within hours or days of the start of such treatment. Different sources and protocols have been used in cats and dogs with lymphoma, but in general 3 to 5 Gy (300 to 500 rad) per fraction is delivered daily or thrice weekly for a total of six to ten fractions (total dose, 30 to 50 Gy [3000 to 5000 rad]). We have successfully used coarse fractionation radiotherapy (7 Gy once a week for 4 treatments) followed by maintenance chemotherapy (discussed later) in dogs with solitary oral T-cell lymphomas. Special settings in which radiotherapy is beneficial include CNS lymphomas (see following paragraphs) and upper airway lymphomas that cause respiratory compromise.

Another decision the clinician must make if chemotherapy is to be used is which protocol to use and for how long. There are also no specific guidelines for this. We use a standard induction chemotherapy protocol (COAP) in most cats and dogs with solitary lymphoma after they have undergone

surgical excision or irradiation. After completion of the induction phase, the animals are treated with a maintenance protocol (LMP) and remission is reinduced as necessary (as in other forms of lymphoma). In our experience, early relapses occur in most animals treated with only maintenance chemotherapy protocols after the surgical excision of solitary lymphomas.

Central nervous system lymphoma. The treatment of choice for cats and dogs with primary or secondary epidural lymphoma is radiotherapy plus multiple-agent chemotherapy. If radiotherapy facilities are not available, multiple-agent chemotherapy is an effective alternative approach. It is my clinical impression that the surgical excision of such masses does not provide a significant advantage over chemotherapy alone or radiotherapy plus chemotherapy, given the fact that the latter two forms of treatment consistently induce rapid remissions (i.e., within 12 to 36 hours of the initiation of therapy). However, because surgery may be necessary to confirm the diagnosis, surgical excision of the mass is usually attempted at that time. If radiotherapy is available, three to five doses weekly of 3 to 4 Gy, to a total of 25 to 30 Gy, are indicated. The COAP protocol alone has been effective in inducing remission in cats with epidural lymphoma.

In cats and dogs with lymphoma of the neuropil (i.e., true CNS lymphoma), chemotherapy with or without radiotherapy is the preferred protocol. In animals in which it is possible to localize the lesion (i.e., by neurologic examination, CT, or MRI), radiotherapy should be used in conjunction with chemotherapy. If this is not possible, diffuse craniospinal irradiation can be performed.

Intrathecal chemotherapy can be used in cats and dogs with confirmed or highly likely neuropil lymphoma. The drug of choice is cytosine arabinoside (Cytosar-U) because it is almost nontoxic, it is inexpensive, and it is easy to administer. However, IV administration of this drug as a constant rate infusion (CRI) at dosages of 200 to 600 mg/m² over 24 to 72 hours achieves similar results and is our preferred approach. Responses to intrathecal or IV CRI cytosine arabinoside are usually quite spectacular. Dogs and cats that are tetraparetic, demented, or comatose usually regain normal neurologic status within 6 to 48 hours of receiving the first dose of this agent. In addition, disappearance of the neoplastic cells from the CSF can be documented within hours of the injection.

We frequently induce clinical and cytologic remission (i.e., normal neurologic status and disappearance of neoplastic cells from CSF) in cats and dogs with primary or secondary CNS lymphoma treated with COAP (using cytosine arabinoside as an IV infusion). As previously discussed, an alternative drug that crosses the blood-brain barrier and is effective in eliminating lymphoma cells is lomustine (CCNU; see Box 80-1) administered at a dosage of 60 mg/m² PO every 3 weeks in dogs and at a dosage of 10 mg/cat every 3 weeks in cats; we have seen marked improvement or disappearance of neurologic signs in dogs and cats with lymphoma treated with this drug.

Despite the fact that remissions are easily attained in dogs and cats with CNS lymphoma, they are relatively short in duration compared with the duration of remissions in dogs and cats with disease in other anatomic locations. Most dogs and cats with CNS lymphoma relapse within 2 to 4 months of diagnosis; however, prolonged remissions (i.e., 6 to 12 months) are possible.

Ocular lymphoma. Ocular lymphoma can be treated using a variety of modalities. However, the eye behaves similarly to the blood-brain barrier in that adequate intraocular concentrations of chemotherapeutic agents are usually difficult to attain. If the clinician and owner want to try to preserve the animal's eye, there are several alternatives to enucleation. As in animals with CNS lymphoma, the administration of cytosine arabinoside as a slow IV drip usually results in remission of the tumor. Lomustine is also effective in dogs and cats with intraocular lymphoma.

Cutaneous lymphoma. Cutaneous lymphoma is the most common extranodal form of lymphoma in dogs seen at the Veterinary Teaching Hospital of The Ohio State University. In dogs with cutaneous involvement secondary to multicentric lymphoma, we use a standard chemotherapy protocol (i.e., COAP). In dogs with epitheliotropic T-cell lymphomas we use either doxorubicin-containing (i.e., CHOP; see Box 80-1) or lomustine (CCNU)-containing protocols. In a recent study of 46 dogs with epidermotropic cutaneous T-cell lymphoma, 15 (33%) underwent CR and 23 (50%) underwent PR, for a response rate of 83% (Risbon et al., 2006). The median number of treatments to achieve a response was 1 (range, 1-6). The overall median duration of response was 94 days (range, 22-282). Sixteen dose reductions were required because of neutropenia (10/46), thrombocytopenia (1/46), anemia (1/46), increased liver enzyme activity (3/46), or unspecified reasons (1/46).

Alimentary lymphoma. We use standard chemotherapy protocols (i.e., COAP) in dogs and cats with solitary mural or nodal (e.g., mesenteric or ileocecocolic lymph node) involvement. Even though surgery is not necessarily indicated for these dogs and cats, a fair number are referred after exploratory surgery and an incisional or excisional biopsy has been performed. In general, the response in these animals is good. Dogs and cats with diffuse intestinal lymphoma usually respond poorly to chemotherapy. Responses to doxorubicin-containing protocols (i.e., CHOP) appear to be better than those to COAP, although survival times are short (4 to 6 months). Dogs with colorectal lymphoma and cats with gastric lymphoma tend to respond extremely well to COAP chemotherapy; we have documented remission times in excess of 3 years in these subsets of patients. In cats this may be related to the fact that Helicobacter spp. may play a role in the development of gastric lymphoma, as H. pilori does in people; we treat all cats with gastric lymphoma with combination chemotherapy and antibiotics proven effective in cats with Helicobacter infection.

In cats with epitheliotropic intestinal lymphoma, a common, small lymphocytic form of the disease in older individuals, we have used a very conservative approach with excellent results. We administer a combination of chlorambucil (20 mg/m<sup>2</sup>, PO q2 weeks) plus prednisone (1-2 mg/kg, PO q24-48h) or dexamethasone (4 mg/cat, PO q1-2 weeks); if clinical signs do not improve within 3 or 4 weeks, we add vincristine (0.5 mg/m<sup>2</sup>, IV, q1-2 weeks). Most cats treated with this protocol have marked improvement of the clinical signs and typically gain weight. Interestingly, some of the cats exhibit no appreciable decrease in mesenteric lymph node size, despite the remarkable clinical improvement. For these cats I use the approach of "treating the patient, not the disease" (i.e., as long as the patient feels well and is free of clinical signs, the current treatment is continued).

# "Low-Budget" Lymphoma Protocols

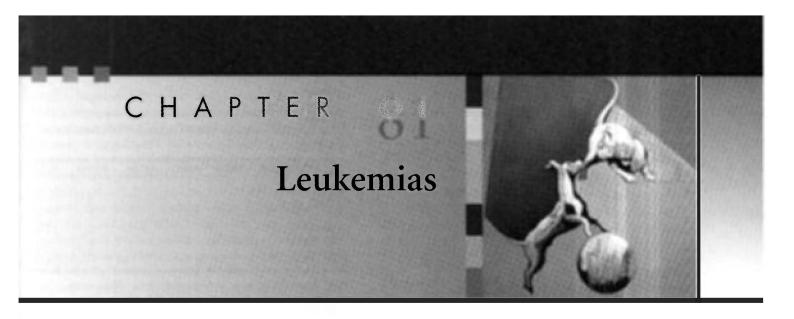

Quite frequently, the clinician is evaluating a dog or cat with lymphoma that should benefit from chemotherapy, but because of finances or other issues (e.g., time commitment) the owners are not interested in the standard multiagent chemotherapy approach. Because most of these patients are asymptomatic, they would benefit from some form of therapy. In our clinic we have used one of the following quite successfully: prednisone alone, prednisone and chlorambucil, chlorambucil alone, lomustine alone, or prednisone and lomustine. Although the duration of remission is shorter than when using COP-based protocols, most of these patients (and their owners) enjoy prolonged (i.e., months), good-quality survival times. These protocols are listed in Box 80-1.

# CHAPTER OUTLINE

DEFINITIONS AND CLASSIFICATION LEUKEMIAS IN DOGS Acute Leukemias

Chronic Leukemias LEUKEMIAS IN CATS

Acute Leukemias Chronic Leukemias

# **DEFINITIONS AND CLASSIFICATION**

Leukemias are malignant neoplasms that originate from hematopoietic precursor cells in the bone marrow. Because these cells are unable to undergo terminal differentiation or apoptosis, they self-replicate as a clone of usually immature (and nonfunctional) cells. The neoplastic cells may or may not appear in peripheral circulation; thus the confusing terms *aleukemic* and *subleukemic* are used to refer to leukemias in which neoplastic cells proliferate within the bone marrow but are absent or scarce in the circulation.

Leukemias can be classified philogenetically into two broad categories according to the cell line they originate from: lymphoid and myeloid (or nonlymphoid; Table 81-1). The term myeloproliferative disease or disorder has also been used to refer to myeloid leukemias (mainly to the acute forms). On the basis of their clinical course and the cytologic features of the leukemic cell population, leukemias can also be classified as acute or chronic. Acute leukemias are characterized by an aggressive biologic behavior (i.e., death ensues shortly after diagnosis if the patient is not treated) and by the presence of immature (blast) cells in bone marrow or blood. Chronic leukemias have a protracted, often indolent course, and the predominant cell is a well-differentiated, late precursor (i.e., lymphocyte in chronic lymphocytic leukemia [CLL] and neutrophil in chronic myeloid leukemia [CML]). In dogs (and possibly in cats) CML can undergo blast transformation (blast crisis), during which the disease behaves like

an acute leukemia and is usually refractory to therapy. Blast crises do not appear to occur in dogs or cats with CLL.

Acute leukemias may be difficult to classify morphologically as myeloid or lymphoid on the basis of the evaluation of Giemsa- or Wright's-stained blood or bone marrow smears because poorly differentiated blasts look similar under the light microscope. In veterinary medicine cytochemical stains are used routinely in several diagnostic laboratories to establish whether the blasts are lymphoid or myeloid and also to subclassify myeloid leukemias, as described later (i.e., myeloid versus monocytic versus myelomonocytic). These cytochemical stains reveal the presence of different enzymes in the cytoplasm of the blasts, which aids in establishing their origin (Table 81-2).

Immunophenotyping of canine and feline leukemic cells using monoclonal antibodies is now available in teaching institutions and some commercial diagnostic laboratories; however, clinical correlations between immunophenotype and prognosis have not yet been established, although it appears that certain phenotypes may be associated with poor prognosis.

A classification scheme for acute leukemia in people was devised by a group of French, American, and British investigators (the FAB scheme) and was based on the morphologic features of the cells in Giemsa-stained smears of blood and bone marrow and the clinical presentation and biologic behavior of the disease. Because this scheme has not yet proved to be prognostically or therapeutically applicable to cats or dogs, it is not discussed here (see Suggested Readings for additional information on the FAB scheme in people and animals).

The terms *preleukemic syndrome* and *myelodysplastic syndrome* (MDS, or myelodysplasia) refer to a syndrome of hematopoietic dysfunction and specific cytomorphologic changes that precedes the development of acute myelogenous leukemia by months to years. The syndrome is characterized by cytopenias and a hypercellular bone marrow and appears to be more common in cats than in dogs. The clinical and hematologic features of cats and dogs with MDS are discussed at the end of this chapter.

TABLE 81-1

Classification of Leukemias in Dogs and Cats

CLASSIFICATION	SPECIES
Acute Leukemias Acute myeloid (myelogenous) leukemia (AML)	
Undifferentiated myeloid leukemia (AML-M <sub>o</sub> ) Acute myelocytic leukemia (AML-M <sub>1-2</sub> ) Acute progranulocytic leukemia (AML-M <sub>3</sub> )	D, C D, C
Acute myelomonocytic leukemia (AMML; AML- M <sub>4</sub> )	D, C
Acute monoblastic/monocytic leukemia (AMoL; AML-M <sub>5</sub> )	D, C
Acute erythroleukemia (AML-M <sub>6</sub> ) Acute megakaryoblastic leukemia (AML-M <sub>7</sub> )	C, D <b>?</b> D, C

# LEUKEMIAS IN DOGS

In dogs leukemias constitute fewer than 10% of all hemolymphatic neoplasms and are therefore considered rare. At our hospital the leukemia: lymphoma ratio is approximately 1:7 to 1:10. However, this ratio is artificially high because most dogs with lymphoma are treated by their local veterinarians, whereas most dogs with leukemia are referred for treatment. Although most leukemias in dogs are considered to be spontaneous in origin, radiation and viral particles have been identified as etiologic factors in some experimental dogs with this disease.

#### **ACUTE LEUKEMIAS**

#### **Prevalence**

Acute myeloid leukemias are more common than acute lymphoid leukemias in dogs, constituting approximately three fourths of the cases of acute leukemia. It should be remembered, however, that morphologically (i.e., as determined by evaluation of a Wright's- or Giemsa's-stained blood or bone marrow smear), most acute leukemias are initially classified as lymphoid. After cytochemical staining of the smears or immunophenotyping is performed, approximately one third to one half of them are then reclassified as myeloid. Approx-

Pallor	>30-60	>50-70?
Fever	>40-50	>40-60?

<sup>2</sup> Unknown

imately half of the dogs with myeloid leukemia have myelomonocytic differentiation when cytochemical staining or immunophenotyping is performed (see Table 81-2).

#### **Clinical Features**

The clinical signs and physical examination findings in dogs with acute leukemia are usually vague and nonspecific (Table 81-3). Most owners seek veterinary care when their dogs become lethargic or anorectic or when persistent or recurrent fever, weight loss, shifting limb lameness, or other nonspecific signs develop; neurologic signs occur occasionally. Some of these signs may be quite acute (e.g., days). Spleno-

<sup>\*</sup> Results are expressed as the approximate percentage of animals showing the abnormality.

megaly, hepatomegaly, pallor, fever, and mild generalized lymphadenopathy are commonly detected during routine physical examination. The spleen in these dogs is usually markedly enlarged, and it has a smooth surface on palpation. Careful inspection of the mucous membranes in dogs with acute leukemia often reveals petechiae, ecchymoses, or both, in addition to pallor. Icterus may also be detected if marked leukemic infiltration of the liver has occurred. The generalized lymphadenopathy seen in dogs with acute leukemia is usually mild, in contrast to that seen in dogs with lymphoma, in which the lymph nodes are massively enlarged. In other words, the hepatosplenomegaly is more striking than the lymphadenopathy. Most dogs with leukemia also have constitutional signs (i.e., they are clinically ill), whereas most dogs with lymphoma are asymptomatic. Although it is usually impossible to distinguish between acute myeloid and acute lymphoid leukemia on the basis of physical examination findings alone, some subtle differences do exist: Mainly, shifting limb lameness, fever, and ocular lesions are more common in dogs with acute myeloid leukemia, whereas neurologic signs are more common in dogs with acute lymphoid leukemia.

# **Hematologic Features**

Marked hematologic changes are usually present in dogs with acute leukemia. Couto (1985) and Grindem et al. (1985b) have published detailed reviews of the hematologic features of dogs with acute leukemia. Briefly, abnormal (leukemic) cells are observed in the peripheral blood of most dogs with acute myeloid leukemia (AML) and acute lymphoblastic leukemia (ALL), although this is slightly more common in the latter (i.e., circulating blasts are absent in some dogs with AML; Fig. 81-1). Isolated cytopenias, bicytopenias, or pancytopenia is present in almost all dogs with AML and ALL. Leukoerythroblastic reactions are detected in approximately half of dogs with AML but are rare in dogs

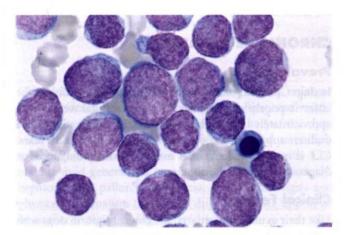

FIG 81-1
Blood smear from a dog with acute lymphoblastic leukemia and a white blood cell count of approximately 1,000,000/μl. Note the predominance of large, immature lymphoid cells with large nuclei, clumped chromatin, and nucleoli. (×1000.)

with ALL. The total white blood cell (WBC) and blast counts are highest in dogs with ALL (median, 298,200/µl; range, 4000 to 628,000/µl), and as a general rule, only dogs with ALL have WBC counts greater than 100,000/µl. Most dogs with AML and ALL are anemic, but dogs with acute monoblastic/monocytic leukemia (AMoL or AML- $M_5$ ) have the least severe anemia (packed cell volume of 30% versus 23% in all other groups). Most dogs with acute leukemias are also thrombocytopenic, although the thrombocytopenia also appears to be less severe in dogs with AML- $M_5$  (median, 102,000/µl; range, 39,000 to 133,000/µl).

# **Diagnosis**

A presumptive diagnosis in dogs with acute leukemia is usually made on the basis of the history and physical examination findings; a CBC is usually confirmatory, although the hematologic changes in dogs with "aleukemic leukemia" may resemble those of ehrlichiosis or other bone marrow disorders. To evaluate the extent of the disease, a bone marrow aspirate or biopsy is indicated. Splenic, hepatic, or lymph node aspirates for cytologic evaluation can also be obtained easily, although the information yielded may not help in establishing the diagnosis or prognosis. For example, if a dog has mild generalized lymphadenopathy and the only sample submitted to a laboratory is a lymph node, spleen, or liver aspirate, the finding of undifferentiated blasts in the smear points toward a cytologic diagnosis of either acute leukemia or lymphoma (i.e., the neoplastic lymphoid cells in lymphoma and leukemia are indistinguishable morphologically); indeed, it is quite common for the clinical pathologist to issue a diagnosis of lymphoma because it is the most common of the two diseases. In these cases, further clinical and clinicopathologic information (i.e., the degree and extent of lymphadenopathy, presence and degree of hepatosplenomegaly, hematologic and bone marrow biopsy or aspiration findings) is required to establish a definitive diagnosis.

It may be difficult to diagnose the tumor type in a dog with generalized lymphadenopathy, hepatosplenomegaly, and a low number of circulating lymphoblasts. The main differential diagnoses are ALL and lymphoma with circulating blasts (lymphosarcoma cell leukemia). It is important to differentiate between these two disorders because the prognosis for dogs with lymphoma is considerably better than that for dogs with acute leukemia. These two entities may be difficult to distinguish on the basis of the clinical, hematologic, and cytologic information obtained, but the guidelines found in Box 81-1 can be used to try to arrive at a definitive diagnosis.

When the neoplastic cells are poorly differentiated, cytochemical staining or immunophenotyping is required to establish a definitive diagnosis (see Table 81-2). This is important if the owner is contemplating treatment because the therapy and prognosis for dogs with AML are different from those for dogs with ALL (i.e., the survival time in dogs with AML is shorter than that in dogs with ALL).

In addition to lymphoma, differential diagnoses in dogs with acute or chronic leukemias include other disorders of

BOX 81-1

Acute Lymphoblastic Leukemia or Lymphoma with Circulating Blasts (Lymphosarcoma Cell Leukemia): Guidelines for a Definitive Diagnosis

- If the lymphadenopathy is massive, the dog is more likely to have lymphoma.
- If the dog is systemically ill, it is more likely to have All
- 3. If bicytopenia or pancytopenia is present, ALL is the more likely diagnosis.
- If the percentage of lymphoblasts in the bone marrow is more than 40% to 50%, the dog is more likely to have All
- 5. If hypercalcemia is present, the more likely diagnosis is lymphoma.

All, Acute lymphoblastic leukemia.

BOX 81-2

Basic Diagnostic Principles for Dogs with Suspected Leukemia

- If cytopenias or abnormal cells are present in peripheral blood, a bone marrow aspirate or biopsy specimen should be obtained.
- If the spleen or liver is enlarged, a fine-needle aspirate of the affected organs should be obtained for cytologic evaluation.
- If blasts are present, blood and bone marrow specimens should be submitted to a veterinary referral laboratory for cytochemical staining or immunophenotyping.
- Other diagnostic tests (e.g., serologic tests or polymerase chain reaction [PCR] testing for Ehrlichia canis) should be performed if appropriate.

the mononuclear-phagocytic or hematopoietic systems, such as malignant or systemic histiocytosis; systemic mast cell disease (mast cell leukemia); and infectious diseases such as ehrlichiosis, bartonellosis, mycoplasmosis, and mycobacteriosis. Box 81-2 lists the basic principles of diagnosis that apply to all dogs with suspected leukemia.

The diagnosis of acute leukemia can be extremely straightforward (i.e., a dog that is evaluated because of weight loss, lethargy, hepatosplenomegaly, pallor, and central nervous system [CNS] signs and that has a WBC of more than 500,000/µl, most of which are blasts, is most likely to have ALL), or it may represent a challenge (i.e., a dog with unexplained cytopenias of prolonged duration in which aleukemic AML-M<sub>1</sub> subsequently develops).

#### **Treatment**

The treatment of dogs with acute leukemias is usually unrewarding. Most dogs with these diseases respond poorly to therapy, and prolonged remissions are rare. Treatment failure usually stems from one or more of the following factors:

- Failure to induce remission (more common in AML than in ALL)
- 2. Failure to maintain remission
- 3. The presence or development of organ failure resulting from leukemic cell infiltration; this precludes the use of aggressive combination chemotherapy (i.e., because of enhanced toxicity)
- 4. The development of fatal sepsis, bleeding, or both caused by already existing or treatment-induced cytopenias

Prolonged remissions in dogs with AML treated with chemotherapy are extremely rare. In most dogs with AML remissions in response to any of the protocols listed in Box 81-3 are rarely observed. If animals do respond, the remission is usually extremely short-lived and survival rarely exceeds 3 months. In addition, more than half of the dogs die during induction as a result of sepsis or bleeding. Furthermore, the supportive treatment required in these patients (e.g., blood component therapy, intensive care monitoring) is financially unacceptable to most owners, and the emotional strain placed on the owner is also quite high. Therefore owners should be aware of all these factors before deciding to treat their dogs.

The prognosis may be slightly better in dogs with ALL; however, responses to treatment and survival times in these patients are considerably lower than those in dogs with lymphoma. The remission rates in dogs with ALL are approximately 20% to 40%, in contrast with those in dogs with lymphomas, which approach 90%. Survival times with chemotherapy in dogs with ALL are also shorter (average, 1 to 3 months) than those in dogs with lymphoma (average, 12 to 18 months). Untreated dogs usually live less than 2 weeks. Chemotherapy protocols used in dogs with acute leukemia are listed in Box 81-3.

# CHRONIC LEUKEMIAS

# Prevalence

In dogs CLL is far more common than CML; in addition, the latter is poorly characterized. At our hospital we evaluate approximately six to eight dogs with CLL a year, whereas we evaluate approximately one dog with CML every 3 to 5 years. CLL is one of the leukemias most commonly diagnosed at diagnostic referral laboratories.

# **Clinical Features**

Like their acute counterparts, the clinical signs in dogs with CLL or CML are vague and nonspecific; however, there is a history of chronic (i.e., months), vague clinical signs in approximately half of the dogs with chronic leukemia. Many cases of chronic leukemia are diagnosed incidentally during routine physical examination and clinicopathologic evaluation (i.e., dogs are asymptomatic). Clinical signs in dogs with

BOX 81-3

Chemotherapy Protocols for Dogs and Cats with Acute Leukemias

# Acute Lymphoblastic Leukemia

# 1. OP protocol

Vincristine, 0.5 mg/m² IV once a week
Prednisone, 40-50 mg/m² PO q24h for a week; then
20 mg/m² PO q48h

#### 2. COP protocol

Vincristine, 0.5 mg/m² IV once a week
Prednisone, 40-50 mg/m² PO q24h for a week; then
20 mg/m² PO q48h
Cyclophosphamide, 50 mg/m² PO q48h

#### 3. LOP protocol

Vincristine, 0.5 mg/m² IV once a week
Prednisone, 40-50 mg/m² PO q24h for a week; then
20 mg/m² PO q48h
L-Asparaginase, 10,000-20,000 IU/m² IM or SC once
every 2-3 weeks

#### 4. COAP protocol

Vincristine, 0.5 mg/m² IV once a week
Prednisone, 40-50 mg/m² PO q24h for a week; then
20 mg/m² PO q48h
Cyclophosphamide, 50 mg/m² PO q48h
Cytosine arabinoside, 100 mg/m² SC daily for 2-4 days\*

# Acute Myelogenous Leukemia

Cytosine arabinoside, 5-10 mg/m<sup>2</sup> SC q12h for 2-3 weeks; then on alternate weeks

Cytosine arabinoside, 100-200 mg/m² in IV drip over 4 hours

Mitoxantrone, 4-6 mg/m² in IV drip over 4 hours; repeat every 3 weeks

IV, Intravenous; PO, by mouth; IM, intramuscular; SC, subcutaneous.

CLL include lethargy, anorexia, vomiting, mildly enlarged lymph nodes, intermittent diarrhea or vomiting, and weight loss. As mentioned previously, more than half of the dogs with CLL are asymptomatic and are diagnosed serendipitously. Physical examination findings in dogs with CLL include mild generalized lymphadenopathy, splenomegaly, hepatomegaly, pallor, and pyrexia. The clinical signs and physical examination findings in dogs with CML appear to be similar to those in dogs with CLL.

A terminal event in dogs with CLL is the development of a diffuse large cell lymphoma, termed *Richter syndrome*; in humans Richter syndrome also includes prolymphocytic leukemia, acute eukemia, and Hodgkin's lymphoma. In dogs Richter syndrome is characterized by a massive, generalized lymphadenopathy and hepatosplenomegaly. Once this multicentric lymphoma develops, chemotherapy-induced, longlasting remissions are difficult to obtain and survival times are short.

Blast crisis, which involves the appearance of immature blast cells in blood and bone marrow, occurs in humans and dogs with CML months to years after the initial diagnosis is made; in humans with CLL acute leukemias are part of the Richter syndrome. In humans with blast crisis associated with CML these blasts are of either myeloid or lymphoid phenotype; the origin of the blast cell in dogs with blast crises has not been determined. Blast crises occurred in five of eleven dogs with CML described in the literature (Leifer et al., 1983). Blast crises do not appear to occur in dogs with CLL.

# **Hematologic Features**

The most common hematologic abnormality in dogs with CLL is a marked lymphocytosis resulting in leukocytosis. The lymphocytes are usually morphologically normal, although large granular lymphocytes (LGLs) are occasionally present. The lymphocyte counts range from 8000/µl to more than 100,000/µl, but lymphocyte counts of more than 500,000/µl are rare. In most dogs with CLL the neoplastic cell population is of T-cell origin. In addition to the lymphocytosis, which may be diagnostic in itself (e.g., a dog with a lymphocyte count of 100,000/µl most certainly has CLL), anemia is detected in more than 80% of the dogs and thrombocytopenia in approximately half of the dogs. Although cytologic evaluation of bone marrow aspirates in dogs with CLL usually reveals the presence of many morphologically normal lymphocytes, normal numbers of lymphocytes are occasionally detected. This is probably because the lymphocytosis in some animals with CLL stems from disorders of recirculation rather than from the increased clonal proliferation of lymphocytes in the bone marrow.

Monoclonal gammopathies have been reported in approximately two thirds of dogs with CLL in which serum was evaluated using protein electrophoresis (Leifer et al., 1986). The monoclonal component is usually IgM, but IgA and IgG components have also been reported. This monoclonal gammopathy can lead to hyperviscosity. Rarely, dogs with CLL have paraneoplastic, immune-mediated blood disorders (e.g., hemolytic anemia, thrombocytopenia, neutropenia). However, in my experience, monoclonal gammopathies are uncommon in dogs with CLL.

The hematologic features of CML in dogs are poorly characterized but include leukocytosis with a left-shift down to myelocytes (or occasionally myeloblasts), anemia, and possibly thrombocytopenia, although thrombocytosis can also occur. The hematologic findings seen during a blast crisis are indistinguishable from those seen in dogs with AML or ALL.

# Diagnosis

Absolute lymphocytosis is the major diagnostic criterion for CLL in dogs. Although other diseases (e.g., ehrlichiosis, babesiosis, leishmaniasis, Chagas' disease, Addison's disease)

<sup>\*</sup>The daily dose should be divided into two to four daily administrations.

should be considered in the differential diagnosis of dogs with mild lymphocytosis (i.e., 7000 to 20,000/µl), marked lymphocytosis (i.e., more than 20,000/µl) is almost pathognomonic for CLL. If the physical examination and hematologic abnormalities discussed in previous paragraphs (i.e., mild lymphadenopathy, splenomegaly, monoclonal gammopathy, anemia) are found, this may help establish a diagnosis of CLL in dogs with lymphocytosis, although all these changes can also be present in dogs with chronic ehrlichiosis (see Chapter 96). In patients with lymphocytosis in which a confirmatory diagnosis of CLL cannot be made, a PCR assay for clonality will typically reveal if the cells are clonal in origin. The phenotypic distribution after performing immunophenotyping may also establish if the cell population is monoclonal or polyclonal.

The diagnosis of CML may be challenging, particularly because this syndrome is poorly characterized in dogs. Some of the markers used to diagnose CML in humans are of no use in dogs. For example, the Philadelphia 1 chromosome and the alkaline phosphatase score were originally used in humans to differentiate CML from leukemoid reactions (i.e., CML cells have the Philadelphia 1 chromosome, and the alkaline phosphatase content of the neutrophils increases in the setting of leukemoid reactions and decreases in the setting of CML). Chromosamal analysis of the cells in question may reveal specific abnormalities that support a diagnosis of CML. As a general rule, a final diagnosis of CML should be made only after the clinical and hematologic findings have been carefully evaluated and the inflammatory and immune causes of neutrophilia have been ruled out.

#### **Treatment**

The clinician usually faces the dilemma of whether to treat a dog with CLL. If the dog is symptomatic, has organomegaly, or has concurrent hematologic abnormalities, treatment with an alkylator (with or without corticosteroids) is indicated. If there are no paraneoplastic syndromes (i.e., immune hemolysis or thrombocytopenia, monoclonal gammopathies), I recommend using single-agent chlorambucil at a dosage of 20 mg/m² given orally once every 2 weeks (Box 81-4). If there are paraneoplastic syndromes, the addition of corticosteroids (prednisone, 50 to 75 mg/m² by mouth [PO] q24h for 1 week, then 25 mg/m² PO q48h) may be beneficial.

Because the growth fraction of neoplastic lymphocytes in CLL appears to be low, a delayed response to therapy is common. In a high proportion of dogs with CLL treated with chlorambucil or chlorambucil and prednisone, it may take more than 1 month (and as long as 6 months) for the hematologic and physical examination abnormalities to resolve. This is in contrast to dogs with lymphoma and acute leukemias, in which remission is usually induced in 2 to 7 days.

The survival times in dogs with CLL are quite long. Indeed, even without treatment, survival times of more than 2 years are common. More than two thirds of the dogs with CLL treated with chlorambucil (with or without prednisone)

BOX 81-4

Chemotherapy Protocols for Dogs and Cats with Chronic Leukemias

#### Chronic Lymphocytic Leukemia

Chlorambucil, 20 mg/m² PO once every 2 weeks Chlorambucil as above, plus prednisone, 50 mg/m² PO q24h for a week; then 20 mg/m² PO q48h

#### COP protocol

Cyclophosphamide, 200-300 mg/m² IV once every 2 weeks

Vincristine, 0.5-0.75 mg/m<sup>2</sup> IV once every 2 weeks (alternating weeks with the cyclophosphamide)

Prednisone as in protocol 2; this treatment is continued for 6-8 weeks, at which time protocol 1 or 2 can be used for maintenance

#### Chronic Myelogenous Leukemia

Hydroxyurea, 50 mg/kg PO q24h for 1-2 weeks; then q48h

Imatinib (Gleevec), 10 mg/kg PO q24h ONLY IN CATS

PO, By mouth; IV, intravenous.

at our clinic have survived in excess of 2 years. In fact, most dogs with CLL do not die as a result of leukemia-related causes but rather of other senior disorders.

The treatment of dogs with CML using hydroxyurea (see Box 81-4) may result in prolonged remission, provided a blast crisis does not occur. However, the prognosis does not appear to be as good as that for dogs with CLL (i.e., survivals of 4 to 15 months with treatment). The treatment of blast crises is usually unrewarding. A novel therapeutic approach targeting tyrosine kinase in the neoplastic cells of humans with CML using imatinib (Gleevec) has shown to be beneficial in inducing remission; however, the drug is hepatotoxic in dogs. New small molecule tyrosine kinase inhibitors are currently under investigation in dogs with CML and other diseases associated with c-kit mutations.

#### LEUKEMIAS IN CATS

#### **ACUTE LEUKEMIAS**

#### **Prevalence**

True leukemias are rare in the cat, constituting fewer than 15% of all hematopoietic neoplasms. Although exact figures regarding the incidences of leukemias and lymphomas are not available for cats, these neoplasms are now rare.

If cytochemical staining or immunophenotyping is used to classify acute leukemias in cats, approximately two thirds are myeloid and one third are lymphoid. However, in contrast to dogs, myelomonocytic leukemias (M<sub>4</sub>) appear to be rare in cats.

Feline leukemia virus (FeLV) is commonly implicated as a cause of leukemias in cats; however, the role of feline immunodeficiency virus (FIV) in the pathogenesis of these neoplasms is still unclear. Originally, it was reported that approximately 90% of cats with lymphoid and myeloid leukemias tested positive for FeLV p27 with enzyme-linked immunosorbent assay or immunofluorescence. As discussed in Chapter 80, because the prevalence of FeLV infection is decreasing, most cats with leukemia diagnosed in our clinic over the past few years have not been viremic for FeLV (i.e., they are FeLV-negative).

#### **Clinical Features**

The clinical features and physical examination findings in cats with acute leukemias are similar to those in dogs and are summarized in Table 81-3. Shifting limb lameness and neurologic signs do not appear to be as common in cats as in dogs with myeloid leukemias.

# **Hematologic Features**

More than three fourths of cats with AML and ALL have cytopenias; leukoerythroblastic reactions are common in cats with AML but extremely rare in those with ALL. In contrast to dogs, circulating blasts appear to be more common in cats with AML than in those with ALL.

Sequential studies of cats with myeloid leukemias have revealed that the cytomorphologic features can change from one cell type to another over time (e.g., sequential diagnoses of erythremic myelosis, erythroleukemia, and acute myeloblastic leukemia are common in a given cat). This is one of the reasons that most clinical pathologists prefer the term *myeloproliferative disorder (MPD)* to refer to this leukemia in cats.

# **Diagnosis and Treatment**

The diagnostic evaluation of cats with suspected acute leukemia follows the same general sequence as that for dogs. If the changes in the CBC are not diagnostic, a bone marrow aspirate can provide information that may confirm the diagnosis (Fig. 81-2). In addition, cats with suspected or confirmed acute leukemias should be evaluated for circulating FeLV p27 and for serum antibodies against FIV.

With treatment cats with ALL apparently have better survival times than cats with AML. Survival times in cats with ALL treated with multichemotherapy range from 1 to 7 months.

There have been several published reports of cats with myeloid leukemias treated with single-agent or combination chemotherapy. The treatment protocols have included single-agent cyclophosphamide or cytosine arabinoside, as well as combinations of cyclophosphamide, cytosine arabinoside, and prednisone; cytosine arabinoside and prednisone; cyclophosphamide, vinblastine, cytosine arabinoside, and prednisone; and doxorubicin, cyclophosphamide, and prednisone. Survival times in these cats have usually ranged from 2 to 10 weeks, with a median of approximately 3 weeks. Therefore, as in dogs, intensive chemo-

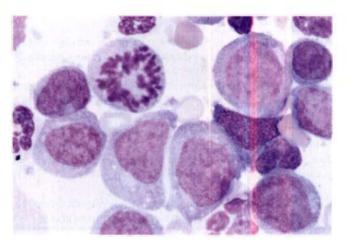

FIG 81-2
Bone marrow aspirate from a cat with peripheral blood cytopenias and absence of circulating blasts. Note the predominance of large immature myeloid cells, characterized by round to kidney-shaped nuclei. A mitotic figure is

therapy does not appear to be beneficial in cats with acute leukemias

New alternatives for the therapy of feline MPD are currently being explored. Low-dose cytosine arabinoside (LDA; 10 mg/m² subcutaneously q12h; Cytosar-U; Upjohn, Kalamazoo, Mich) has been used as an inductor of differentiation of the neoplastic clone. In several studies this treatment was observed to induce complete or partial remission in 35% to 70% of humans with MDS and MPD. Moreover, although myelosuppression was observed in some patients, the treatment was exceedingly well tolerated and associated with minimal toxicity.

We have treated several cats with MPD using LDA and have observed in most complete or partial remissions, with transient hematologic improvement. Although no major toxicities were seen, the remissions were short-lived (3 to 8 weeks).

# **CHRONIC LEUKEMIAS**

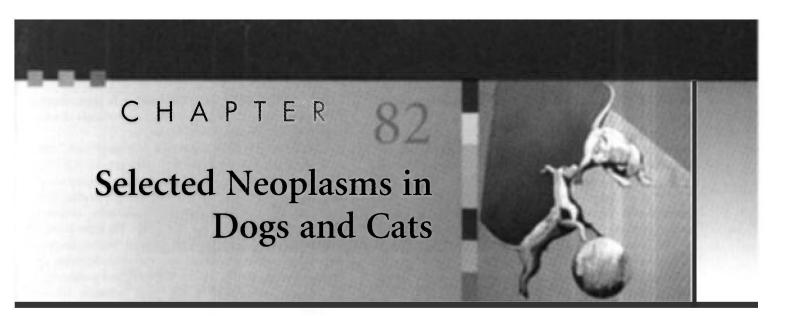

evident. (×1000.)

Chronic leukemias are are becoming more common in cats; this may be due to the relative decrease in the prevalence of acute leukemias, or it may represent a true phenomenon. CLL is occasionally found incidentally during routine physical examination. More often, cats with CLL are seen by a veterinarian because of a protracted history of vague signs of illness, including anorexia, lethargy, and gastrointestinal tract signs. In cats with CLL mature, well-differentiated lymphocytes predominate in peripheral blood and bone marrow, and the response to therapy appears to be good. In most cats with CLL the leukemic population is of T-cell origin. Most cats with CLL evaluated at our clinic showed a complete remission in response to chlorambucil with or without prednisone treatment. As in dogs, CML is poorly characterized in cats.

Mast Cell Tumors in Cats
INJECTION SITE SARCOMAS IN CATS

# HEMANGIOSARCOMA IN DOGS

Hemangiosarcomas (HSAs, hemangioendotheliomas, angiosarcomas) are malignant neoplasms that originate from the vascular endothelium. They occur predominantly in older dogs (8 to 10 years of age) and in males; German Shepherd Dogs and Golden Retrievers are at high risk for this neoplasm.

The spleen, right atrium, and subcutis are common sites of involvement at the time of presentation. Approximately 50% of the tumors originate in the spleen, 25% in the right atrium, 13% in subcutaneous tissue, 5% in the liver, 5% in the liver-spleen–right atrium, and 1% to 2% simultaneously in other organs (i.e., kidney, urinary bladder, bone, tongue, prostate). The latter are referred to as *multiple tumor*, *undeterminable primary*. In Greyhounds most of the HSAs evaluated have been intramuscular.

In general, the biologic behavior of this neoplasm is highly aggressive, with most anatomic forms of the tumor infiltrating and metastasizing early in the disease. The exception are primary dermal and conjunctival or third eyelid HSAs, which have a low metastatic potential.

# **Clinical and Clinicopathologic Features**

The nature of owners' complaints and the clinical signs at presentation are usually related to the site of origin of the primary tumor; to the presence or absence of metastatic lesions; and to the development of spontaneous tumor rupture, coagulopathies, or cardiac arrhythmias. More than half of the dogs with HSA are evaluated because of acute collapse after spontaneous rupture of the primary tumor or a metastatic lesion. Some episodes of collapse may stem from ventricular arrhythmias, which are relatively common in dogs with splenic or cardiac HSA. In addition, dogs with splenic HSA often are seen because of abdominal distention secondary to tumor growth or hemoabdomen.

Dogs with cardiac HSA usually are presented for evaluation of right-sided congestive heart failure (caused by cardiac tamponade or obstruction of the posterior vena cava by a neoplasm) or cardiac arrhythmias (see the chapters on cardiovascular system disorders for additional information). Dogs with cutaneous or subcutaneous neoplasms are usually evaluated because of a lump. Greyhounds with intramuscular HSA typically present with a swollen and bruised rear limb; the tumor is frequently in the biceps femoris or quadriceps.

Two common problems in dogs with HSA, regardless of the primary location or stage, are anemia and spontaneous bleeding. The anemia is usually the result of intracavitary bleeding or microangiopathic hemolysis (MAHA), whereas the spontaneous bleeding is usually caused by disseminated intravascular coagulation (DIC) or thrombocytopenia secondary to MAHA (see later discussion). HSA is so highly associated with clinical DIC (see Chapter 87) that at our hospital dogs with DIC of acute onset but without an obvious primary cause are evaluated for HSA first.

Hemangiosarcomas are usually associated with a wide variety of hematologic and hemostatic abnormalities. Hematologic abnormalities in dogs with HSA have been well characterized and include anemia; thrombocytopenia; the presence of nucleated red blood cells (RBCs), RBC fragments (schistocytes), and acanthocytes in the blood smear; and leukocytosis with neutrophilia, a left shift, and monocytosis. In addition, hemostatic abnormalities are also common in dogs with HSAs. However, these hematologic abnormalities are location dependent; for example, in our clinic anemia, thrombocytopenia, schistocytosis, and acanthocytosis were significantly more common in dogs with splenic, right atrial,

or visceral HSA than in dogs with subcutaneous or dermal HSA (Alvarez et al., 2006).

Most dogs with HSA (83%) evaluated at our clinic were anemic; more than one half had RBC fragmentation and acanthocytosis (Hammer et al., 1991b). The pretreatment coagulograms of these dogs were normal in only four dogs (17%). Most dogs (75%) had thrombocytopenia, with a mean platelet count of 137,000/µl. Approximately one half of the coagulograms met three or more criteria for diagnosis of DIC, whereas fewer than 12% of them were compatible with microangiopathic thrombocytopenia. Approximately 25% of these dogs died as a result of their hemostatic abnormalities.

# **Diagnosis**

Hemangiosarcomas can be diagnosed cytologically on the basis of the appearance of fine-needle aspirates (FNA) or impression smears. The neoplastic cells are similar to those in other sarcomas in that they are spindle-shaped or polybedral; however, they are quite large; have large nuclei with a lacy chromatin pattern and one or more nucleoli; and a bluish gray, usually vacuolated cytoplasm (Fig. 82-1). Nucleated RBCs are frequently present cytologically in HSAs. Although HSA cells are relatively easy to identify in tissue aspirates or impression smears, they are extremely difficult to identify in HSA-associated effusions. The probability of establishing a cytologic diagnosis of HSA after evaluating effusions is less than 25%. A further problem with effusions is that a specimen may contain reactive mesothelial cells that may resemble neoplastic cells, leading to a false-positive diagnosis of HSA.

In general, a presumptive clinical or cytologic diagnosis of HSA should be confirmed histopathologically. Because of the large size of some splenic HSAs, however, multiple samples (from different morphologic areas) should be submitted in appropriate fixative. Histochemically, HSA cells are

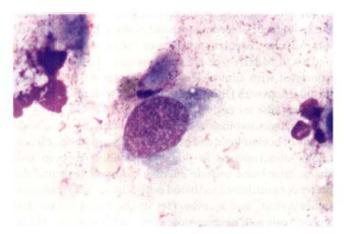

FIG 82-1
Cytologic features of canine hemangiosarcoma. Note the spindle-shaped cells, with a dark, vacuolated cytoplasm, and the fine nuclear chromatin pattern with prominent nucleolus. (×1000.)

positive for von Willebrand factor antigen in approximately 90% of the cases; CD31 is a relatively new marker of endothelial origin positive in most HSAs.

Metastatic sites can be detected radiographically, ultrasonographically, or on computed tomography (CT). Our routine staging system for dogs with HSA includes a complete blood count (CBC), serum biochemistry profile, hemostasis screen, urinalysis, thoracic radiographs, abdominal ultrasonography, and echocardiography. The latter is used to identify cardiac masses and determine the baseline fractional shortening before instituting doxorubicin-containing chemotherapy (see the section on treatment and prognosis).

Thoracic radiographs in dogs with metastatic HSA are typically characterized by the presence of interstitial or alveolar infiltrates, as opposed to the common "cannonball" metastatic lesions seen with other tumors. The radiographic pattern may be due to true metastases or to DIC and intrapulmonary bleeding, or adult respiratory distress syndrome (ARDS).

Ultrasonography constitutes a reliable way to evaluate dogs with suspected or confirmed HSA for intraabdominal disease. Neoplastic lesions appear as nodules with variable echogenicity, ranging from anechoic to hyperechoic (Fig. 82-2). Hepatic metastatic lesions can often be identified using this imaging technique. However, the clinician should bear in mind that what appear to be metastatic nodules in the liver of a dog with a splenic mass may represent regenerative hyperplasia rather than true metastatic lesions. Contrast ultrasonography appears to enhance the operator's ability to detect hepatic metastatic nodules from HSA.

# **Treatment and Prognosis**

Historically, the mainstay of treatment for dogs with HSA has been surgery, although the results have been poor. Survival times vary with the location and stage of the tumor, but in general (with the exception of dermal and conjunctival or third eyelid HSAs), they are quite short (approximately 20 to 60 days, with a 1-year survival rate of <10%). Results of treatment combining surgery and postoperative adjuvant

FIG 82-2 Ultrasonogram of an intraabdominal hemangiosarcoma.

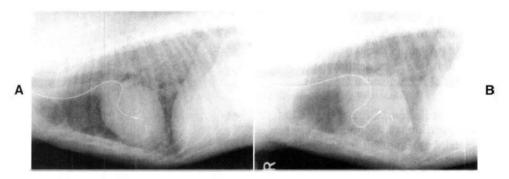

FIG 82-3

Thoracic radiographs of a 10-year-old, spayed female German Shepherd Dog with pulmonary metastases from a primary splenic hemangiosarcoma before **(A)** and 9 weeks after initiating VAC chemotherapy **(B)**. chemotherapy with doxorubicin; doxorubicin and cyclophosphamide (AC protocol); and vincristine, doxorubicin, and cyclophosphamide (VAC protocol) are better than with surgery alone. Median survival times range from 140 to 202 days.

The median survival times of dogs with HSA treated with the VAC protocol (see box on cancer chemotherapy protocols in Chapter 81) are approximately 190 days, with a 30% 1-year survival rate. Interestingly, in a recent study conducted in our clinic, the presence of metastasis was not a negative prognostic factor in dogs with HSA receiving VAC chemotherapy (Alvarez et al., 2007). Dogs with metastatic HSA had a 70% response rate (Fig. 82-3). Adverse effects associated with this protocol include myelosuppression, gastroenteritis, alopecia and hyperpigmentation, and cardiotoxicity. There was no apparent difference in the survival times between dogs with bulky disease (i.e., no surgical cytoreduction) and those that had undergone surgery. Similar results were reported for dogs treated either with doxorubicin and cyclophosphamide or with doxorubicin alone; however, in my experience, the prognosis for dogs with HSA is better if a three-drug combination, instead of a two-drug combination or monochemotherapy, is used. In our clinic we have rarely been able to administer more than 3 or 4 doses of single agent doxorubicin in dogs with HSA because they have already relapsed. The coagulopathies in HSA patients should be managed simultaneously, as discussed in Chapter 85.

Biologic response modifiers and antiangiogenic factors have also been used in dogs with HSA in combination with doxorubicin-containing chemotherapy. Dogs receiving liposome-encapsulated MTP (muramyl tripeptide—the active immunomodulatory molecule in bacille Calmette-Guerin [BCG]) and AC chemotherapy after splenectomy for HSA had significantly longer survival times (277 days) than those receiving chemotherapy and placebo (144 days; Vail et al., 1995). However, liposomal MTP is not readily available to the practicing veterinarian. Recently, minocycline, an antiangiogenic antibiotic, used at a dosage of 5 mg/kg by mouth every 24 hours, was added to the AC protocol in dogs with HSA (Sorenmo et al., 2000); the median survival time was

170 days, similar to the median survival times obtained when using chemotherapy alone.

In summary, HSAs are usually diagnosed on the basis of historical, physical examination, and clinicopathologic findings, in conjunction with ultrasonographic and radiographic changes. A morphologic diagnosis can usually be made on the basis of cytologic or histopathologic findings. Although surgery is the preferred treatment, survival times in such animals are extremely short (except in dogs with dermal or conjunctival/third eyelid HSA). Postoperative adjuvant chemotherapy using doxorubicin-containing protocols prolongs survival in dogs with this malignancy.

# OSTEOSARCOMA IN DOGS AND CATS

# **Etiology and Epidemiology**

Primary bone neoplasms are relatively common in dogs but rare in cats. Most primary bone tumors in dogs are malignant in that they usually cause death as a result of local infiltration (e.g., pathologic fractures or extreme pain leading to euthanasia) or metastasis (e.g., pulmonary metastases in osteosarcoma [OSA]). In cats most primary bone neoplasms, although histologically malignant, are cured by wide surgical excision (i.e., amputation). Neoplasms that metastasize to the bone are rare in dogs; some that occasionally metastasize to bones in dogs are transitional cell carcinoma of the urinary tract, osteosarcoma of the appendicular skeleton, hemangiosarcoma, mammary adenocarcinoma, and prostatic adenocarcinoma. Bone metastases are exceedingly rare in cats.

Osteosarcomas are the most common primary bone neoplasm in dogs. They can affect either the appendicular or axial skeletons, and they occur primarily in large- and giantbreed dogs and in Greyhounds; they are common in middleage to older dogs. There is a distinct genetic predisposition to OSA in dogs; for example, in former racing Greyhounds OSA is the most common cause of death (i.e.; 25%), whereas OSAs are extremely rare in show Greyhounds in the U.S. The biologic behavior of OSA is characterized by aggressive local infiltration of the surrounding tissues and rapid hematogenous dissemination (usually to the lungs). Although historically it was believed that OSAs of the axial skeleton had a low metastatic potential, it now appears that their metastatic rate is similar to that of the appendicular OSAs.

#### **Clinical Features**

Appendicular OSAs occur predominantly in the metaphyses of the distal radius, distal femur, and proximal humerus, although other metaphyses can also be affected. As just mentioned, they typically affect Greyhounds and male dogs of large (and giant) breeds, and owners seek veterinary care because of lameness or swelling of the affected limb. Physical examination usually reveals a painful swelling in the affected area, with or without soft tissue involvement. The pain and swelling can be acute in onset, leading to the presumptive diagnosis of a nonneoplastic orthopedic problem and thus considerably delaying diagnosis and definitive therapy for the neoplasm. Pathologic fractures are common in Greyhounds with OSA but rare in other breeds.

# **Diagnosis**

Radiographically, OSAs exhibit a mixed lytic-proliferative pattern in the metaphyseal region of the affected bone (Fig. 82-4). Adjacent periosteal bone formation leads to the development of the so-called Codman's triangle, which is composed of the cortex in the affected area and the periosteal proliferation. OSAs typically do not cross the articular space, but occasionally they can infiltrate adjacent bone (e.g., ulnar lysis resulting from an adjacent radial OSA). Because other primary bone neoplasms and some osteomyelitis lesions can mimic the radiographic features of OSAs, cytology or biopsy specimens of every lytic or lytic-proliferative bone lesion should be obtained before the owners decide on a specific treatment. An exception to this rule is an owner who has already decided that amputation is the initial treatment of choice for that lesion (i.e., the limb is amputated and the lesion is submitted for histopathologic evaluation).

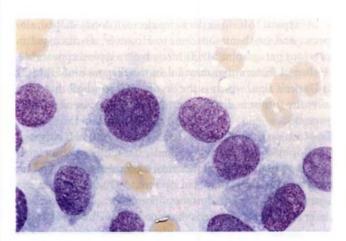

Once a presumptive radiographic diagnosis has been established and if the owners are contemplating treatment, thoracic and/or bone (i.e., skeletal survey) radiographs should be obtained to determine the extent of the disease. We usually obtain three radiographic views of the thorax and do not perform a skeletal radiographic survey (or radionuclide bone scan). Fewer than 10% of dogs with OSA initially have radiographically detectable lung lesions; the presence of metastases is a strong negative prognostic factor.

The radiographic diagnosis can be confirmed before surgery (i.e., limb amputation or limb salvage) on the basis of the findings yielded either by FNA or by aspiration of the affected area using a bone marrow aspiration needle. In most cases a blind percutaneous FNA can be performed with only manual restraint; if the operator cannot penetrate through the cortex, ultrasonographic guidance almost always allows visualization of a "window" through which the needle is inserted. OSA cells are usually round or oval; have distinct

FIG 82-4
Radiographic appearance of a typical osteosarcoma of the radius in a dog. Note the lytic and proliferative changes characteristic of this neoplasm. (Courtesy RM Gamblin.)

cytoplasmic borders; have a bright blue, granular cytoplasm; and have eccentric nuclei with or without nucleoli (Fig. 82-5); multinucelatedgiant cells are common, and there is frequenly pink amorphous material (osteoid) in the background or in the cytoplasm of the osteoblasts. If the round cells cannot be convincingly identified as osteoblast, most diagnostic laboratories can perform an alkaline phosphatase (ALP) cytochemical stain in unstained slides; osteoblasts are typically ALP-positive. A preamputation diagnosis can also be made after histopathologic evaluation of core biopsy specimens from the affected areas. To obtain a bone biopsy, a 13- or 11-gauge Jamshidi bone marrow biopsy needle (Monoject) is used with the animal under general anesthesia, and a minimum of two (and preferably three) cores of tissue are obtained from both the center of the lesion and the area between affected and unaffected bone. The diagnostic yield of this procedure is quite high (approximately 70% to 75%). In our clinic we obtain cytologic diagnoses in the vast majority of patients with OSA; we rarely need to perform a biopsy in order to confirm a diagnosis.

Characteristic cytologic features of osteosarcoma in a fineneedle aspirate of a lytic/proliferative lesion in the proximal scapula of a 12-year-old Wirehaired Terrier. Note the round to oval eccentric nuclei with a fine chromatin pattern and prominent nucleoli. (×1000.)

As long as the owners understand the biologic behavior of the neoplasm (i.e., the high likelihood of their dog dying of metastatic lung disease within 4 to 6 months of amputation if no chemotherapy is used) and as long as the clinical and radiographic features of the lesion are highly suggestive of OSA, the limb can be amputated in the absence of a histopathologic diagnosis. The amputated leg (or representative samples) and the regional lymph nodes should always be submitted for histopathologic evaluation. The presence of pulmonary or lymph node metastases is a negative prognostic factor for survival in dogs with OSA.

# **Treatment and Prognosis**

The treatment of choice for dogs with OSA is amputation with adjuvant single-agent or combination chemotherapy. The median survival time in dogs with appendicular OSA treated with amputation alone is approximately 4 months, whereas in dogs treated with amputation and cisplatin, amputation and carboplatin, amputation and doxorubicin, or amputation and combination chemotherapy it is approximately 1 year. The dosages for chemotherapy in dogs with OSA are given in the box on cancer chemotherapy protocols at the end of this chapter and Box 82-1. At our hospital we use either doxorubicin or carboplatin immediately after amputation for a total of five and four treatments, respectively. With the advent of generic carboplatin, the cost is now acceptable to most owners.

An alternative therapeutic approach for dogs with distal radial or ulnar OSAs consists of sparing the limb in affected dogs. Instead of amputation, the affected bone is resected and an allograft from a cadaver (or a prosthetic device) is used to replace the neoplastic bone; novel biomaterials are also currently being investigated for this purpose. The dogs are also treated with intravenous (IV) chemotherapy and, in

# BOX 82-1

Chemotherapy Protocols and Palliative Treatment for Dogs with Osteosarcoma

#### **Chemotherapy Protocols**

- 1. Carboplatin: 300 mg/m<sup>2</sup>, IV, q3 weeks for 4-6 doses
- Doxorubicin: 30 mg/m², IV, q2 weeks, for 5 doses
   Carboplatin: 300 mg/m², IV, on weeks 1 and 6 plus Doxorubicin: 30 mg/m<sup>2</sup>, IV, on weeks 3 and 9.

#### **Palliative Treatment**

- 1. Pamidronate: 1-2 mg/kg, IV CRI in 0.9% saline, over 1-2 hours, q2-4 weeks
- 2. Tramadol (Ultram®): 1-2 mg/kg, PO, q8-12h
- 3. Deracoxib (Deramaxx®): 1-2 mg/kg, PO, q24h\*

general, have almost normal limb function. Survival times in dogs treated with limb-sparing procedures are comparable to those in dogs that undergo amputation plus chemotherapy, with the added benefit to the owners of having a fourlegged pet. The main complication is the development of osteomyelitis in the allograft; if that occurs, the limb frequently needs to be amputated. However, in patients with infected allografts that eventually undergo amputation, the survival times are significantly longer than in dogs that did not experience complications (Lascelles et al., 2005).

If owners are reluctant to allow the veterinarian to amputate the limb, local radiotherapy plus chemotherapy may be beneficial. We usually avoid using doxorubicin as the chemotheraputic agent to prevent radiosensitization and severe cutaneous reactions to irradiation. In addition to radiation therapy, we use bisphosphonates (pamidronate 1-2 mg/kg, IV constant rate infusion, q2-4 weeks) and analgesics (see Box 82-1) for pain control and palliative care.

Chemotherapy may modify the biologic behavior of the tumor, resulting in a higher prevalence of bone metastases and a lower prevalence of pulmonary metastases. Moreover, the doubling time (i.e., growth rate) of metastatic lesions appears to be longer than that in dogs that have not received chemotherapy, and there appear to be fewer metastatic nodules in treated than in untreated dogs. Therefore surgical removal of the metastatic nodules (i.e., metastasectomy) followed by additional chemotherapy may be recommended for a dog that has been treated with chemotherapy after amputation of the limb and in which one to three pulmonary metastatic lesions are detected (O'Brien et al., 1993).

As discussed in previous paragraphs, the treatment of choice for OSAs in cats is limb amputation alone. Extremely long survival times (in excess of 2 years) are common in such cats. As discussed in Chapter 69, cisplatin is extremely toxic in cats and should therefore not be used in this species. If necessary, carboplatin or doxorubicin can be used instead.

<sup>\*</sup>Other nonsteroidal antiinflamatories are also effective. IV, Intravenous; CRI, continuous rate infusion; PO, by mouth.

# MAST CELL TUMORS IN DOGS AND CATS

Not one of them is like the other, don't ask me why, please ask your mother.

From One Fish, Two Fish, Red Fish, Blue Fish, by Dr. Seuss

Mast cell tumors (MCTs) are among the most common skin tumors in dogs and are relatively common in cats. They originate from mast cells, which are intimately involved in the local control of vascular tone and which contain a large array of intracytoplasmic bioactive molecules, including heparin, histamine, leukotrienes, and several cytokines. Given their unpredictable biologic behavior, the term *mast cell tumor* is preferred to *mastocytoma* or *mast cell sarcoma*. Because of differences in the clinical and pathologic features of canine and feline MCTs, they are discussed separately.

# MAST CELL TUMORS IN DOGS

# **Etiology and Epidemiology**

MCTs constitute approximately 20% to 25% of the skin and subcutaneous tumors seen by practicing veterinarians. Brachiocephalic breeds (Boxer, Boston Terrier, Bull Mastiff, English Bulldog) are at high risk for MCTs. These tumors are also more common in middle-age to older dogs (mean age, approximately 8.5 years) than in younger dogs, but there is no gender-related predilection. MCTs have been found in sites of chronic inflammation or injury, such as burn scars.

# **Clinical and Pathologic Features**

MCTs occur either as dermoepidermal masses (i.e., a superficial mass that moves with the skin) or subcutaneous masses (i.e., the overlying skin moves freely over the tumor). Grossly, MCTs can mimic any primary or secondary skin lesion, including a macula, papula, nodule, tumor, and crust. Approximately 10% to 15% of all MCTs in dogs are clinically indistinguishable from the common subcutaneous lipomas. As a rule, an MCT cannot be definitively diagnosed until the lesion has been evaluated cytologically or histopathologically.

Most MCTs are solitary, although multifocal MCTs can occur in dogs. Regional lymphadenopathy caused by metastatic disease is also common in dogs with invasive MCTs. Occasionally, splenomegaly or hepatomegaly is present in dogs with systemic dissemination.

Given the fact that mast cells produce a variety of bioactive (mainly vasoactive) substances, dogs with MCTs may be evaluated because of diffuse swelling (i.e., edema and inflammation around a primary tumor or its metastatic lesion), erythema, or bruising of the affected area. These episodes may be acute, and they may occur during or shortly after exercise or exposure to cold weather. Percutaneous FNA of an unexplained subcutaneous swelling in dogs should always be performed as part of the workup.

A "typical" MCT is a dermoepidermal, dome-shaped, alopecic, and erythematous lesion. However, as discussed in previous paragraphs, MCTs rarely have a typical appearance. A clinical feature that may aid in the diagnosis of an MCT is Darier's sign, which is the crythema and wheal that form after the tumor is slightly traumatized (i.e., scraped or compressed).

Most dogs with MCTs have a normal CBC, although eosinophilia (sometimes marked), basophilia, mastocythemia, neutrophilia, thrombocytosis, or anemia (or a combination of these) may be present. Serum biochemistry abnormalities are uncommon.

From a histopathologic standpoint, MCTs are traditionally classified into three categories: well differentiated (grade 1), moderately differentiated (grade 2), and poorly differentiated (grade 3). Several studies have shown that dogs with grade 1 tumors treated with surgery or radiotherapy have longer survival times than identically treated dogs with grade 3 tumors, mainly because well-differentiated neoplasms have a lower metastatic potential (i.e., most tumors in dogs with systemic mast cell disease are grade 3). Special stains may be required to identify the typical intracytoplasmic granules in poorly differentiated neoplasms. The mitotic index is of prognostic relevance in dogs with MCTs, so it should be provided by the pathologist (Romansik et al., 2007). In addition to the grading of the tumor, the pathologist should provide the clinician with information regarding the completeness of the excision. A dog with an incompletely excised MCT is rarely cured by the initial surgical procedure and requires either a second surgery or irradiation of the affected area.

From a molecular standpoint, a variable percentage of canine MCTs have c-kit mutations; c-kit is the stem cell growth factor receptor, and its mutation results in immortalized clones that do not undergo apoptosis (Jones et al., 2004).

# **Biologic Behavior**

The biologic behavior of canine MCTs can be summed up in one word: unpredictable. Even though several criteria may help in establishing the biologic behavior of these neoplasms, they rarely apply to an individual dog (i.e., they may be meaningful from the statistical viewpoint).

In general, well-differentiated (grade 1), solitary cutaneous MCTs have a low metastatic potential and low potential for systemic dissemination. However, the clinician may encounter a dog with several dozen cutaneous MCTs, which on histopathologic evaluation are well differentiated.

Grade 2 and 3 tumors have a higher metastatic potential and a higher potential for systemic dissemination than grade 1 MCTs. Metastases to the regional lymph nodes commonly occur (particularly in dogs with grade 3 tumors), although occasionally a tumor "skips" the draining lymph node and metastasizes to the second or third regional node (e.g., a digital MCT in the rear limb metastasizing to the iliac or sublumbar node). Because nodal metastases can be present in normal-size lymph nodes, every lymph node in the region

of an MCT should be aspirated regardless of whether it is enlarged or not. Pulmonary metastases are extremely rare. Although not evident from published clinical data, it appears that MCTs in certain anatomic locations are more aggressive than tumors in other areas. For example, distal limb (e.g., toe), perineal, inguinal, and extracutaneous (e.g., oropharyngeal, intranasal) MCTs appear to have a higher metastatic potential than similarly graded tumors in other regions (e.g., trunk, neck).

Another biologic characteristic of canine MCTs is that they may become systemic, behaving like a hematopoietic malignancy (i.e., a lymphoma or leukemia). These dogs usually have a history of a cutaneous MCT that was excised. Most dogs with systemic mast cell disease (SMCD) are evaluated because of lethargy, anorexia, vomiting, and weight loss in association with splenomegaly, hepatomegaly, pallor, and (occasionally) detectable cutaneous masses. The CBC in affected dogs commonly reveals cytopenias, with or without circulating mast cells.

MCTs can release bioactive substances that may cause edema, erythema, or bruising of the affected area. Gastrointestinal tract ulceration may also occur as a result of hyperhistaminemia (approximately 80% of dogs euthanized because of advanced MCTs have gastroduodenal ulceration). Therefore any dog with an MCT should undergo occult fecal blood testing. Profuse intraoperative and postoperative bleeding and delayed wound healing occur in some dogs as a consequence of the bioactive substances released from mast cells.

# Diagnosis

The evaluation of a dog with a suspected MCT should include FNA of the affected area. MCTs are extremely easy to diagnose cytologically. They consist of a monomorphic population of round cells with prominent intracytoplasmic purple granules; eosinophils are frequently present in the smear (see Fig. 75-6). In approximately one third of MCTs, the granules do not stain with Diff-Quik; hence if agranular round cells are found in a dermal or subcutaneous mass resembling an MCT, the clinician should stain the slide with Giemsa or Wright's stain to reveal the characteristic purple granules. A cytologic diagnosis of MCT allows the clinician to discuss treatment options with the owner and to plan therapeutic strategies (see the section on treatment and prognosis).

Although clinical pathologists frequently state the degree of differentiation of the cells in a cytologic specimen of an MCT, that scheme does not necessarily correlate with the histopathologic grading system. In other words, a cytologic diagnosis of a well-differentiated MCT does not necessarily imply that it will be a grade 1 tumor when evaluated histopathologically (i.e., cytologic grading may not have the same prognostic implications as histopathologic grading).

The clinical evaluation of a dog with a cytologically confirmed MCT should include careful palpation of the affected area and its draining lymph nodes; abdominal palpation, radiography, or ultrasonography to search for hepatosplenomegaly; a CBC, serum biochemistry profile, and urinalysis; and thoracic radiography if the neoplasm is in the anterior one half of the body (i.e., to detect intrathoracic lymphadenopathy). If lymphadenopathy, hepatomegaly, or splenomegaly is present, FNA of the enlarged lymph node or organ should be performed to detect mast cells (i.e., local neoplasm versus metastatic tumor versus SMCD).

The use of a buffy coat smear to search for circulating mast cells is controversial. It was thought that the presence of mast cells in a buffy coat smear indicated systemic dissemination and therefore a poor prognosis. However, dogs with a solitary, potentially curable MCT occasionally have low numbers of circulating mast cells that disappear from circulation shortly after the primary tumor is excised or irradiated. Moreover, a recent study revealed that circulating mast cells are more common in dogs with diseases other than MCTs; over 95% of the CBCs with circulating mast cells were from dogs with inflammatory disorders, regenerative anemia, tumors other than MCTs, and trauma (McManus, 1999). Also, dogs with MCT had significantly lower circulating mast cell counts (71 per buffy coat smear) than those with other diseases (276 per buffy coat smear). Cytologic evaluation of a bone marrow aspirate may therefore be more beneficial for staging purposes. Dogs with more than five mast cells per 500 nucleated cells are believed to have SMCD; however, bone marrow mast cells have also been documented to disappear after excision or irradiation of the primary tumor. Therefore the appropriate staging procedures in dogs with MCTs remains controversial. At our clinic we do not use buffy coat smears or bone marrow aspirates routinely in dogs with MCT and a normal CBC; if cytopenias or leukoerythroblastic reactions are present, we perform a bone marrow aspirate.

As discussed previously, all dogs with MCTs should be tested for occult blood in the stool even if melena is not evident. There are several kits for this purpose. The presence of blood in the stool is suggestive of upper gastrointestinal tract bleeding. If this is found on repeat testing, the dog should be treated with H<sub>2</sub> antihistamines (i.e., famotidine, ranitidine) with or without a coating agent (i.e., sucralfate; see Chapter 30). Once this clinical information is obtained, the tumor should be staged to determine the extent of disease (Table 82-1).

# **Treatment and Prognosis**

As discussed previously, it is imperative to know whether the mass the clinician is preparing to excise is an MCT because this information is useful when discussing treatment options with the client and when planning the treatment strategy. Dogs with MCT can be treated with surgery, radiotherapy, chemotherapy, or a combination of these. However, the first two treatment options are potentially curative, whereas chemotherapy is usually only palliative. Treatment guidelines are provided in Table 82-2.

A solitary MCT in an area in which complete surgical excision is feasible should be removed by aggressive en bloc resection (i.e., 2- to 3-cm margins around and underneath

the tumor). If a complete excision is obtained (according to the pathologist evaluating the specimen), the tumor is grade 1 or 2, and no metastatic lesions are present; there is usually no need for further treatment (i.e., the dog is most likely cured). If the excision appears incomplete, the clinician can take one of three courses of action: (1) perform a second surgery in an attempt to excise the remaining tumor (the excised area should be submitted for histopathologic evaluation to assess the completeness of excision); (2) irradiate the surgical site (35 to 40 Gy delivered in 10 to 12 fractions); or (3) administer a short course (3-6 months) of lomustine chemotherapy (discussed later). The three options appear to be equally effective, resulting in approximately an 80% probability of long-term survival.

闘

	b. With systemic signs
111	Multiple dermal tumors or a large infiltrating
	tumor with or without regional lymph node
	involvement
	a. Without systemic signs
	b. With systemic signs
IV	Any tumor with distant metastases or
	recurrence with metastases
	a. Without systemic signs
	b. With systemic signs

A solitary MCT in an area in which surgical excision is difficult or impossible, or at a site where the cosmetic or functional results are unacceptable (e.g., prepuce, eyelid), can be successfully treated with radiotherapy. Approximately two thirds of dogs with a grade 1 or 2 localized MCT treated with radiotherapy alone are cured. Irradiation is also recommended for the management of tumors in high-risk areas. Intralesional injections of corticosteroids (triamcinolone [Vetalog], 1 mg intralesionally per centimeter of tumor diameter q2-3 weeks) can also successfully shrink the tumor (although it is usually only palliative). Intralesional injections of deionized water have also been reported to be beneficial in managing local MCTs, although that has not been my experience. An alternative approach is to use neodajuvant chemotherapy (ie; chemotherapy before and after surgery). In these dogs a combination of lomustine and prednisone is used, with or without vinblastine, in order to decrease the tumor size; then surgery is performed, followed by chemotherapy (discussed later).

Once metastatic or disseminated MCTs (or SMCD) develop, a cure is rarely obtained. Treatment in these dogs consists of chemotherapy and supportive therapy and is aimed at palliating the neoplasm and its complications. Results of prospective studies of chemotherapy in dogs with MCTs have not been very encouraging; two chemotherapy protocols have been widely used (see box on cancer chemotherapy protocols at the end of this chapter): (1) prednisone and (2) the CVP protocol (cyclophosphamide, prednisone, vinblastine). Over the past several years, lomustine (CCNU) has been used with a high degree of success in dogs with nonresectable, metastatic, or systemic MCTs. The probability of response is high (>50%), and remissions in excess of 18 months in dogs with metastatic grade 2 and 3 MCTs have been documented. Lomustine can be combined with prednisone, vinblastine, or both (see Table 82-2).

Traditionally, I used lomustine, with or without prednisone (see Table 82-2), and famotidine and/or sucralfate in dogs with metastatic or nonresectable MCTs. Although

TABLE 82-2

Treatment Guidelines for Dogs with Mast Cell Tumors

STAGE	GRADE	RECOMMENDED TREATMENT	FOLLOW-UP
1	1, 2	Surgical excision	Complete→observe Incomplete→second surgery or radiotherapy
1	3	Chemotherapy*	Continue chemotherapy
11	1, 2, 3	Surgical excision or radiotherapy	CCNU and prednisone (see below)*
III, IV	1, 2, 3	Chemotherapy*	Continue chemotherapy
Chemothe	erapy protoco	ols for dogs with mast cell tumors:	

1. Prednisone, 50 mg/m² by mouth (PO) q24h for 1 week; then 20-25 mg/m² PO q48h indefinitely plus lomustine (CCNU, Ceenu), 60 mg/m² PO q3 weeks.

Prednisone, 50 mg/m² by mouth (PO) q24h for 1 week; then 20-25 mg/m² PO q48h indefinitely plus lomustine (CCNU, Ceenu), 60 mg/m² PO q6 weeks, alternating doses with vinblastine, 2 mg/m², IV, q6 weeks (the dog receives lomustine, 3 weeks later vinblastine, 3 weeks later lomustine again, and so on)

<sup>\*</sup> For more information, see box at the end of this chapter.

lomustine is potentially myelosuppressive, clinically relevant cytopenias are rare; however, hepatotoxicity is common (see Chapter 78), so chemistry profiles should be evaluated periodically. The addition of vinblastine allows administration of lomustine every 6 weeks instead of every 3 weeks; this may decrease the prevalence of hepatotoxicity.

Small molecule tyrosine kinase inhibitors have demonstrated efficacy against some canine MCTs with c-kit mutations and will likely be available in the near future (Pryer et al., 2003; London et al., 2003)

#### MAST CELL TUMORS IN CATS

#### **Etiology and Epidemiology**

Although MCTs are relatively common in cats, they rarely result in the considerable clinical problems seen in dogs with this neoplasm. Most cats with MCTs are middle-age or older (median, 10 years old), there is apparently no gender-related predilection, and Siamese cats may be at high risk. Feline leukemia virus and feline immunodeficiency virus do not play a role in the development of this tumor.

As opposed to the dog, in which most of the MCTs are cutaneous or subcutaneous, cats exhibit two main forms of feline MCTs: visceral and cutaneous. There is controversy as to whether cutaneous forms are more common than visceral forms and whether both forms can co-exist in the same cat. At our clinic the cutaneous form is considerably more common than the visceral form, and it is extremely rare for the cutaneous and visceral forms to coexist.

#### **Clinical and Pathologic Features**

Visceral MCTs are characterized by either hemolymphatic or intestinal involvement. Cats with hemolymphatic disease are classified as having SMCD (or mast cell leukemia) because the bone marrow, spleen, liver, and blood are commonly involved. Most cats initially have nonspecific signs such as anorexia and vomiting; abdominal distention caused by massive splenomegaly is a consistent feature. As in dogs, the hematologic abnormalities in cats with SMCD are extremely variable and include cytopenias, mastocythemia, basophilia, eosinophilia, or a combination of these; however, a high percentage of cats may have normal CBCs. Cats with the intestinal form of SMCD usually are evaluated because of gastrointestinal signs such as anorexia, vomiting, or diarrhea. Abdominal masses are palpated in approximately one half of these cats. Most tumors involve the small intestine, where they can be solitary or multiple. Metastatic disease affecting the mesenteric lymph nodes, liver, spleen, and lungs is commonly found at the time of presentation. Multiple intestinal masses in cats are most commonly associated with lymphoma and with MCT, although both neoplasms can co-exist. Gastrointestinal tract ulceration has also been documented in affected cats.

Cats with cutaneous MCTs usually initially have solitary or multiple, small (2 to 15 mm), white to pink dermoepidermal masses primarily in the head and neck regions, although solitary dermoepidermal or subcutaneous masses also occur

in other locations. It has been reported that, on the basis of the clinical, epidemiologic, and histologic features, MCTs in cats can be classified as either mast cell-type MCTs (common) or histiocytic-type MCTs (rare). Cats with mast cell-type MCTs are usually older than 4 years of age and have solitary dermal masses; there is no apparent breed predilection. Cats with histiocytic-type MCTs are primarily Siamese cats younger than 4 years of age. Typically, such cats have multiple (miliary) subcutaneous masses that exhibit a benign biologic behavior. Some of these neoplasms appear to regress spontaneously. We have never seen the histiocytic type of disease in cats treated at our clinic, even in Siamese cats with multiple dermoepidermal nodules. The subcutaneous MCTs commonly seen in dogs are extremely rare in cats. Unlike the situation in dogs, the histopathologic grade does not appear to correlate well with the biologic behavior of MCTs in cats (Molander-McCrary et al., 1998).

#### **Diagnosis and Treatment**

The diagnostic approach to cats with MCT is similar to that in dogs. As in dogs, some mast cells in cats are poorly granulated and the granules may not be easily identified during a routine cytologic or histopathologic evaluation.

The treatment for cats with MCTs is controversial. As a general rule, surgery is indicated for cats with a solitary cutaneous mass, for cats with two to five skin masses, and for cats with intestinal or splenic involvement. As discussed previously, cutaneous MCTs in cats are less aggressive than in dogs, and in most affected cats removal of a solitary dermoepidermal MCT using a biopsy punch is curative; the same applies to cats with fewer than five dermoepidermal MCTs. The combination of splenectomy, prednisone, and chloramibucid (Leukeran) treatment is recommended for cats with SMCD, in which survival times in excess of approximately 1 year are common; splenectomy alone does not result in prolonged survival. Surgical excision and prednisone treatment are recommended for cats with intestinal MCT. Prednisone alone (4 to 8 mg/kg by mouth q24-48h) may also be beneficial for cats with systemic or metastatic MCTs. Cats with multiple skin MCTs are best treated with prednisone, in the dosage just given. Although radiotherapy is as effective in cats as in dogs, it is rarely necessary in cats with this neoplasm. When an additional chemotherapeutic agent is needed in cats with MCTs, I usually use chlorambucil (Leukeran, 20 mg/m² by mouth q2 weeks); this drug seems to be quite effective and well tolerated. In my limited experience, lomustine (CCNU) is not very effective in cats with MCTs.

#### INJECTION SITE SARCOMAS IN CATS

An association between injections/vaccination and the development of sarcomas has been recently recognized in cats, and epidemiologic studies have confirmed the association. In this syndrome fibriosarcomas (FSAs) or occasionally other types of sarcomas develop in the subcutis

or muscle in the interscapular region or the thigh, common sites of injection/vaccination. It is estimated that a sarcoma develops in one to two of 10,000 cats that receive an injection. Although the exact pathogenesis is still unclear, both the adjuvants and the local immune response against the antigens (i.e.; inflammation) have been implicated as causative agents.

A rapidly growing soft tissue mass develops in the region weeks to months after vaccination or injection in cats with injection site sarcomas (ISSs). A vaccine- or injection-associated inflammatory reaction may precede the development of this neoplasm. Therefore an ISS should be suspected in any cat with a superficial or deep mass in the interscapular or thigh regions, and every effort should be made to establish a diagnosis immediately. Although FNA findings may provide a definitive answer, more often a surgical biopsy is necessary because sarcomas do not consistently exfoliate cells (see Chapter 75).

Although most FSAs in dogs and cats have a low metastatic potential, ISSs are quite aggressive and should be treated accordingly. Although studies are currently in progress, on the basis of the results of studies reported in the literature and on the findings in cats seen at our clinic, the rate of metastasis of ISSs is high (probably as high as 50% to 70%). Pulmonary metastatic lesions can be detected at presentation in a high proportion of cats; we have also seen ocular metastases as the main presenting feature in a few cats with ISSs.

The treatment of choice for cats with ISS is aggressive surgical excision (see Chapter 76). In keeping with the maxim "cut it once, but cut it all," an en bloc resection (to include any biopsy tracts) should be performed immediately after the diagnosis is established, provided there is no metastatic disease. In a recent study cats treated with aggressive surgery had significantly longer disease-free survival times than cats treated with conservative surgery (274 versus 66 days); also, cats with tumors in the limbs had significantly longer diseasefree survival times than cats with tumors in the trunk (325 versus 66 days; Hershey et al., 2000). Complete surgical excision of a relatively small ISS (i.e., <2 cm in diameter) is usually associated with long-term remissions. Although the role of postoperative adjuvant chemotherapy has not been thoroughly evaluated, cats with large or incompletely excised tumors may benefit from treatment with mitoxantrone and cyclophosphamide, doxorubicin and cyclophosphamide, or carboplatin. We have seen objective complete or partial responses in cats with nonresectable or metastatic ISS treated with doxorubicin/ cyclophosphamide combinations or with carboplatin alone; some of these cats have been in remission for longer than 1 year. If metastatic disease is already present, chemotherapy is not usually effective.

#### Cancer Chemotherapy Protocols Commonly Used at the l Ohio State University Veterinary Teaching Hospital

#### 1. Lymphoma

A. Induction of remission

1. COAP protocol

Cyclophosphamide: 50 mg/m² PO q48h for 8 weeks in dogs; 200-300 mg/m² PO q3 weeks in cats

Vincristine: 0.5 mg/m<sup>2</sup> IV once per week for 8 weeks

Cytosine arabinoside: 100 mg/m² IV or SC divided q12h for 4 days

Prednisone: 40-50 mg/m² PO q24h for 1 week; then 20-25 mg/m² PO q48h for 7 weeks

In cats cystosine arabinoside is administered for only 2 days and the remaining three drugs (cyclophosphamide, vincristine, prednisone) are administered for 6 weeks rather than 8 weeks.

<sup>\*</sup> The daily dose should be divided into two to four daily administrations.

<sup>\*</sup> The duration of chemotherapy using this protocol varies.

PO, Orally; IV, intravenously; SC, subcutaneously; IM, intramuscularly; CRI, constant rate infusion.

# X

#### Cancer Chemotherapy Protocols Commonly Used at the Ohio State University Veterinary Teaching Hospital—cont'd

2. COP protocol

Cyclophosphamide: 50 mg/m<sup>2</sup> PO q48h or 300 mg/m<sup>2</sup> PO q3 weeks\*

Vincristine: 0.5 mg/m<sup>2</sup> IV once per week

Prednisone: 40-50 mg/m<sup>2</sup> PO q24h for 1 week; then 20-25 mg/m<sup>2</sup> PO q48h

3. CLOP protocol

As in COP protocol but with the addition of Lasparaginase at a dosage of 10,000-20,000 IU/m² IM q4-6 wk

4. CHOP protocol (21-day cycle)

Cyclophosphamide:  $200-300 \text{ mg/m}^2 \text{ PO}$  on day  $10 \text{ Doxorubicin: } 30 \text{ mg/m}^2 \text{ IV or } 1 \text{ mg/kg if } < 10 \text{ kg on day } 1$ 

Vincristine: 0.75 mg/m<sup>2</sup> IV on days 8 and 15

Prednisone: 40-50 mg/m<sup>2</sup> PO q24h on days 1-7; then 20-25 mg/m<sup>2</sup> PO q48h on days 8-21

Sulfa-trimethoprim: 15 mg/kg PO g12h

5. UW-19 protocol (This protocol uses no maintenance chemotherapy—for additional information please see text)

Week 1: Vincristine: 0.5-0.75 mg/m², IV L-asparaginase: 400 IU/KG IM or SC Prednisone: 2 mg/kg PO q24h

Week 2: Cyclophosphamide: 200-250 mg/m², IV

Prednisone: 1.5 mg/kg PO q24h

Week 3: Vincristine: 0.5-0.75 mg/m², IV Prednisone: 1 mg/kg PO q24h

Week 4: Doxorubicin: 30 mg/m² (or 1 mg/kg if <10 kg) IV

Prednisone: 0.5 mg/kg PO q24h

Week 5: No treatment

Week 6: Vincristine: 0.5-0.75 mg/m<sup>2</sup>, IV

Week 7: Cyclophosphamide: 200-250 mg/m², IV

Week 8: Vincristine: 0.5-0.75 mg/m², IV

Week 9: Doxorubicin: 30 mg/m² (or 1 mg/kg if <10 kg) IV

Week 10: No treatment

Week 11: Vincristine: 0.5-0.75 mg/m<sup>2</sup>, IV

Week 12: Cyclophosphamide: 200-250 mg/m², IV

Week 13: Vincristine: 0.5-0.75 mg/m<sup>2</sup>, IV

Week 14: Doxorubicin: 30 mg/m<sup>2</sup> (or 1 mg/kg if <10 kg) IV

Week 15: No treatment

Week 16: Vincristine: 0.5-0.75 mg/m<sup>2</sup>, IV

Week 17: Cyclophosphamide: 200-250 mg/m<sup>2</sup>, IV

Week 18: Vincristine: 0.5-0.75 mg/m², IV

Week 19: Doxorubicin: 30 mg/m<sup>2</sup> (or 1 mg/kg if <10 kg) IV

#### B. Maintenance

1. LMP protocol

Chlorambucil: 20 mg/m<sup>2</sup> PO every other week

Prednisone: 20-25 mg/m<sup>2</sup> PO q48h

Methotrexate: 2.5-5 mg/m<sup>2</sup> PO 2 or 3 times per week

2. LAP protocol

Chlorambucil: 20 mg/m² PO every other week

Prednisone: 20-25 mg/m<sup>2</sup> PO q48h

Cytosine arabinoside (Cytosar): 200-400 mg/m<sup>2</sup> SC q2 weeks; alternating with chlorambucil

3. COP protocol used every other week for 6 cycles; then every third week for 6 cycles; then monthly thereafter

#### C. "Rescue" DOGS

1. D-MAC protocol (repeat continuously for 10-16 weeks)

Dexamethasone: 0.5 mg/lb (0.23 mg/kg) PO or SC on days 1 and 8

Actinomycin D (Cosmegen): 0.75 mg/m² IV push on day 1

Cytosine arabinoside (Cytosar): 200-300 mg/m² IV drip over 4 hours or SC on day 1

Melphalan (Alkeran): 20 mg/m<sup>2</sup> PO on day 8 (after 4 doses of melphalan, substitute Leukeran at the same dose)

2. CHOP protocol if second relapse in response to COAP protocol or if good response to Adriamycin was previously observed

#### Cancer Chemotherapy Protocols Commonly Used at the Ohio State University Veterinary Teaching Hospital—cont'd

#### **CATS**

1. ACD protocol (21-day cycle)

Doxorubicin: 1 mg/kg IV on day 1

Cyclophosphamide: 200-300 mg/m<sup>2</sup>, PO, on day 10

Dexamethasone: 4 mg/cat, PO q1-2 weeks

AMD protocol

Cytosine arabinoside: 100-200 mg/m²/day IV drip for 1-2 days Mitoxantrone: 4 mg/m<sup>2</sup> in IV drip, mixed in the bag with the Cytosar

Dexamethasone: 0.5-1 mg/lb (0.23-0.45 mg/kg) PO weekly; repeat q3 weeks

II. Acute lymphoid leukemia (ALL)

COAP, CLOP, or COP protocols

III. Chronic lymphocytic leukemia (CLL)

1. Chlorambucil: 20 mg/m² PO q2 weeks (with or without prednisone, 20 mg/m² PO q48h)

2. Cyclophosphamide: 50 ma/m<sup>2</sup> PO a48h

Prednisone: 20 mg/m<sup>2</sup> PO g48h

IV. Acute myelogenous leukemia

1. Cytosine arabinoside: 5-10 mg/m<sup>2</sup> SC q12h for 2-3 weeks; then on alternate weeks

2. Cytosine arabinoside: 100-200 mg/m<sup>2</sup> in IV drip over 4 hours

Mitoxantrone: 4-6 mg/m² in IV drip over 4 hours; repeat every 3 weeks

V. Chronic myelogenous leukemia

1. Hydroxyurea (Hydrea): 50 mg/kg PO q24-48h until normal white blood count

VI. Multiple myeloma

1. Melphalan (Alkeran): 2-4 mg/m² PO g24h for 1 week; then g48h. Can also be given at 6-8 mg/m² PO for 5 days, repeating every 21 days

Prednisone: 40-50 mg/m<sup>2</sup> PO q24h for 1 week, then 20 mg/m<sup>2</sup> PO q48h

2. As in III.2

VII. Mast cell tumors (systemic)

1. Prednisone: 40-50 mg/m<sup>2</sup> PO g24h for 1 week; then 20-25 mg/m<sup>2</sup> PO g48h

2. Lomustine (CCNU): 60- mg/m<sup>2</sup> PO g3 wks (with or without prednisone as in 1)

3. LVP protocol

Vinblastine (Velban): 2 mg/m<sup>2</sup> IV q6 weeks alternating with

Lomustine (CCNU): 60 mg/m<sup>2</sup> PO q6 weeks

Prednisone: 20-25 mg/m<sup>2</sup> PO q48h

VIII. Soft-tissue sarcomas—dogs

1. VAC protocol (21-day cycle)

Vincristine: 0.75 mg/m<sup>2</sup> IV on days 8 and 15

Doxorubicin: 30 mg/m<sup>2</sup> IV (or 1 mg/kg if <10 kg) on day 1

Cyclophosphamide: 200-300 mg/m² PO on day 10

Sulfa-trimethoprim: 15 mg/kg PO q12h

IX. Soft-tissue sarcomas—cats

1. AC protocol (21 day cycle)

Doxorubicin: 1 mg/kg IV on day 1

Cyclophosphamide: 200-300 mg/m<sup>2</sup> on day 10

2. VAC protocol (28-day cycle)

Vincristine: 0.5 mg/m<sup>2</sup> IV on days 8, 15, and 22

Doxorubicin: 1 mg/kg IV on day 1

Cyclophosphamide: 200-300 mg/m<sup>2</sup> on day 10

3. MiC protocol (21-day cycle)

Mitoxantrone: 4-6 mg/m<sup>2</sup> in IV drip over 4 hours on day 1 Cyclophosphamide: 200-300 mg/m² PO on day 10

4. Carboplatin: 200-280 mg/m<sup>2</sup> IV q3 weeks

X. Osteosarcoma-dogs

1. Doxorubicin: 30 mg/m<sup>2</sup> IV q2 weeks for 5 doses

2. Carboplatin: 300 mg/m<sup>2</sup> IV a3 weeks for 4-6 doses

Doxorubicin and carboplatin as above, alternating drugs q3 weeks for 2-3 doses each

# X

#### Cancer Chemotherapy Protocols Commonly Used at the Ohio State University Veterinary Teaching Hospital—cont'd

#### XI. Carcinomas—dogs

1. FAC protocol

5-Fluorouracil: 150 mg/m<sup>2</sup> IV on days 8 and 15

Doxorubicin: 30 mg/m<sup>2</sup> (or 1 mg/kg if <10 kg) IV on day 1

Cyclophosphamide: 200-300 mg/m<sup>2</sup> PO on day 10

Sulfa-trimethoprim: 15 mg/kg PO q12h

2. VAF protocol

Vincristine: 0.75 mg/m<sup>2</sup> IV on days 8 and 15

Doxorubicin: 30 mg/m² (or 1 mg/kg if <10 kg) IV on day 1

5-Fluorouracil:  $150 \text{ mg/m}^2$  IV on days 1, 8, and 15

3. VAC protocol

4. Carboplatin: 300 mg/m<sup>2</sup> IV q3 weeks

5. Gemcitabine: 675 mg/m<sup>2</sup>, IV CRI for 30 minutes, q2 weeks

#### XII. Carcinomas—cats

## 5-Fluorouracil is toxic for the cat, producing severe, and often fatal, central nervous system signs. Cisplatin is also extremely toxic, causing acute pulmonary toxicity in this species.

1. Carboplatin: 200-280 mg/m<sup>2</sup> IV q3 weeks

2. AC protocol (21-day cycle)

Doxorubicin: 1 mg/kg IV on day 1

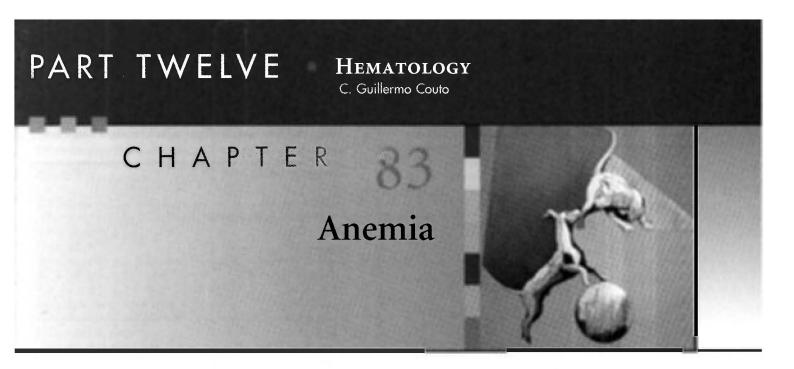

Cyclophosphamide: 200-300 mg/m<sup>2</sup> PO on day 10

3. MiC protocol (21-day cycle)

Mitoxantrone: 4-6 mg/m² IV drip over 4 hours on day 1 Cyclophosphamide: 200-300 mg/m² PO on day 10

4. MiCO protocol (21-day cycle)

Mitoxantrone: 4-6 mg/m² IV drip over 4 hours on day 1 Cyclophosphamide: 200-300 mg/m² PO on day 10 Vincristine: 0.5-0.6 mg/m² IV on days 8 and 15

Complications of Transfusion Therapy

#### **DEFINITION**

Anemia is defined as a decrease in the red blood cell (RBC) mass. In practical terms it can be defined as a decrease in the packed cell volume (PCV) or hematocrit (HCT), the hemoglobin (Hb) concentration, or the RBC count below reference values for the species. In the context of this chapter, PCV and HCT are used interchangeably. In special circumstances, anemia is diagnosed in a given patient with a HCT that has decreased over time even though it may remain within reference values. For example, Greyhounds rarely

have HCT values less than 50%, so an anemic Greyhound may have a HCT within the reference range for the dog. Because the reference values reflect the actual status in 95% of the feline and canine population, occasionally an "abnormal" value is indeed normal for a particular animal, prompting a needless evaluation in search of other abnormalities. Of note, anemia does not constitute a primary diagnosis; therefore every effort should be made to identify its cause.

## CLINICAL AND CLINICOPATHOLOGIC EVALUATION

When interpreting the HCT, Hb concentration, or RBC count, the clinician should keep in mind that in some situations these values are above (e.g., sight hounds) or below (e.g., puppyhood, pregnancy) the reference value for the species. From a practical standpoint, when evaluating the erythroid series, the clinician does not need to assess all the values in the complete blood count (CBC) because several of them provide identical information. For example, the HCT, Hb concentration, and RBC count provide the same type of information (i.e., an increase in the number of RBCs usually results in an increased HCT and Hb concentration, and vice versa). Thus when evaluating the erythron in a CBC, the HCT is typically used as an indirect index of the RBC mass (or number).

The main clinical manifestations of anemia in cats and dogs include pale or icteric mucous membranes, lethargy, exercise intolerance, pica (mainly in cats), and decreased overall activity (Box 83-1). These clinical signs can be acute or chronic and can vary in severity; the duration of the clinical signs may not reflect the mechanism of anemia. For example, "acute" clinical signs are common in cats with chronic anemia; most cats with chronic anemia compensate by shifting the oxyhemoglobin dissociation curve to the right, thus releasing oxygen to the tissues more readily.

BOX 83-1

Clinical Manifestations of Anemia in Cats and Dogs

#### History

- 1. Family history
- 2. Exercise intolerance, syncopal episodes
- 3. Pallor, jaundice
- 4. Localized or generalized bleeding
- 5. FeLV or FIV infection
- 6. Malnutrition, malabsorption
- 7. Chronic inflammation, cancer
- 8. Travel history

#### **Physical Examination**

- 1. Pallor, jaundice, petechiae, ecchymoses
- 2. Lymphadenopathy
- 3. Hepatomegaly, splenomegaly
- Tachycardia, heart murmur, cardiomegaly, left ventricular hypertrophy
- 5. Occult blood in the stool
- 6. Hematuria

FeLV, Feline leukemia virus; FIV, feline immunodeficiency virus.

Therefore cats are clinically stable until their HCT level gets below a specific percent and they develop "acute" signs. Owners may also detect some of the adaptive changes to anemia, such as tachycardia or an increased precordial beat. Following are several important questions to ask the owner of an anemic cat or dog:

- Is the pet currently receiving any medication? Certain drugs can cause hemolysis, gastrointestinal blood loss, or bone marrow hypoplasia.
- Have the owners detected any blood loss or dark (tarry) stool? Gastrointestinal tract bleeding from a gastric ulcer or a tumor can lead to iron deficiency anemia (IDA).
- Have the owners noticed any fleas? Severe flea infestation can cause IDA.
- Has the cat recently been tested for feline leukemia (FeLV)
  or feline immunodeficiency virus (FIV) infections? Retroviruses can cause bone marrow hypoplasia, myelodysplasia, or leukemias, leading to cytopenias.
- Has the owner noticed any ticks on the dog? Ehrlichiosis can cause bone marrow hypoplasia; babesiosis can cause hemolysis.
- Has the pet been vaccinated recently? Modified live vaccines can cause bleeding as a result of platelet dysfunction or thrombocytopenia, or they can be associated with immune-mediated hemolysis.
- Has the bitch received any "shots" for mismating recently?
   Estrogen derivatives can cause bone marrow aplasia or hypoplasia.

In addition to these questions, a detailed travel and pharmacologic history should be obtained. Certain infectious

diseases associated with anemia may have geographic distribution (e.g., babesiosis in the southeastern part of the United States); however, because dogs frequently travel throughout the United States, the geographic disease distribution is becoming less common. Some drugs and toxins that have been associated with anemia in cats and dogs are listed in Box 83-2.

When evaluating a patient with pallor, determine whether it is attributable to hypoperfusion or anemia (i.e., not every patient with pale mucous membranes is anemic). The simplest approach is to evaluate the HCT and the capillary refill time (CRT). Dogs and cats with cardiovascular disease and hypoperfusion usually have normal HCT values and additional clinical signs, whereas symptomatic anemic dogs have low HCT. Dogs and cats with congestive heart failure occasionally have dilutional anemia caused by intravascular fluid retention. The CRT may be difficult to evaluate in anemic cats and dogs because of the absence of contrast from the pallor.

The clinician should also look for petechiae, ecchymoses, and evidence of deep bleeding in animals with pallor. These findings are suggestive of a platelet or clotting factor deficiency (as seen in animals with Evans syndrome, disseminated intravascular coagulation [DIC], or acute leukemias; see Chapter 87), resulting in bleeding and secondary anemia. Particular attention should be paid to the lymphoreticular organs, such as the lymph nodes and spleen, because several disorders associated with anemia may also result in lymphadenopathy, hepatosplenomegaly, or both (Table 83-1).

Disorders Commonly Associated with Anemia and Hepatomegaly, Splenomegaly, and/or Lymphadenopathy

DISORDER	FREQUENCY	SPECIES
lumnhama	c	D, C
Lymphoma	<u></u>	
Mycoplasmosis	F	C > D
Acute leukemias	F	C, D
Ehrlichiosis	F*	D > C
Systemic mast cell disease	R	C > D
Bone marrow hypoplasia	R	C, D
1HA	F	D > C
Hypersplenism	R	D, C

<sup>\*</sup>Geographic variation.

Abdominal radiographs in a dog with intravascular hemolysis may show metallic foreign bodies in the stomach, a potential source of zinc that frequently results in RBC lysis.

The degree of anemia may be helpful in establishing its cause. To this end, anemias are graded according to HCT level as follows:

	Dogs	Cats
Mild	30%-36%	20%-24%
Moderate	18%-29%	15%-19%
Severe	<18%	<14%

For example, if an anemic dog or cat has severe anemia, certain causes (e.g., bleeding, anemia of chronic disease, anemia of renal disease, IDA) can immediately be ruled out because none of those mechanisms is likely to result in such a severe decrease in the HCT; therefore the patient most likely has hemolysis or a bone marrow disorder (see below). The severity of the clinical signs usually also correlates with the pathogenesis of the anemia. For example, a dog or cat with severe anemia and mild to moderate clinical signs more likely has a chronic cause of anemia (e.g., bone marrow disease); acute causes of severe anemia (e.g., hemolysis) result in clinical signs of marked severity because the adaptive compensatory changes have not yet occurred.

As part of the evaluation of a patient's HCT, the plasma should be examined for evidence of icterus or hemolysis and the protein content should be determined with a refractometer. The microhematocrit tube should be carefully inspected for evidence of autoagglutination (see p. 1215) and a slide agglutination test should be performed (see below). A blood smear should be evaluated to detect morphologic changes that may point the clinician toward the cause of the anemia.

A common issue that comes up often is whether a general practicing veterinarian should do CBCs in-house or send them to a referral laboratory. The recent introduction of accurate, user-friendly, benchtop hematology analyzers has

BOX 83-3

Pathogenetic Classification of Anemias

Regenerative	
Blood loss (after 48-96 hours) Hemolysis	
Semiregenerative	
IDA	
Nonregenerative	
ACD	
ARD	
Bone marrow disorder	
Blood loss/hemolysis (first 48-96 hours)	
Endocrine anemia	

IDA, Iron deficiency anemia; ACD, anemia of chronic disease; ARD, anemia of renal disease.

revolutionized the practice of small animal hematology. Most of these instruments are trouble free and provide accurate results. However, when values are outside the reference range or are flagged, the clinician or technician should evaluate a blood smear from the patient in question.

Once the patient has been established as anemic, it should be determined whether the anemia is regenerative or nonregenerative. This is accomplished by obtaining a reticulocyte count during a routine CBC (some of the in-house analyzers, such as the LaserCyte from IDEXX Laboratories, Westbrook, Maine, provide reticulocyte counts) or by evaluating a blood smear for the presence of polychromasia. This reflects the pathogenesis of the anemia, thereby dictating the most logical diagnostic and therapeutic approach (Box 83-3).

In brief, regenerative anemias always stem from extramarrow causes because the presence of reticulocytes or polychromatophilic RBCs (i.e., immature RBCs) in the circulation is a clear indication of a functional bone marrow. Regenerative anemias can result only from hemolysis or blood loss. Nonregenerative anemias can be caused by bone marrow or extra-marrow disorders, such as erythroid hypoproliferation, chronic inflammatory disease, chronic kidney disease, and acute hemorrhage or hemolysis (first 48 to 96 hours). Although IDA is traditionally classified as nonregenerative, most dogs with chronic blood loss leading to iron deficiency display a mild to moderate degree of regeneration, and the RBC indices are different than in other nonregenerative anemias (see below). Therefore I prefer to classify IDA in a separate category. Regenerative anemias are usually acute, whereas nonregenerative anemias are either peracute (i.e., blood loss or hemolysis of less than 48 hours' duration) or, more often, chronic.

During the initial clinical evaluation of an anemic patient, examination of the blood smear usually suffices in determining whether the bone marrow is responding appropriately to the anemia (i.e., whether the anemia is regenerative or not).

Leukopenia See text Thrombocytopenia See text

Pancytopenia Bone marrow disorder; hypersplenism

Modified from Couto CG et al: Hematologic and oncologic emergencies. In Murtaugh R et al, editors: Veterinary emergency and critical care medicine, St Louis, 1992, Mosby.

RBC, Red blood cell; FeLV, feline leukemia virus; FIV, feline immunodeficiency virus; DIC, disseminated intravascular coagulation; IHA, immune hemolytic anemia.

Several pieces of information can be acquired during the examination of a good-quality, properly stained blood smear, including the RBC size and morphology, the presence of autoagglutination, the approximate numbers and morphology of white blood cells and platelets, the presence of nucleated RBCs, the presence of polychromasia (indicative of regeneration), and the presence of RBC parasites. The clinician should perform this cursory evaluation of the blood smear; a blood sample should be submitted to a diagnostic laboratory for further analysis and evaluation by a clinical pathologist if the diagnosis is still uncertain after evaluating the blood smear. Some of the abnormalities detected during a careful examination of the blood smear and their clinical implications are summarized in Table 83-2. This evaluation should be conducted under oil immersion lens in a monolayer field, in which the erythrocytes are in a single layer and 50% of the cells are touching.

A CBC and a reticulocyte count in an anemic patient provide more absolute data by which to assess the degree of regeneration. However, the information presented below must be used cautiously because the number of reticulocytes should increase proportionally to the decrease in the HCT. For example, a reticulocyte count of  $120,000/\mu L$  or 4% represents an appropriate response for a dog with an HCT of 30% but not for one with an HCT of 10%. The following points generally hold true:

- If the RBC indices are macrocytic and hypochromic, the anemia is most likely associated with the presence of high numbers of reticulocytes (which are larger and contain less Hb than mature RBCs); therefore the anemia is likely regenerative.
- If the reticulocyte count is more than 120,000/μL or 4% and the anemia is mild to moderate, the anemia is likely regenerative.

As part of the evaluation of a patient with regenerative anemia, it is beneficial to determine the serum or plasma protein concentration because blood loss usually results in hypoproteinemia and hemolysis does not. Other physical examination and clinicopathologic findings that help distinguish blood loss from hemolytic anemias are listed in Table 83-3.

## PRINCIPLES OF MANAGEMENT OF THE ANEMIC PATIENT

The first basic principle of the management of anemic (or bleeding) patients is to collect *all* blood samples before instituting any therapy. Because the condition in most of these patients may constitute a true emergency at the time of presentation, samples often are not collected until the patient

#### Criteria for Differentiating Blood Loss from Hemolytic Anemias

VARIABLE	BLOOD LOSS	HEMOLYSIS	
Serum (plasma) protein concentration	Normal-low	Normal-high	
Evidence of bleeding	Common	Rare	
Icterus	No	Common	
Hemoglobinemia	No	Common	
Spherocytosis	No	Common	
Hemosiderinuria	No	Yes	
Autoagglutination	No	Occasional	
Direct Coombs test	Negative	Usually positive (in IHA)	
Splenomegaly	No	Common	
RBC changes	No	Common (see Table 83-2)

IHA, Immune hemolytic anemia; RBC, red blood cell.

has been completely stabilized, resulting in treatmentinduced changes in hematologic or serum biochemical values.

As a general rule, because of the acute onset of these disorders, patients with regenerative anemias (i.e., blood loss or hemolysis) require more aggressive therapy than those with nonregenerative forms. Specific therapy should be instituted once the clinician has determined that the patient's condition is stable and whether or not the anemia is regenerative. The diagnosis and management of different forms of anemia in cats and dogs are discussed throughout the remainder of this chapter.

#### REGENERATIVE ANEMIAS

#### **BLOOD LOSS ANEMIA**

Acute blood loss in otherwise normal dogs and cats results in reticulocytosis (i.e., regeneration) within 48 to 96 hours. Therefore animals evaluated shortly after a traumatic injury and severe blood loss usually have nonregenerative anemias with low-to-normal serum (plasma) protein concentrations. The source of bleeding should be identified and the bleeding stopped; if the patient is bleeding as a result of a systemic hemostatic defect, it should be identified and specific treatment should be initiated (see Chapter 87). Aggressive intravenous (IV) fluid therapy with crystalloids or colloids or the transfusion of blood or blood products is often required in patients with anemia caused by acute blood loss.

#### **HEMOLYTIC ANEMIA**

In human beings the bone marrow is capable of undergoing hyperplasia until its production rate is increased approximately sixfold to eightfold; the same is probably true for dogs and cats. As a consequence, a considerable number of RBCs must be destroyed before anemia develops. As is the case in cats and dogs with blood loss anemia, patients with peracute

hemolysis can be in a nonregenerative state at the time of presentation because the bone marrow has not yet been able to mount a regenerative response. In addition, in some dogs with immune-mediated hemolysis, the destruction of erythroid precursors in the bone marrow results in a lack of regeneration.

On the basis of their pathogenesis, hemolytic anemias can be classified as extravascular (i.e., the RBCs are destroyed by the mononuclear phagocytic cells) or intravascular (i.e., the RBCs are lysed by antibody-complement, drugs, toxins, or by hitting fibrin strands). On the basis of the age of the animal at onset, anemias can be classified as congenital or acquired (Table 83-4). Most dogs and cats with hemolytic anemia seen at my clinic have acquired extravascular hemolysis.

In extravascular hemolysis, RBCs are phagocytosed by the mononuclear-phagocytic system (MPS) in the spleen, liver, and bone marrow. Stimuli that trigger RBC phagocytosis consist mainly of intracellular inclusions, such as RBC parasites or Heinz bodies (the latter are commonly seen in cats) and membrane coating with immunoglobulin (Ig) G or M (common in dogs). Congenital RBC enzymopathies can also precipitate extravascular hemolysis. Once abnormal RBCs are recognized, the MPS rapidly phagocytoses them, resulting in a decrease in the number of circulating RBCs and the generation of cells with specific morphologic changes (e.g., spherocytes). Anemia develops if the destruction of RBCs continues. Spherocytes are RBC "leftovers," in that after a mononuclear-phagocytic cell takes a "bite" of cytoplasm and membrane, the membrane is resealed; the RBC then loses its redundant membrane and consequently its central pallor. Spherocytes are characteristic of immune hemolytic anemia (IHA), although they can occasionally be seen in other disorders, such as Babesia gibsoni infection or zinc toxicity. Immune hemolysis is the most common cause of extravascular hemolytic anemia in dogs at my hospital. Drugassociated hemolysis (e.g., \beta-lactam antibiotics) and

Modified from Couto CG et al: Hematologic and oncologic emergencies. In Murtaugh R et al, editors: Veterinary emergency and critical care medicine, St Louis, 1992, Mosby.

PFK, Phosphofructokinase; IHA, immune hemalytic anemia.

mycoplasmosis (formerly known as haemobartonellosis) are the two most common causes in cats, although IHA is now more common in this species. Other causes of extravascular hemolytic anemia in dogs and cats are listed in Table 83-4.

Intravascular hemolysis can occur as a consequence of direct RBC lysis caused by antibodies that activate complement (e.g., immune-mediated hemolysis), infectious agents (e.g., Babesia canis infection), drugs or toxins (e.g., zinc in pennies minted after 1983, in pet carrier bolts, other hardware, and zinc oxide-containing ointments), metabolic imbalances (e.g., hypophosphatemia in dogs and cats with diabetes mellitus treated with insulin), or increased shearing

of RBCs (e.g., microangiopathy, DIC). Intravascular hemolysis is considerably less common in dogs and cats than extravascular hemolysis, with the notable exception of DIC in dogs with hemangiosarcoma, zinc toxicity, and hypophosphatemia. Certain congenital enzymopathies (e.g., phosphofructokinase [PFK] deficiency) in dogs also result in intravascular hemolysis.

Dogs with *congenital* (frequently familial) hemolytic anemias may have relatively prolonged clinical courses at the time of presentation, with the notable exception of English Springer Spaniels with PFK deficiency—induced hemolysis, in which acute hemolytic episodes occur after they hyper-

ventilate during excitement or field work (i.e., alkaline hemolysis). Dogs and cats with acquired hemolytic anemias are usually evaluated because of acute clinical signs consisting of pallor, with or without icterus (in my experience, only approximately half of dogs and a lower percentage of cats with hemolytic anemia are icteric); splenomegaly may be a prominent finding. If the patient has associated thrombocytopenia (e.g., Evans syndrome, DIC), petechiae and ecchymoses may be present. Clinical signs and physical examination findings associated with the primary disease can also be present in cases of secondary hemolytic anemias; however, as opposed to human beings, they are extremely rare in dogs and cats.

In the evaluation of dogs or cats with hemolytic anemia, a careful examination of the blood smear is mandatory. Morphologic abnormalities pathognomonic for or highly suggestive of a particular etiology are often detected with this method (see Table 83-2). The sample should also be tested for autoagglutination; this is done by placing a large drop of anticoagulated blood on a glass slide at room temperature and at 4° C. Agglutination can be distinguished from rouleaux formation by diluting the blood 5:1 or 10:1 in saline solution (this disaggregates rouleaux); rouleaux formation is common in cats but rare in dogs. A direct Coombs test to detect RBC-bound Ig should always be performed in dogs and cats with suspected hemolysis (see below). As a general rule, the presence of Ig coating on the RBCs indicates immune-mediated hemolysis. A positive Coombs test result should be interpreted with caution, however, because certain drugs and hemoparasites can induce formation of antibodies that bind to the RBCs, thus causing secondary immune hemolysis (e.g., cats with mycoplasmosis). The pretreatment of an animal with corticosteroids may also result in decreased binding of Ig molecules to the surface of the RBC, thus resulting in false-negative results. Direct Coombs tests are usually not necessary in animals with autoagglutination because this phenomenon connotes the presence of Ig on the surface of the RBCs (i.e., biologic Coombs test). Cryoagglutination (i.e., the agglutination of RBCs if the blood sample is refrigerated for 6 to 8 hours) occurs in a large proportion of cats with mycoplasmosis and is usually associated with IgM coating on the RBCs.

If an etiologic agent cannot be identified (e.g., RBC parasite, drug, pennies in the stomach), the patient should be treated for primary or idiopathic IHA while further test results (e.g., serologic tests or polymerase chain reaction [PCR] for hemoparasites) are pending. As previously mentioned, primary IHA is considerably more common in dogs than in cats; thus every effort should be made to identify a cause of hemolysis in cats, such as drugs or hemoparasites. A detailed discussion of IHA is presented below.

Hemolytic anemias not associated with immune destruction of the RBCs are treated by removal of the cause (e.g., drug, infectious agent, gastric foreign body) and supportive therapy. Corticosteroids (see below) can be administered to suppress MPS activity while the etiologic agent is being eliminated, although this is not always beneficial. Doxycy-

cline (5 to 10 mg/kg PO q12-24h for 21 to 42 days) usually results in resolution of the signs in dogs and cats with mycoplasmosis and in dogs with ehrlichiosis.

#### **Immune Hemolytic Anemia**

IHA constitutes the most common form of hemolysis in dogs (see Chapter 104). Although two pathogenetic categories of hemolytic anemia are recognized (primary, or idiopathic, and secondary), most cases of IHA in dogs are primary (i.e., a cause cannot be found after exhaustive clinical and clinicopathologic evaluation). The immune-mediated destruction of RBCs can occur in association with drug administration (e.g.,  $\beta$ -lactam antibiotics, barbiturates) or vaccination. With the exception of the immune hemolysis secondary to hemoparasitism, IHA is rare in cats (although its prevalence is higher than 5 years ago). The clinical course in dogs is typically acute, but peracute presentations are also common.

In IHA, the RBCs become coated primarily with IgG, which leads to the early removal of the coated cells by the MPS, mainly in the spleen and liver. As a consequence spherocytes are generated; therefore the presence of spherocytes in the blood smear of a dog with anemia is highly suggestive of IHA. Spherocytes are difficult to identify in cats.

The typical patient with IHA is a middle-aged, female spayed Cocker Spaniel or small breed dog, although I have recently noticed a higher prevalence of IHA (and other immune-mediated cytopenias) in Golden Retrievers. Clinical signs in dogs with IHA include depression of acute (or peracute) onset, exercise intolerance, and pallor or jaundice, occasionally accompanied by vomiting or abdominal pain. Physical examination findings usually consist of pallor or jaundice, petechiae and ecchymoses (if immune thrombocytopenia is also present), splenomegaly, and a heart murmur. As previously noted, jaundice can be absent in dogs with IHA. A subset of dogs with acute (or peracute) IHA with icterus (and usually autoagglutination) shows clinical deterioration within hours or days of admission, resulting from multifocal thromboembolic disease or a lack of response to conventional therapy. I treat these dogs more aggressively than the typical dog with IHA (see next page).

Hematologic findings in dogs with IHA typically include strongly regenerative anemia, leukocytosis from neutrophilia with a left shift and monocytosis, increased numbers of nucleated RBCs, polychromasia, and spherocytosis. The serum (plasma) protein concentration is usually normal to increased, and hemoglobinemia or bilirubinemia may be present (i.e., pink or yellow plasma). As previously noted, autoagglutination is prominent in some dogs. Thrombocytopenia is also present in dogs with Evans syndrome or DIC.

The presence of polychromasia with autoagglutination and spherocytosis in a clinically ill dog with anemia of acute onset is virtually pathognomonic of IHA. In these cases a direct Coombs test is usually not necessary to confirm the diagnosis. In dogs that lack some of these physical examination and hematologic findings, a direct Coombs test

should be performed to detect Ig adsorbed to the RBC membrane.

The direct Coombs test is negative in approximately 10% to 30% of dogs with IHA, yet they tend to respond to immunosuppressive therapy (see below). In these cases enough Ig or complement molecules may be bound to the RBC membrane to induce the MPS to stimulate phagocytosis but not enough to result in a positive Coombs test. Hemolysis can occur in human beings with approximately 20 to 30 molecules of Ig bound to the RBC, whereas the direct Coombs test can only detect more than 200 to 300 molecules of Ig per cell. Another explanation for the findings in this subset of patients is that the previous administration of exogenous corticosteroids has resulted in decreased antibody binding to the surface of the RBCs.

Immunosuppressive doses of corticosteroids (equivalent to 2 to 4 mg/kg of prednisone q12-24h in the dog and up to 8 mg/kg q12-24h in the cat) constitute the treatment of choice for primary IHA. Although dexamethasone can be used initially, it should not be used as maintenance therapy for prolonged periods because of its higher potential to cause gastrointestinal tract ulceration or pancreatitis; in addition, if given on an alternate-day basis, it causes interference with the hypothalamic-pituitary-adrenal axis. In equivalent doses dexamethasone does not appear to be more beneficial than prednisone in dogs. In cats with IHA, I have used dexamethasone (4 mg/cat, PO, q1-2wk) with a high degree of success.

A high percentage of dogs treated with corticosteroids shows a marked improvement within 24 to 96 hours (Fig. 83-1). Corticosteroids act mainly by three different mechanisms: they suppress MPS activity, decrease complement and

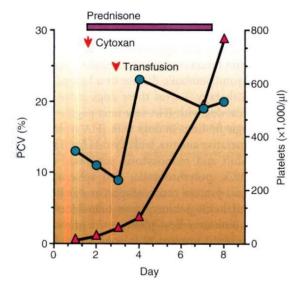

FIG 83-1
Response to treatment in a dog with immune hemolytic anemia (IHA) and immune-mediated thrombocytopenia (Evans syndrome). *PCV*, Packed cell volume; →, PCV; →, platelets; ↓, treatment administered.

antibody binding to the cells, and suppress Ig production. The first two effects are rapid in onset (hours), whereas the third effect is delayed (1 to 3 weeks).

I have observed a high number of dogs with acute or peracute IHA generally associated with icterus and autoagglutination that show a rapid deterioration and that usually die of thromboembolism of the liver, lungs, or kidneys despite aggressive corticosteroid therapy. Such animals are treated with cyclophosphamide (Cytoxan) at a dosage of 200 to 300 mg/m<sup>2</sup> given orally or intravenously in a single dose over a 5- to 10-minute period in conjunction with a single IV dose of dexamethasone sodium phosphate (1 to 2 mg/ kg). I also advocate the use of prophylactic heparin therapy because dogs with hemolysis are at high risk for DIC and thrombosis. In my practice heparin therapy of 50 to 75 IU/kg is routinely given subcutaneously every 8 hours. These dosages of heparin usually do not result in therapy-related prolongation of the activated clotting time (ACT) or the activated partial thromboplastin time (Aptt), tests used routinely to monitor heparinization. The use of low- or minidose aspirin (0.5 mg/kg q24-48h) has been associated with lower mortality rates in dogs with IHA. Because dogs with IHA are at high risk for thromboembolic events, I refrain from placing central venous lines; thrombosis of the anterior vena cava commonly leads to severe pleural effusion in these dogs. Aggressive fluid therapy should be administered in conjunction with these treatments in an attempt to flush the microaggregates of agglutinated RBCs from the microcirculation (Note: circulating blood does not clot). Importantly, however, is that depending on the degree of anemia, the resultant hemodilution may be detrimental to the patient. If deemed necessary, oxygen therapy should also be used, but it is rarely beneficial unless the HCT or Hb can be increased.

I have been using human intravenous IgG (HIVIGG-0.5 to 1.5 g/kg IV infusion, single dose) with a high degree of success in dogs with refractory IHA. This treatment is aimed at blocking the Fc receptors in the MPS with a foreign Ig, thus minimizing the phagocytosis of antibody-coated RBCs. This treatment appears to have other immunomodulatory effects as well. However, the product is moderately expensive (approximately \$300 to \$400 per dose for a 10-kg dog). This approach has had such an impact, however, that I frequently use it as the first line of therapy in dogs with severe IHA.

Drugs used for the maintenance treatment of dogs with IHA include prednisone (1 mg/kg PO q48h) and azathioprine (50 mg/m² PO q24-48h), used either singly or in combination. Azathioprine is associated with few adverse effects, although close hematologic and serum biochemical monitoring is necessary because of its potential to suppress bone marrow function and cause mild hepatopathy. A dose reduction is necessary if myelosuppression or hepatotoxicity occurs; occasionally azathioprine must be discontinued in dogs with hepatotoxicity. In cats, chlorambucil is an effective immunosuppressor with very low toxicity; I have used it successfully in cats with IHA, immune-mediated thrombo-

cytopenia, or other cytopenias at a dosage of 20 mg/m² PO q2wk. In general, dogs and cats with IHA require prolonged (often lifelong) immunosuppressive treatment. Whether an animal requires continuous treatment is determined by trial and error; decremental doses of the immunosuppressive drug(s) are administered for a given period (usually 2 to 3 weeks), at which time the patient is reevaluated clinically and hematologically. If the PCV has not decreased or has increased and the patient is clinically stable or has shown improvement, the dose is reduced by 25% to 50%. This procedure is repeated until the drug is discontinued or the patient relapses. In the latter case, the previously used dosage that had beneficial effects is used again. In my experience, more than two thirds of dogs with IHA require lifelong treatment.

Alternative treatments for dogs with refractory IHA include danazol (5 to 10 mg/kg PO q12h), cyclosporine (10 mg/kg PO q12-24h), and possibly splenectomy. However, splenectomy has rarely been of benefit in dogs with IHA treated at my clinic.

Chlorambucil (20 mg/m² PO q2wk) appears to be the best induction and maintenance agent in cats with IHA refractory to corticosteroids or in those who develop corticosteroid-induced diabetes mellitus. In my experience azathioprine causes pronounced myelosuppression in this species and should not be used.

One of the biggest dilemmas the clinician faces in the treatment of a dog with IHA is whether to administer a transfusion of blood or blood products. As a general rule, a transfusion should not be withheld if it represents a lifesaving procedure. However, because patients with IHA are already destroying their own antibody-coated RBCs, they may also be prone to destroying transfused RBCs (although this has not been scientifically proven). My recommendation is to administer a transfusion to any animal with IHA that is in dire need of RBCs (i.e., withholding a transfusion would result in the animal's death). I usually pretreat these patients with dexamethasone sodium phosphate (0.5 to 1 mg/kg IV), administer fluids through an additional IV catheter, and continue the heparin therapy. Although cross-matching is indicated, time is usually of the essence; therefore non-crossmatched universal donor blood is frequently administered; moreover, if autoagglutination occurs, the results of a crossmatch may be difficult to interpret.

Another issue pertaining to transfusion in dogs with IHA autoagglutination deals with blood typing; if blood typing cards are used, the results will be false-positive for DEA 1.1 (see Principles of Transfusion Therapy, p. 1221). Finally, no rule of thumb exists (e.g., PCV value, lack of response to oxygen therapy) regarding when to administer a transfusion. The clinician should use his or her best clinical judgment to determine when a transfusion of blood or blood products is necessary (e.g., does the patient exhibit tachypnea, dyspnea, or orthopnea?). If available, universal donor packed RBCs should be used instead of whole blood because they deliver a high oxygen-carrying capacity in a smaller volume and administration usually does not result in hypervolemia.

A polymer of bovine Hg has been available for use in dogs with acute anemia that are in dire need of oxygen-carrying capacity (Oxyglobin, Biopure Corp., Cambridge, Mass.). This compound has a long shelf life; it does not require refrigeration, blood typing, or cross-matching. Administration of Oxyglobin typically results in clinical improvement of the signs associated with anemia, but the duration of response is limited (2 or 3 days). Because of the nature of this compound, the PCV does not increase after infusion (the Hg concentration does increase). Some laboratory test results may be difficult to obtain after infusion of Oxyglobin because of interference with colorimetric analysis. Unfortunately this product is not readily available for veterinarians at this time.

#### **NONREGENERATIVE ANEMIAS**

With the exception of anemia of chronic disease (ACD), nonregenerative anemias do not appear to be clinically as common as regenerative forms in dogs, whereas the opposite is true in cats.

Five forms of nonregenerative anemia are typically recognized in cats and dogs (see Box 83-3). Because IDA can be mildly to moderately regenerative and the RBC indices are typically different from those in other forms of nonregenerative anemia (microcytic, hypochromic versus normocytic, normochromic; see Boxes 83-3 and 83-4 and Tables 83-2 to 83-4), I prefer to classify it in a separate category. Anemia of endocrine disease is typically mild and usually is an incidental finding in dogs with hypothyroidism or hypoadrenocorticism (see Chapters 51 and 53). In general, most nonregenerative anemias and IDA in cats and dogs are chronic, thus allowing for physiologic adaptation to the decrease in the RBC mass. As a consequence, these types of anemia may be detected incidentally during the routine evaluation of a cat or dog, which to the owner is asymptom-

atic. In many cases (e.g., ACD) the anemia is mild and clinical signs are absent. Although most nonregenerative anemias are chronic, two situations are commonly encountered in which this form of anemia is acute: acute blood loss (first 48 to 96 hours) and peracute hemolysis. In these two instances the bone marrow has not yet had time to mount a regenerative reticulocyte response.

When evaluating dogs and cats with symptomatic nonregenerative anemias of acute onset, the clinician should try to answer the following questions:

- Has this patient had an acute blood loss or does it have hemolytic anemia and has not yet been able to mount a regenerative response (i.e., less than 48 to 96 hours have elapsed since the event)?
- Does this patient have chronic anemia but is now symptomatic because of intercurrent disease (e.g., heart failure, sepsis)?

Most clinical and clinicopathologic abnormalities in cats and dogs with nonregenerative anemia have been discussed (see p. 1209). In general, the RBCs in dogs and cats with nonregenerative anemias are normocytic and normochromic; however, the RBCs are usually macrocytic and normochromic in cats with FeLV- or FIV-related hypoproliferative anemias. As previously discussed, the RBC indices are microcytic and hypochromic in dogs and cats with IDA

The clinical evaluation of a cat or dog with nonregenerative anemia differs radically from that of a patient with regenerative forms because the absence of regeneration reflects primary or secondary bone marrow abnormalities (e.g., bone marrow disorder, ACD). Therefore after extramarrow causes have been ruled out by performing a physical examination and a serum biochemical profile and urinalysis, a bone marrow aspiration or biopsy is indicated in these patients.

#### **ANEMIA OF CHRONIC DISEASE**

ACD is the most common form of nonregenerative anemia in cats and dogs; however, because it is mild, it almost never results in clinical signs of anemia and the patients are usually evaluated as a consequence of their primary disorder (e.g., cancer, infection). ACD develops secondary to a variety of chronic inflammatory, degenerative, or neoplastic conditions. Although the term anemia of chronic disease implies a chronic onset, it has recently been established that cats can develop ACD in as little as 2 weeks. However, some of those cats were receiving fluid therapy that may have resulted in hemodilution (Ottenjan et al., 2006). In most cats with ACD the PCV percentage values range from the high teens to the mid-20s, whereas in dogs they range from the mid-20s to the low 30s. Therefore ACD can usually be excluded in dogs with PCVs of less than 20% and in cats with PCVs of less than 17% to 18%. The RBC indices are normocytic and normochromic, and the CBC may also reflect the nature of the primary problem (e.g., leukocytosis, neutrophilia, monocy-

tosis, hyperproteinemia resulting from a polyclonal gammopathy); some cats with ACD have microcytic hypochromic RBC indices, a condition that mimics IDA.

Sustained inflammatory or neoplastic processes cause iron to be sequestered within the bone marrow MPS, and it is therefore not available to the erythroid precursors for normal erythropoiesis. This unavailability of iron is mainly mediated by lactoferrin and other acute-phase reactants released from neutrophils during inflammation. In cats and dogs with ACD, the serum iron concentration and total ironbinding capacity (TIBC, or transferrin concentration) are usually decreased and the Hb saturation is low, but iron stores in the bone marrow are increased (Table 83-5). Although serum ferritin concentrations are the main feature that distinguishes ACD from IDA (i.e., high in ACD and low in IDA) in human beings, the results of ferritin assays in dogs and cats with IDA and ACD are not as clear cut. Therefore, to conclusively differentiate ACD from IDA, evaluation of bone marrow iron stores by Prussian blue staining is important. After a diagnosis of ACD has been confirmed, every effort should be made to identify the cause of the problem if it is not already evident.

Dogs and cats with ACD usually do not require specific or supportive therapy because treatment of the primary disorder causes the anemia to resolve. Although some have advocated the use of anabolic steroids in dogs and cats with ACD, these agents appear to be of little or no benefit.

#### **BONE MARROW DISORDERS**

Neoplastic, hypoplastic, or dysplastic bone marrow disorders can result in anemia and other cytopenias. In these conditions a "crowding out" of the normal erythroid precursors by neoplastic or inflammatory cells (myelophthisis), a paucity or absence of erythroid precursors (hypoplasia or aplasia, respectively), or a maturation arrest of the erythroid precursors (dysplasia) occur. All these disorders, with the exception of pure RBC aplasia (PRCA) (see following section), typically affect more than one cell line and the patients are bicytopenic or pancytopenic (see Chapter 86).

In general, these disorders are chronic and the clinical signs are those of anemia (see p. 1209) with or without signs of the underlying disorder. Although some information regarding the pathogenesis of this type of anemia can be obtained by evaluating the clinical and hematologic data, a definitive diagnosis is usually made on the basis of the cytologic or histopathologic appearance of a bone marrow specimen and, possibly, the results of serologic tests or PCR for infectious agents (e.g., FeLV, FIV, Ehrlichia canis).

#### Bone Marrow (or Erythroid) Aplasia-Hypoplasia

Bone marrow aplasia-hypoplasia is characterized by aplasia or hypoplasia of all the bone marrow cell lines (bone marrow aplasia-hypoplasia or aplastic pancytopenia) or the erythroid precursor (RBC aplasia-hypoplasia or PRCA). This form of anemia (or combined cytopenias) can be caused by a variety of agents or disorders (see Chapter 86) (Box 83-5). The following discussion pertains to PRCA.

Clinically, dogs and cats with PRCA are evaluated because of the clinical signs already discussed. In contrast to ACD, in which the degree of anemia, and thus the severity of the clinical signs, is mild, cats and dogs with PRCA usually have a PCV of less than 15% and are therefore symptomatic. Hematologically, severe (normocytic normochromic) nonregenerative anemia is usually the only abnormality; macrocytosis in the absence of reticulocytes is a consistent finding in cats with FeLV- or FIV-related PRCA, and mild microcytosis can occasionally be present in dogs with PRCA. The large RBC volume in cats with retroviral infections is attributed to the erythroid dysplasia or dyserythropoiesis induced by the virus. Dogs with PRCA occasionally have circulating spherocytes, pointing toward an immune basis for the anemia. The direct Coombs test is also positive in more than half of these dogs, and their anemia responds to immunosuppressive therapy. Cats and dogs with bone marrow aplasia-hypoplasia are pancytopenic (see Chapter 86).

In addition to the above, FeLV and FIV testing should be done in cats with PRCA. A bone marrow aspiration or biopsy specimen should also be obtained to rule out other bone marrow disorders.

The FeLV envelope protein p15E suppresses erythropoiesis in vitro and is postulated to cause PRCA in FeLV-infected cats. The anemia in these cats is usually chronic and severe (a PCV of 5% to 6% is relatively common), and despite supportive therapy the condition of the patient deteriorates, leading the owners to request euthanasia. The supportive treatment of these cats includes whole blood or packed RBC transfusions as needed; the interval between transfusions usually shortens with each transfusion until the cat needs transfusions weekly. Anabolic steroids may be beneficial in some cats, although no clinical evidence supports this. Interferon administered orally may improve clinical signs (without resolution of the anemia) in some of these cats (see Chapter 102).

FeLV-negative cats with PRCA often have a positive direct Coombs test and frequently benefit from immunosuppressive doses of corticosteroids; I typically use 4 mg of dexamethasone (per cat) once every 1 to 2 weeks instead of the conventional prednisone or prednisolone daily to every other day. This steroid formulation is safe and effective, and I have not yet seen secondary diabetes mellitus in the cats treated. The use of human recombinant erythropoietin (Epo) (see below) does not appear to be indicated in these cats because their endogenous Epo activity is higher than that of normal cats. In addition, the long-term use of human recombinant Epo may lead to the development of anti-Epo antibodies and resultant refractory anemia.

PRCA of presumptive immune origin is relatively common in dogs and cats. The postulated mechanism is similar to that of IHA, except that in PRCA the antibodies (or cell-mediated immunity) are directed against the erythroid precursors. Humoral factors (antibodies) that block erythropoiesis in vitro have been well characterized in dogs with PRCA. As previously discussed, the direct Coombs test result is positive in some of these dogs (60%) and cats (50%),

and they respond well to immunosuppressive and supportive therapy. Bone marrow aspirates in dogs and cats with PRCA reveal either erythroid hypoplasia or hyperplasia of the early erythroid precursors and a maturation arrest at the rubricyte or metarubricyte stage. This poses an interesting situation because most clinical pathologists use the term "PRCA" only for the dogs and cats that have crythroid hypoplasia and "IHA with delayed erythroid regeneration" for those with erythroid hyperplasia and a maturation arrest. However, from a clinical standpoint both situations behave the exact way and respond to the same treatment. Therefore I prefer to use the term PRCA for dogs and cats with either of these bone marrow cytologic findings.

The same treatment as that used during the maintenance phase of IHA is recommended for these dogs (prednisone 2 to 4 mg/kg PO q24-48h and/or azathioprine 50 mg/m<sup>2</sup> PO q24-48h). In cats, I have successfully used dexamethasone alone (as previously discussed) or in combination with chlorambucil (Leukeran) at a dosage of 20 mg/m<sup>2</sup> given orally every 2 weeks. Responses occur in approximately 70% to 80% of the patients, but clinical and hematologic recovery may take 2 to 3 months; long-term (lifelong) treatment is usually required. Supportive treatment and transfusions of blood or packed RBCs are sometimes necessary. Because these patients are normovolemic, the latter is preferable. In addition, because transfusions may need to be administered on an ongoing basis, cross-matching is recommended before the administration of each transfusion. Of note, in dogs one of the mechanisms of adaptation to chronic hypoxia (e.g., anemia) is an increase in the intraerythrocytic 2,3diphosphoglycerate (2,3-DPG) concentration, resulting in a lower oxygen affinity (i.e., the delivery of oxygen to the tissues is facilitated). Therefore, because stored RBCs have lower concentrations of 2,3-DPG, the transfused cells have a higher affinity for oxygen. As a result the transfusion of stored blood to a patient with chronic anemia may result in transient decompensation because approximately 24 hours is usually required for the transfused, stored RBCs to regain 50% of the normal 2,3-DPG concentrations and get "recharged."

#### Myelophthisis, Myelodysplastic Syndromes, Myelofibrosis, Osteosclerosis-Osteopetrosis

These disorders are discussed in Chapter 86.

#### ANEMIA OF RENAL DISEASE

The kidney is the main site of production of Epo, the principal stimulus of erythropoiesis. In addition, in dogs and cats with chronic renal failure, the life span of RBCs is considerably shorter and subclinical to clinical gastrointestinal tract bleeding is present; high concentrations of parathyroid hormone also suppress crythropoiesis. Because of these factors, anemia is common in such patients. The anemia is usually normocytic and normochromic, with few or no reticulocytes. HCT levels in dogs and cats with anemia of renal disease (ARD) are usually in the 20% to low 30% range,

although HCT levels in the teens are common. Of note, the HCT in these patients is usually that low only after they have undergone intensive fluid therapy (i.e., on presentation the anemia is not that severe because the patients are markedly dehydrated).

Improvement in renal function may result in marginal increases in the RBC mass. Anabolic steroids are rarely beneficial in improving the anemia in these patients. Human recombinant Epo (Epogen, Amgen, Thousand Oaks, Calif.) has been used successfully to treat anemia in cats and dogs with chronic renal failure. A dose of 100 to 150 IU/kg given subcutaneously twice weekly is administered until the HCT returns to a target value (usually 20% to 25%); the interval between injections is then lengthened for maintenance therapy. The HCT usually returns to normal within 3 to 4 weeks of the start of treatment. Given the fact that this Epo is foreign to dogs and cats, an appropriate antibody response usually nullifies the beneficial effects of long-term therapy (6 to 8 weeks) in more than 50% of the patients.

#### ACUTE AND PERACUTE BLOOD LOSS OR HEMOLYSIS (FIRST 48 TO 96 HOURS)

After an acute episode of blood loss or hemolysis, bone marrow takes approximately 48 to 96 hours to release enough reticulocytes to result in regeneration. Therefore blood loss and hemolytic anemias are nonregenerative during the initial phases of recovery.

In most dogs and cats with acute blood loss, profound bleeding is either historically or clinically evident. If no obvious cause of bleeding is found or if the patient is bleeding from multiple sites, the hemostatic system should be evaluated in search of a coagulopathy (see Chapter 89). Sites of internal bleeding should be evident after a complete physical examination is performed.

Once the bleeding has been stopped, the anemia typically resolves within days to weeks. The initial management of a bleeding episode should include supportive therapy and IV crystalloids or plasma expanders. If necessary, blood or packed RBCs or Hg solutions should be administered.

The management of dogs with peracute hemolysis was discussed earlier in the chapter.

#### SEMIREGENERATIVE ANEMIAS

#### IRON DEFICIENCY ANEMIA

IDA is traditionally classified as nonregenerative even though mild to moderate regeneration usually occurs. Moreover, as previously discussed, the RBC indices in dogs and cats with IDA are microcytic and hypochromic, distinguishing it from other forms of nonregenerative anemia, which are normocytic and normochromic. When evaluating the CBC of a dog with microcytic hypochromic anemia, the clinician must remember that microcytosis occurs in some breeds (e.g., Akita, Shiba Inu, Sharpei) and in dogs with other disorders, such as portosystemic shunts (see Table 83-2).

This form of anemia is well characterized in dogs with chronic blood loss. In cats, IDA has been well documented only in wearling kittens, in whom iron supplementation results in rapid resolution of the clinical and hematologic abnormalities. IDA is extremely rare in adult cats, and I have seen it primarily in association with chronic blood loss in cats with gastrointestinal (GI) lymphoma. Given its rarity in cats, the following discussion of IDA pertains primarily to dogs.

Chronic blood loss leading to iron depletion is common in dogs with GI tract bleeding caused by neoplasia, gastric ulcers, or endoparasites (e.g., hookworms) and in those with heavy flea infestation. Other causes of chronic blood loss, such as urogenital bleeding and iatrogenic bloodletting, are extremely rare. In my experience the most common cause of symptomatic IDA in dogs that present for evaluation of signs associated with anemia is GI neoplasia.

Dogs with IDA are typically evaluated because of the signs of the anemia or because of GI tract signs such as diarrhea, melena, or hematochezia. Mild IDA is occasionally recognized during the routine evaluation of heavily parasitized dogs (mostly pups). Hematologically, most dogs with IDA have microcytic, hypochromic indices, mild reticulocytosis (1% to 5%), a high RBC distribution width (RDW) with an occasional bimodal population of RBCs, thrombocytosis, low serum iron and TIBC (transferrin) concentrations, an extremely low percentage of saturation (usually less than 10%), a low serum ferritin concentration, and low iron stores in the bone marrow (see Box 83-5). The RDW generated by a particle counter represents a histogram of RBC sizes; a high RDW is indicative of anisocytosis. The typical tetrad of hematologic abnormalities in dogs with IDA is microcytosis, hypochromasia, mild regeneration, and thrombocytosis.

Because the most common cause of IDA in adult dogs is chronic GI tract bleeding, the stools should always be evaluated for occult blood with commercially available kits (see Chapter 29); if the results are negative, they should be evaluated again two or three times during a period when the animal is not eating canned dog food (myoglobin in canned dog food can occasionally result in false-positive reactions). If occult blood is present in the stool, a GI tract neoplasm should be ruled out. Tumors commonly associated with IDA in dogs include GI stromal tumors (GISTs), such as leiomyomas, leiomyosarcomas, and true GISTs; lymphomas; and carcinomas. In dogs with IDA, positive fecal blood test results, and lack of clinical signs associated with the GI tract, the most likely diagnosis is a jejunal tumor (usually a GIST); I refer to these tumors as the "silent" GI neoplasms.

Another condition that can lead to IDA is chronic upper GI tract bleeding secondary to gastroduodenal ulceration, although most of these dogs have overt clinical signs associated with the GI tract (e.g., vomiting, hematemesis, weight loss). In pups or kittens with IDA, fecal flotation or a direct smear for hookworms and a thorough physical examination (to search for fleas) are mandatory because these are the two most common causes of IDA in young dogs and cats.

IDA usually resolves within 6 to 8 weeks after the primary cause has been eliminated. Oral or intramuscular iron supplementation is usually not necessary to hasten the resolution of the hematologic abnormalities; a sound commercial diet usually achieves the same effect. As a general rule, if the cause can be eliminated, I do not use iron supplementation. The dietary iron requirement for adult dogs and cats is approximately 1.3 mg/kg/day.

#### PRINCIPLES OF TRANSFUSION THERAPY

In the past 2 decades veterinary transfusion medicine has advanced radically. Several commercial blood banks are now available for pets, and most of them store blood components derived from processing units of whole blood or collected by apheresis. In a typical situation a unit of blood is spun immediately after collection, and packed RBCs (pRBCs) and fresh frozen plasma (FFP) stored at -20° C to -30° C are prepared; the pRBCs are preserved by adding a nutrient solution, and can be stored for up to 5 weeks. After 1 year of storage at -20° C to -30° C, FFP loses the labile clotting factors (V and VIII) and is referred to as stored plasma (SP) or frozen plasma (FP). Some blood banks prepare platelet-rich plasma (PRP) or platelet concentrates by apheresis. If FFP is allowed to warm up in a refrigerator, when it reaches approximately 4° C to 6° C a sludge forms in the bottom of the bag. That sludge can be separated by a short centrifugation, yielding cryoprecipitate (CRYO), a small volume rich in factor VIII, fibringen, and von Willebrand factor (vWF); the supernatant is referred to as cryo-poor plasma.

The transfusion of whole blood or blood components (e.g., pRBCs, PRP, FFP, CRYO, or SP) is indicated in several clinical situations. Whole blood or pRBC transfusion is most commonly required to restore the oxygen-carrying capacity in patients with anemia. Whole blood should be used if the anemic patient is hypovolemic or if it needs clotting factors, whereas pRBCs are recommended for normovolemic dogs and cats with anemia (i.e., PRCA, ARD, hemolysis). Transfusion therapy should be used with caution in animals with IHA (see p. 1217) because a massive transfusion reaction may occur; in those patients, Hg derivatives may be a better alternative if available.

Clotting factor deficiencies (see Chapter 87) resulting in hemorrhage can be corrected through the administration of whole fresh blood (if a considerable blood loss has occurred) or, more ideally, FFP or SP. Cryoprecipitate contains a high concentration of factor VIII and vWF, so it is typically used in dogs with hemophilia A or von Willebrand disease. Cryopoor plasma is a good source of clotting factors (except for factor III and vWF) and albumin. PRP or platelet transfusions, if available, can be used in dogs and cats with severe thrombocytopenia resulting in spontaneous bleeding (Table 83-6). However, the platelet count of the recipient is rarely raised enough to halt bleeding. PRP and platelet transfusions are of no benefit in patients with peripheral platelet destruction (e.g., immune-mediated thrombocytopenia) because

#### Practical Use of Blood Components

the platelets are removed from the circulation immediately after the transfusion. Transfusion with whole fresh blood, PRP, or FFP is also indicated for the management of patients with DIC (see Chapter 87).

Less frequently, plasma is prescribed to correct hypoalbuminemia. However, only rarely can relevant increases in the recipient's serum albumin concentration be achieved. Colloids or human albumin solutions are more effective in restoring plasma oncotic pressure.

#### **BLOOD GROUPS**

Several blood groups have been recognized in dogs; these include dog erythrocyte antigen (DEA) 1.1 and 1.2 (formerly known as blood group A) and DEA 3 through 8. Dogs do not have naturally occuring antibodies against blood group antigens; therefore they can only acquire them after receiving a transfusion or after pregnancy. Transfusion reactions can occur if blood positive for DEA 1.1, 1.2, or 7 is transfused, so donors should be negative for those antigens. However, clinically relevant acute hemolytic transfusion reactions are extremely rare in dogs. Transfusion of blood from a donor who has not been typed and has never been pregnant or transfused to a recipient, independently of their blood types, is generally safe.

Blood groups in cats include A, B, and AB. Cats tested in the United States have almost exclusively been type A; the prevalence of type B cats varies greatly from region to region and among breeds. Breeds in which 15% to 30% of the cats are type B include Abyssinian, Birman, Himalayan, Persian, Scottish Fold, and Somali; breeds in which more than 30% of cats are type B include the British Shorthair and the Devon Rex. Because fatal transfusion reactions commonly occur in type B cats receiving type A blood, cats should always be cross-matched or typed before receiving a transfusion. In those cases a type B cat should be used as a donor. All the type B cats seen in our clinic in the past 5 years have

been domestic short-haired cats. Blood typing is also vital in cattery situations to prevent neonatal isoerythrolysis in type A or AB kittens born to type B queens.

#### **CROSS-MATCHING AND BLOOD TYPING**

Cross-matching is an alternative to blood typing in in-house donors or animals that have had prior transfusions, in cats, or in animals that will require multiple transfusions. Cross-matching detects many incompatibilities but does not guarantee complete compatibility. Rapid, cage-side blood typing cards for DEA 1.1 in dogs and for groups A and B in cats are commercially available (RapidVet-H, DMS Laboratories, Flemington, NJ). A kit for rapid cross-matching will soon be commercially available.

#### **BLOOD ADMINISTRATION**

Refrigerated blood may be warmed before or during administration, particularly in small dogs or cats; excessive heat should be avoided, however, because fibrinogen precipitation or autoagglutination may occur. I typically do not warm blood or pRBCs before administration. The administration set should have a filter in place (Baxter International, Deerfield, Ill.) to remove clots and other particulate matter, such as platelet aggregates. The blood is usually administered by way of the cephalic, saphenous, or jugular veins. However, intraosseous infusion may be performed in small animals, neonates, or animals with poor peripheral circulation. To administer fluids or blood intraosseously, the skin over the femur is surgically prepared and the skin and periosteum of the femoral trochanteric fossa are anesthetized with 1% lidocaine. A bone marrow needle (18 gauge) is placed into the marrow cavity parallel to the shaft of the femur. Suction with a 10-mL syringe should yield marrow elements (fat, spicules, and blood), confirming correct placement of the needle. The blood is administered through a standard blood administration set.

The recommended rate of administration is variable but should not exceed 22 mL/kg/day (up to 20 mL/kg/hr can be used in hypovolemic animals). Dogs and cats in heart failure may not tolerate a rate of more than 5 mL/kg/day. To prevent bacterial contamination, blood should not be exposed to room temperature during administration for longer than 4 to 6 hours (blood is considered to be contaminated if it is at room temperature for more than 6 hours). If necessary, two smaller volumes of blood can be administered in succession. Blood should never be administered with lactated Ringer's solution because of the calcium chelation with citrate and consequent clot formation that may occur. Normal saline solution (0.9% NaCl) should be used instead. A simple rule of thumb to predict the increase in the recipient's HCT is to remember that 2.2 mL/kg (or 1 mL/lb) of transfused whole blood will raise the HCT by 1% if the donor has an HCT of approximately 40%.

## COMPLICATIONS OF TRANSFUSION THERAPY

Transfusion-related complications can be divided into those that are immunologically mediated and those that are of nonimmunologic origin. Immune-mediated reactions include urticaria, hemolysis, and fever. Non-immune-mediated complications include fever resulting from the transfusion of improperly stored blood, circulatory overload, citrate intoxication, disease transmission, and the metabolic burden associated with the transfusion of aged blood. Signs of immediate immune-mediated hemolysis appear within minutes of the start of transfusion and include tremors, emesis, and fever; these are extremely rare in dogs but common in cats receiving incompatible blood products. Delayed hemolytic reactions are more common and are manifested primarily by an unexpected decline in the HCT after transfusion over days, in association with hemoglobinemia, hemoglobinuria, and hyperbilirubinemia. Circulatory overload may be manifested by vomiting, dyspnea, or coughing. Citrate intoxication occurs when the infusion rate is too great or the liver is not able to metabolize the citrate. Signs of citrate intoxication are related to hypocalcemia and include tremors and cardiac arrhythmias. If signs of a transfusion reaction are recognized, the transfusion must be slowed or halted.

#### CHAPTER OUTLINE

**DEFINITION AND CLASSIFICATION** 

#### **DEFINITION AND CLASSIFICATION**

Erythrocytosis is defined as an increase in the circulating red blood cell (RBC) mass and is manifested hematologically as an increase in the packed cell volume (PCV) or hematocrit (HCT) above reference values. Because determination of the RBC mass in a clinical setting is cumbersome and impractical, a diagnosis of erythrocytosis is typically made on the basis of the high HCT, not an increased RBC mass. Certain dog breeds, such as sight hounds, have HCT values above the reference range for the species; this also occurs in dogs that live at high altitudes. For example, normal retired racing Greyhounds can have a HCT as high as 70%. An increase in the RBC numbers may lead to severe hemorheologic alterations, resulting in clinical signs secondary to hyperviscosity. Although the term polycythemia is commonly used to refer to this hematologic abnormality, it is incorrect because the term actually means an increase in the numbers of all circulating cells (-poly means multiple).

On the basis of its pathogenesis, erythrocytosis can be classified as either relative or absolute (Box 84-1). The term relative erythrocytosis refers to hemoconcentration (i.e., dehydration), and it is characterized by an increased PCV, usually in association with an increased serum or plasma protein concentration; in dogs and cats with relative erythrocytosis the RBC mass is normal. Dogs with hemorrhagic gastroenteritis (HGE) frequently have relative erythrocytosis associated with normal serum or plasma protein concentration; the reason for the lack of increase in the protein concentration is unknown, but the erythrocytosis resolves with appropriate fluid therapy. In absolute, or true, erythrocytosis the RBC mass is increased; it can be classified as primary or secondary depending on the pathogenesis and the serum erythropoietin (Epo) concentration or activity.

Primary erythrocytosis (polycythemia rubra vera [PRV]) results from an autonomous, Epo-independent proliferation of RBC precursors in the bone marrow and is considered a myeloproliferative disease. As a consequence, most dogs and cats with PRV have low to nondetectable serum Epo concentrations. Secondary erythrocytosis results from increased orthotopic (i.e., produced by the kidneys) or heterotopic (i.e., produced in sites other than the kidneys) Epo production. Orthotopic (physiologically appropriate) Epo production occurs in response to tissue hypoxia, such as that occurring at a high altitude and in the settings of chronic cardiopulmonary disease, right-to-left cardiovascular shunts, and carboxyhemoglobinemia. Tumor-associated erythrocytosis (i.e., heterotopic or orthotopic Epo production) has been observed in human beings with a wide variety of neoplasms, in dogs with renal masses, and in dogs with spindle cell sarcomas (nasal fibrosarcoma, schwannoma, and cecal gastrointestinal stromal tumor). Hormonal stimuli may also trigger erythrocytosis in animals with normal tissue oxygenation, such as in dogs with hyperadrenocorticism and cats with hyperthyroidism. At the author's clinic, secondary erythrocytosis is more common in dogs and PRV is more common in cats. However, erythrocytosis is rare in both species. Interestingly, although infiltrative renal diseases (e.g., lymphoma, feline infectious peritonitis) are common in cats, they rarely, if ever, result in secondary erythrocytosis.

#### **Clinical and Clinicopathologic Findings**

The clinical signs may occur acutely and consist primarily of functional abnormalities of the central nervous system (e.g., behavioral, motor, or sensory changes; seizures). In cats signs of a transverse myelopathy are common. A common manifestation of erythrocytosis in dogs is paroxysmal sneezing, attributed to increased blood viscosity in the nasal mucosa. Cardiopulmonary signs may occasionally be present. Although the erythrocytosis usually develops gradually, most affected animals do not exhibit clinical signs until the RBCs have reached a critical mass (or the PCV has reached a certain percentage). PCVs of 70% to 80% are relatively common in cats and dogs with absolute

erythrocytosis. Physical examination and historical findings in dogs and cats with erythrocytosis may also include bright red mucous membranes (plethora), erythema, polyuria, polydipsia, splenomegaly, renal masses, or a neoplasm elsewhere.

Hematologic abnormalities are usually limited to the erythrocytosis, although thrombocytosis may be present in cats and dogs with PRV. Microcytosis caused by relative iron deficiency (i.e., the erythron is extremely active and is relatively iron deficient) is common in dogs with erythrocytosis.

#### **Diagnosis and Treatment**

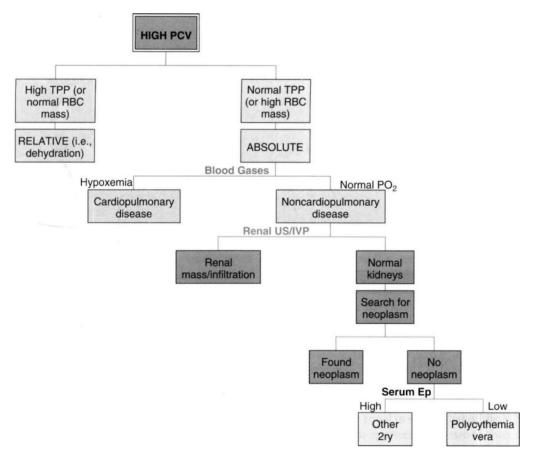

Relative erythrocytosis (i.e., dehydration) should be ruled out first. This is done primarily on the basis of the serum (or plasma) protein concentration, which is typically high in dogs and cats with this form of erythrocytosis. However, in certain circumstances, such as HGE, dogs may have a high HCT but a relatively normal serum protein concentration. Radioisotopic RBC mass determinations are commonly performed in human beings with erythrocytosis, but this test is usually not done in small animals.

The initial approach used in small animals with absolute erythrocytosis is to decrease the blood viscosity by reducing the number of circulating RBCs. This can be accomplished by performing therapeutic phlebotomies, in which a certain volume of blood (approximately 20 mL/kg) is collected from a central vein through a blood collection set. In cats a 19-gauge butterfly catheter coupled to a 60-mL syringe

containing 500 to 600 U of heparin diluted in 3 to 5 mL of saline solution is typically used to collect blood from the jugular vein under chemical restraint (the author uses sevoflurane inhalant anesthesia). Interestingly, leeches have recently been used in a cat with PRV (Nett et al., 2001). Gradual phlebotomy (5 mL/kg, repeated as needed) is recommended for dogs and cats with right-to-left shunts and erythrocytosis because an increased RBC mass appears to be the body's way of enhancing oxygen delivery to the tissues, thereby compensating for the chronic hypoxemia in these animals. Because sudden decreases in blood volume can result in marked hypotension, a peripheral vein catheter can be used to administer an equivalent volume of saline solution at the same time that blood is being collected. However, collapsing episodes during or immediately after phlebotomy are extremely rare. As a result of its high viscosity in patients with erythrocytosis, it may be extremely difficult to obtain blood through a relatively small (e.g., 19-gauge) catheter.

Once the patient's condition has been stabilized, the cause of the erythrocytosis should be sought (Fig. 84-1). The following approach is recommended. The patient's cardiopulmonary status should first be evaluated by auscultation, precordial palpation, thoracic radiography, or echocardiography (see Chapters 1 and 2). An arterial blood sample should be obtained for blood gas analysis to rule out hypoxemia and pulse oxymetry used to evaluate oxygenation. In some animals with erythrocytosis the blood viscosity is so high that the blood gas analyzer (which is usually flow dependent) cannot generate results; in this event a therapeutic phlebotomy should be performed before a sample is resubmitted for testing (i.e., the blood oxygen content [PO<sub>2</sub>] does not change after therapeutic phlebotomy). If the PO2 is normal, excretory abdominal ultrasonography or computerized tomography should be performed to determine whether masses or infiltrative lesions are present in the kidneys. If no such lesions are found, the patient most likely does not have renal secondary crythrocytosis, so a search for an extrarenal neoplasm should be conducted. A serum sample for determination of Epo activity or concentration should be sent for analysis to a reliable laboratory (e.g., Dr. Urs Giger, Department of Genetics, School of Veterinary Medicine, University of Pennsylvania). In the author's experience, bone marrow evaluations of cats and dogs with erythrocytosis are unrewarding; in most cases the only abnormality is a decreased myeloid/erythroid ratio as a result of erythroid hyperplasia.

If PRV is established in the animal, hydroxyurea (30 mg/kg PO q24h) is administered for 7 to 10 days, after which the dose can be gradually decreased or the dosing interval gradually lengthened to fulfill the patient's needs. Phlebotomy should be repeated as dictated by the patient's clinical signs. If the final diagnosis is secondary erythrocytosis, the primary disorder should be treated (e.g., surgery for a renal mass). The author and others have successfully used the hydroxyurea protocol in dogs with right-to-left shunts and secondary erythrocytosis (Moore & Stepien, 2001).

**FIG 84-1** Diagnostic approach to the dog or cat with erythrocytosis. *PCV*, Packed cell volume; *TPP*, total plasma protein; *RBC*, red blood cell; *US/IVP*, ultrasonography/intravenous pyelography; *Ep*, erythropoietin; *2ry*, secondary.

Most dogs and cats with PRV have extremely long survival times (longer than 2 years) if treated with hydroxyurea, with or without phlebotomies. Because this drug is potentially myelosuppressive, complete blood counts should be performed every 4 to 8 weeks and the dose adjusted according to the neutrophil count (see Chapter 80). The prognosis in dogs and cats with secondary erythrocytosis depends on the nature of the primary disease.

Lymphopenia

Lymphocytosis

#### **GENERAL CONSIDERATIONS**

The leukogram, evaluated as part of the complete blood count (CBC), includes a quantification of the total number of white blood cells (WBCs) and the differential WBC count. Although a specific disorder is rarely diagnosed on the basis of a leukogram, the information obtained may be useful in limiting the number of differential diagnoses or in predicting the severity of the disease and its prognosis. Sequential leukograms may also be helpful in monitoring a patient's response to therapy.

According to standard laboratory techniques, all nucleated cells are counted during a WBC count, including nucleated red blood cells (nRBCs). Differential leukograms determined by particle counters used at human referral laboratories are not valid for cats and dogs. New veterinary benchtop analyzers (LaserCyte, IDEXX, Westbrook, Maine; and CBC-Diff, Heska Corporation, Fribourg, Switzerland) provide reliable WBC total and differential counts. The LaserCyte provides a five-part differential WBC count (neutrophils, lymphocytes, monocytes, eosinophils, and basophils), whereas the CBC-Diff provides a three-part differential count. As a general rule, when a benchtop hematology analyzer yields values outside the reference range or

the values are flagged, the clinician or a technician should carefully examine a blood smear.

Leukocytosis occurs if the WBC count exceeds the upper limit of normal for the species; leukopenia occurs if the WBC count is below the reference range. In some breeds of dogs (Belgian Tervuren, Greyhound) the WBC and neutrophil counts are frequently below the reference range for the species, thus resulting in an erroneous diagnosis of leukopenia and neutropenia in an otherwise healthy dog.

A differential WBC count may be reported in either relative (percentages) or absolute numbers (number of cells per microliter). However, the *absolute* leukocyte numbers, not the percentages, should always be evaluated because the latter may be misleading, particularly if the WBC count is very high or very low. For example, a total WBC of 3000/ L (or  $3 \times 10^9$ /L) and a differential WBC count of 90% lymphocytes and 10% neutrophils can lead to one of the following two conclusions:

- 1. According to the percentages alone, the dog has lymphocytosis and neutropenia; in this situation the clinician may erroneously focus on the "lymphocytosis" rather than the neutropenia.
- 2. According to the absolute numbers, the dog has severe neutropenia (300 cells/ L) with a normal lymphocyte count (i.e., 2700 cells/ L).

The latter obviously reflects the actual clinical situation. The clinician should then concentrate on determining the cause of the neutropenia and ignore the normal lymphocyte count.

#### NORMAL LEUKOCYTE MORPHOLOGY AND PHYSIOLOGY

From a morphologic standpoint, leukocytes can be classified as either polymorphonuclear or mononuclear. Polymorphonuclear cells include the neutrophils, eosinophils, and basophils; the mononuclear cells include the monocytes and lymphocytes. Their basic morphologic and physiologic characteristics are reviewed elsewhere (Feldman et al., 2000).

The following morphologic changes have important clinical implications and should thus be recognized:

- 1. Neutrophils may become toxic in response to injury; toxic neutrophils display characteristic cytoplasmic changes, including basophilia or granulation, vacuolation, and Döhle bodies (small, bluish cytoplasmic inclusions that consist of aggregates of endoplasmic reticulum). This change occurs in the bone marrow and indicates that the neutrophils are losing the battle against the offending agent.
- Giant neutrophils, bands, and metamyelocytes are large, polyploidal cells that may result from skipped cell division; they represent yet another manifestation of toxic changes and are more common in cats than dogs.

Other neutrophil morphologic abnormalities recognized during a careful examination of blood smears include the Pelger-Huët anomaly (cats and dogs) and Chédiak-Higashi syndrome (cats). The Pelger-Huët anomaly occurs when the nucleus of polymorphonuclear leukocytes fails to divide, but the nuclear chromatin and cytoplasm maturation is complete (i.e., the nucleus has a bandlike appearance with mature, clumped chromatin). Cats and dogs with this anomaly typically have profound left shifts in the absence of clinical signs. On careful examination of the smear, however, the cells in the left shift are mature cells with nuclear hyposegmentation and not immature neutrophils. This anomaly may be acquired or inherited (autosomal dominant) and is usually considered of minimal clinical relevance. We have seen it primarily in Australian Cattle dogs and in dogs undergoing chemotherapy.

Chédiak-Higashi syndrome, a lethal autosomal recessive condition of Persian cats with smoke-colored haircoats and yellow eyes, is characterized by enlarged neutrophilic and eosinophilic granules in association with partial albinism, photophobia, increased susceptibility to infections, bleeding tendencies, and abnormal melanocytes.

Nuclear hypersegmentation (i.e., four or more distinct nuclear lobes) may result from a prolonged neutrophil transit time ("old" neutrophils). It occurs in dogs with hyperadrenocorticism, cats and dogs receiving corticosteroid therapy, and cats and dogs with chronic inflammatory disorders.

A basic review of neutrophil physiology follows. Three theoretical physiologic neutrophil compartments exist in the bone marrow (Fig. 85-1). The proliferative compartment is composed of dividing cells (myeloblasts, progranulocytes, and myelocytes); myeloblasts take approximately 48 to 60 hours to mature into metamyelocytes. The maturation compartment consists of metamyelocytes and band neutrophils; the transit time through this compartment is 46 to 70 hours. The storage compartment is composed of mature neutrophils; the transit time in this compartment is approximately

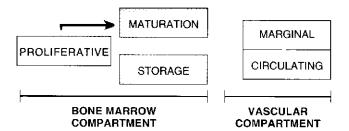

FIG 85-1 Theoretical neutrophil compartments in bone marrow and

50 hours, and it contains an estimated 5-day supply of neutrophils. Mature neutrophils leave the bone marrow by a random process that involves changes in cell deformability and adhesiveness.

Two neutrophil pools are present in the vascular compartment (see Fig. 85-1). The marginal neutrophil pool (MNP) consists of neutrophils that are adhered to the vascular endothelium (and are thus not counted during a CBC). The circulating neutrophil pool (CNP) consists of the neutrophils circulating in the blood (i.e., the cells counted during a differential WBC count). The total blood neutrophil pool is composed of the MNP plus the CNP. In dogs the CNP is approximately equal in size to that of the MNP. However, in cats the MNP is approximately two to three times the size of the CNP. The neutrophil has an average blood transit time of approximately 6 to 8 hours in dogs and 10 to 12 hours in cats, with all blood neutrophils replaced every 2 to 2.5 days. Once the neutrophils leave the blood vessel (by diapedesis), they normally do not return to the circulation and are lost in the lungs, gut, other tissues, urine, or saliva.

#### LEUKOCYTE CHANGES IN DISEASE

Because the lower limit for the reference range for basophil and monocyte counts is 0, basopenia and monocytopenia are not discussed.

#### **NEUTROPENIA**

Neutropenia is defined as an absolute decrease in the number of circulating neutrophils. It can result from decreased (or impaired) cell production within the bone marrow or from the increased margination or destruction of circulating neutrophils (Box 85-1). Neutropenia is relatively common in cats and dogs. The clinician should keep in mind, however, that normal cats may have neutrophil counts of 1800 to 2300/μL; this reference range is also true for Greyhounds.

In a recent study of 232 dogs and 29 cats evaluated in a teaching hospital (Brown & Rogers, 2001), infectious diseases (feline leukemia virus, feline immunodeficiency virus, parvovirus) were the most common comorbid conditions, accounting for almost 52% of the cases of neutropenia. Sepsis or endotoxemia accounted for 11% of the cases, as did drug-associated neutropenia (e.g., chemotherapy, phenobar-

bital, antibacterials); primary bone marrow disease was found in 4% of the patients. The cause of the neutropenia was unclear in 21% of the patients.

Clinical signs in neutropenic cats and dogs are usually vague and nonspecific; they include anorexia, lethargy, pyrexia, and mild gastrointestinal tract signs. Oral ulceration, a common feature of neutropenia in human beings, does not seem to occur in small animals. Neutropenia is frequently an incidental finding in an otherwise healthy dog or cat (i.e., the patient is asymptomatic). If the neutropenia is caused by peripheral neutrophil consumption (i.e., a septic process), most animals exhibit clinical signs. Dogs and cats with parvoviral enteritis have neutropenia in association with severe vomiting or diarrhea or both. Cats and dogs with neutropenia can occasionally present in septic shock (pale, hypoperfused, hypothermic) and should be treated aggressively.

The evaluation of neutropenic cats and dogs should include a detailed drug history (e.g., estrogen or phenylbutazone in dogs, griseofulvin in cats; see Box 85-1); vaccination

history (e.g., was the cat vaccinated against panleukopenia or the dog against parvoviral enteritis?); a complete physical examination and imaging in search of a septic focus; serologic, virologic, or molecular tests for infectious diseases (e.g., feline leukemia virus, feline immunodeficiency virus, canine ehrlichiosis, parvoviral enteritis); and, if necessary, bone marrow cytologic or histopathologic studies. Evaluation of changes in a blood smear is important in establishing the pathogenesis of the neutropenia. Benchtop hematology analyzers provide total neutrophil counts and do not distinguish mature neutrophils from bands, reemphasizing the value of evaluating the blood smear. If a dog or cat has anemia and/or thrombocytopenia in association with the neutropenia, particularly if the anemia is nonregenerative, a primary bone marrow disorder should be strongly suspected. If a dog or cat has regenerative anemia and spherocytosis in association with neutropenia, an immune-mediated disease should be considered a likely diagnosis.

The presence of toxic changes in the neutrophils or a left shift (see below) tend to suggest infection (i.e., toxic changes and left shifts are typically absent in dogs and cats with steroid-responsive neutropenia or primary bone marrow disorders). In a recent study of 248 dogs with toxic neutrophil changes conducted in Israel (Aroch et al., 2005) dogs with pyometra, parvoviral infection, peritonitis, pancreatitis, and septicemia were significantly, and not surprisingly, more likely to have toxic changes than those in the control group. Interestingly, toxic neutrophil changes were also significantly associated with acute renal failure, immune-mediated hemolytic anemia, and disseminated intravascular coagulation.

Evaluation of sequential leukograms in neutropenic dogs and cats is helpful in excluding transient or cyclic neutropenia (or cyclic hematopoiesis).

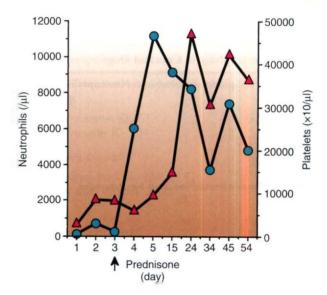

If the pathogenesis of neutropenia cannot be ascertained in an animal, sophisticated diagnostic techniques such as testing for antineutrophil antibodies, leukocyte nuclear scanning, or leukocyte kinetic studies can be performed. As previously noted, normal cats and Greyhounds can have low neutrophil counts. Therefore if a cat or a Greyhound with a neutrophil count of 1800 to 2300/µL is brought in for evaluation (or, more likely, if the "neutropenia" is detected during a routine hematologic evaluation), a conservative approach (e.g., repeat the CBC in 2 to 3 weeks) is indicated as long as no other clinical or hematologic abnormalities are found (e.g., left shift, toxic changes).

Because corticosteroid-responsive neutropenia has been well characterized in cats and dogs, if most infectious and neoplastic causes of neutropenia have been ruled out in an asymptomatic neutropenic animal, an in-hospital therapeutic trial of immunosuppressive doses of corticosteroids (prednisone, 2 to 4 mg/kg/day PO for dogs; 4 to 8 mg/kg/day PO for cats) can be instituted. Responses are usually observed within 24 to 96 hours of the start of treatment in such patients. Treatment is continued as it is for dogs with immune hemolytic anemia and other immune-mediated disorders (see Chapter 93) (Fig. 85-2).

Asymptomatic, afebrile neutropenic dogs and cats should be treated with broad-spectrum bactericidal antibiotics because they are at high risk for sepsis. The authors' drug of choice in dogs is sulfamethoxazole and trimethoprim, at a dosage of 15 mg/kg PO q12h; another drug that can be used in both dogs and cats is enrofloxacin (Baytril) at a dosage of 5 mg/kg PO q12-24h. Antibiotics with an anaerobic spectrum should not be used because they deplete intestinal anaerobes, a protective bacterial population.

Neutropenic febrile (or symptomatic) cats and dogs constitute a medical emergency and should be treated with aggressive intravenous antibiotic therapy. The authors' treatment of choice consists of a combination of ampicillin (20 mg/kg IV q8h) and enrofloxacin (5-10 mg/kg IV q24h).

Neutrophil production can be stimulated by the administration of human recombinant granulocyte colony-stimulating factor (G-CSF) (5  $\mu g/kg$  SQ q24h). Although results are quite spectacular, the responses are usually short lived because of the counteractive effects of anti-CSF antibodies produced by the affected dog or cat. Lithium carbonate

(10 mg/kg PO q12h) can increase the neutrophil counts in dogs; the therapeutic trough serum concentration of lithium is 0.8 to 1.5 mmol/L. This drug should be used with caution in dogs with decreased glomerular filtration rate because it is primarily excreted by the kidneys. Lithium carbonate does not appear to be effective in cats and may be toxic.

#### **NEUTROPHILIA**

Neutrophilia is defined as an absolute increase in the number of neutrophils; it is the most common cause of leukocytosis in dogs and cats. Several terms used to characterize neutrophilia are defined below.

The term mature neutrophilia refers to an increase in the number of segmented (mature) neutrophils without an increase in the number of immature forms (e.g., bands). Neutrophilia with a left shift refers to an increase in the number of both mature and immature neutrophils (more than 300/µL bands). A regenerative left shift is neutrophilia with increased numbers of immature neutrophils in which the number of immature forms does not exceed the number of mature neutrophils; most dogs and cats with a regenerative left shift have leukocytosis. A degenerative left shift occurs when the number of immature forms exceeds that of mature neutrophils; the number of the latter may be normal, low, or high. Degenerative left shifts are usually suggestive of an aggressive disease; toxic neutrophil changes (see previous section) are common in dogs and cats with degenerative left shifts. Disorders commonly associated with degenerative left shifts include pyothorax, septic peritonitis, bacterial pneumonia, pyometra, prostatitis, and acute pyelonephritis. The term extreme neutrophilia refers to situations in which the

**Common**; relatively common; uncommon; D, dog; C, cat; ₹, poorly documented.

neutrophil count is above 50,000/µI.; it can be associated with a left shift or mature neutrophilia. Diseases typically associated with extreme leukocytosis include septic foci (e.g., pyometra), immune-mediated diseases, hepatozoonosis, mycobacteriosis, and chronic myelogenous leukemia. A leukemoid reaction refers to a marked neutrophilia with a severe left shift, which includes metamyelocytes and myelocytes. It indicates severe inflammatory disease and may be difficult to distinguish from chronic granulocytic (myelogenous) leukemia (see Chapter 81).

Although a high percentage of cats and dogs with neutrophilia have underlying infectious disorders, neutrophilia is not synonymous with infection. Rather, neutrophilia in cats and dogs is commonly the result of inflammatory or neoplastic processes. Several disorders resulting in neutrophilia are listed in Box 85-2.

Of note, neutrophilia commonly results from endogenous epinephrine release (physiologic neutrophilia). This neutrophilia, which is associated with the release of neutrophils from the MNP, is transient (lasting 20 to 30 minutes after endogenous release of catecholamines) and is commonly associated with erythrocytosis and lymphocytosis (the latter primarily in cats).

The endogenous release or exogenous administration of corticosteroids results in stress- or corticosteroid-induced

neutrophilia, which is associated with decreased neutrophil egress from the vasculature and increased bone marrow release of neutrophils from the storage pool. Other hematologic changes typical of a stress leukogram include lymphopenia, eosinopenia, and monocytosis (the latter does not occur in cats). These abnormalities are commonly seen in sick dogs and cats.

Clinical signs in cats and dogs with neutrophilia are usually secondary to the underlying disorder. Pyrexia may or may not be present. If the patient has persistent neutrophilia, if the neutrophils display toxic changes (see p. 1229), or if a degenerative left shift is present, every effort should be made to identify a septic focus or an infectious agent promptly. The workup in such animals should include a thorough physical examination (e.g., abscess); thoracic and abdominal radiography (e.g., pneumonia, pleural or abdominal effusion); abdominal ultrasonography (e.g., peritonitis, pancreatic or hepatic abscess); and the collection of blood, urine, fluid, or tissue samples for cytology and bacterial and fungal cultures. As previously discussed, autologous or allogeneic neutrophils labeled with radionuclides (i.e., technetium 99m or indium 111) can be injected intravenously and the septic focus, or foci, identified by gamma camera imaging; an inflammatory focus can also be detected by radiolabeled ciprofloxacin.

The treatment of dogs and cats with neutrophilia is aimed at the primary cause. Empiric antibiotic therapy with a broad-spectrum bactericidal antibiotic (e.g., sulfa-trimethoprim, enrofloxacin, cephalosporin, amoxicillin) is an acceptable approach if a cause for the neutrophilia cannot be identified after exhaustive clinical and clinicopathologic evaluation or as the first line of treatment in a fairly asymptomatic dog or cat.

#### **EOSINOPENIA**

Eosinopenia is defined as an absolute decrease in the number of circulating eosinophils. It is commonly seen as part of the stress leukogram or with exogenous corticosteroid administration and is usually of little clinical relevance.

#### EOSINOPHILIA

Eosinophilia is defined as an absolute increase in the circulating eosinophil numbers. It is relatively common in small animals and can have a variety of causes (Box 85-3). Because eosinophilia is quite common in dogs and cats with parasitic disorders, no animal should undergo a thorough evaluation for eosinophilia before parasitic causes have been ruled out. In cats, flea infestation usually results in marked increases in the eosinophil count. In dogs, eosinophilia is frequently seen in roundworm and hookworm infestations or with dirofilariasis or dipetalonemiasis. Three additional relatively common causes of eosinophilia in cats include eosinophilic granuloma complex, bronchial asthma, and eosinophilic gastroenteritis. A clinical entity resembling feline hypereosinophilic syndrome has been reported in Rottweilers (Sykes et al.); in addition, lesions compatible with oral eosinophilic granulomas have been reported in Siberian Huskies.

#### Miscellaneous

Soft tissue trauma (D?, C?) Feline urologic syndrome (C?) Cardiomyopathy (D?, C?) Renal failure (D?, C?) Hyperthyroidism (C?) Estrus (D?)

Common; relatively common; uncommon; D, dog; C, cat; ?, poorly documented.

Eosinophilia can also occur in dogs and cats with mast cell tumors, but it is rare.

Clinical signs in dogs and cats with eosinophilia are related to the primary disorders rather than to the hematologic abnormality. Because eosinophilia is so commonly found in animals with parasitic diseases, clinical evaluation of these animals should be aimed mainly at excluding these disorders. Once this has been done, other causes of eosinophilia should be pursued (see Box 85-3) by using the appropriate diagnostic procedures (e.g., tracheal wash or pulmonary

fine-needle aspiration for pulmonary infiltrates with eosinophils, endoscopic biopsy for eosinophilic gastroenteritis). Treatment is usually aimed at the primary disorder.

A syndrome with high eosinophil counts in peripheral blood and tissue infiltration with eosinophils has been well documented in cats, Rottweilers, and occasionally other dog breeds. This syndrome is termed hypereosinophilic syndrome and is usually indistinguishable from eosinophilic leukemia. These patients have primary gastrointestinal tract signs, although multisystemic signs are also common. In cats, treatment with immunosuppressive doses of corticosteroids, 6-thioguanine, cytosine arabinoside, cyclophosphamide, and other anticancer agents (see Chapter 79) has been unrewarding, and most affected patients die within weeks of diagnosis. Clinical response to some of these drugs has been documented in Rottweilers.

#### BASOPHILIA

Basophilia is defined as an absolute increase in the basophil numbers and is commonly associated with eosinophilia. Because basophils are similar to tissue mast cells, their numbers increase in disorders characterized by excessive immunoglobulin E production and binding and in a variety of nonspecific inflammatory disorders. Causes of basophilia are listed in Box 85-4.

#### **MONOCYTOSIS**

Monocytosis refers to an absolute increase in monocyte numbers. It can occur in response to inflammatory, neoplastic, or degenerative stimuli. Although monocytosis has traditionally been observed primarily in chronic inflammatory processes, it is also common in acute disorders. Causes of monocytosis in cats and dogs are listed in Box 85-5. **Common**; relatively common; uncommon; D, dog; C, cat; ?, poorly documented.

Because monocytes are precursors of tissue macrophages, granulomatous and pyogranulomatous reactions commonly result in monocytosis (see Box 85-5). In addition, immunemediated injury resulting in cell destruction (e.g., immune hemolysis, polyarthritis) and certain neoplasms (e.g., lymphomas) may cause monocytosis. Some neoplasms secrete CSFs for monocytes and can result in marked monocytosis (more than  $5000/\mu L$ ).

The nature of the clinical evaluation in patients with monocytosis is similar to that used with neutrophilia: it should concentrate on identifying infectious foci. If an immune-mediated disorder is suspected, arthrocentesis to obtain fluid for analysis or other immune tests (see Chapter 92) should be performed. Treatment should be aimed at the primary disorder.

#### **LYMPHOPENIA**

Lymphopenia is defined as an absolute decrease in the lymphocyte count. It constitutes one of the most common hematologic abnormalities in hospitalized or sick dogs and cats, in which it is attributed to the effects of endogenous corticosteroids (stress leukogram). Lymphopenia is also commonly identified in dogs and cats with chronic loss of lymph, such as those with chylothorax or intestinal lymphangiectasia (Box 85-6).

In general, cats and dogs with lymphopenia have obvious clinical abnormalities. As a general rule, it should be "ignored" (i.e., a diagnosis should not be pursued) in sick cats and dogs and in those receiving corticosteroids. The lymphocyte count should be reevaluated after the clinical abnormalities have resolved or steroid therapy has been discontinued. Contrary to popular belief, lymphopenia does not appear to predispose to infection.

Lymphoblastic (C, D)

Hypoadrenocorticism (D)

**Common;** relatively common; uncommon; D, dog; C, cat; ?, poorly documented.

#### LYMPHOCYTOSIS

Lymphocytosis is defined as an absolute increase in lymphocyte numbers. It is common in several clinical situations, including fear (cats; see Neutrophilia, above), vaccination (dogs and possibly cats), chronic ehrlichiosis (dogs), Addison's disease (hypoadrenocorticism; dogs), and chronic lymphocytic leukemia (CLL). The lymphocytes are morphologically normal in all these disorders, with the exception of vaccination reactions, in which reactive lymphocytes (larger cells with a dark blue cytoplasm) are commonly seen. High numbers of morphologically abnormal (i.e., blast) lymphoid cells are found in dogs and cats with acute lymphoblastic leukemia (see Chapter 81).

In cats with marked lymphocytosis and neutrophilia, endogenous release of catecholamines should be ruled out as the cause of these hematologic abnormalities. If the cat is fractious and blood cannot be collected without a considerable struggle, a blood sample should be collected under chemical restraint.

Recent vaccination should be ruled out in dogs with lymphocytosis and reactive lymphocytes in the blood smear. Most dogs with lymphocyte counts of more than 10,000 cells/µL have either chronic ehrlichiosis or CLL; most dogs with monocytic ehrlichiosis have increased numbers of large granule lymphocytes (LGL), larger lymphocytes with abundant cytoplasm, and large azurophilic cytoplasmic granules. LGL lymphocytosis can also occur in dogs with CLL. Lymphocyte counts of more than 20,000 cells/µL are extremely rare in dogs with ehrlichiosis (i.e., dogs with more than 20,000 lymphocytes/µL more likely have CLL). A high proportion of these dogs also has hyperproteinemia caused by

a monoclonal or polyclonal gammopathy (see Chapter 89). The clinical and hematologic features of monocytic ehrlichiosis and CLL are quite similar (e.g., cytopenia, hyperproteinemia, hepatosplenomegaly, lymphadenopathy). Serologic tests or polymerase chain reaction (PCR) testing for Ehrlichia canis, immunophenotyping of peripheral blood lymphocytes, PCR for clonality, and bone marrow aspiration findings may be helpful in differentiating these two disorders. Bone marrow cytologic findings in dogs with chronic ehrlichiosis usually consist of generalized hematopoietic hypoplasia and plasmacytosis, whereas hypoplasia with increased numbers of lymphocytes is more common in dogs with CLL. Causes of lymphocytosis in cats and dogs are listed in Box 85-7.

## CHAPTER

# Combined Cytopenias and Leukoerythroblastosis

#### CHAPTER OUTLINE

DEFINITIONS AND CLASSIFICATION CLINICOPATHOLOGIC FEATURES

#### **DEFINITIONS AND CLASSIFICATION**

Combined cytopenias commonly result from decreased bone marrow production or, less frequently, from increased destruction or sequestration of circulating cells. Following are the definitions of several terms used throughout this chapter. Bicytopenia is a decrease in the numbers of two circulating blood cell lines (anemia and neutropenia, anemia and thrombocytopenia, or neutropenia and thrombocytopenia). If all three cell lines are affected (anemia, neutropenia, thrombocytopenia), this is called pancytopenia (from the Greek word pan, meaning "all"). In most cases, if anemia is present it is nonregenerative. If regenerative anemia occurs in association with other cytopenias, the cause usually is peripheral destruction of cells. Leukoerythroblastic reaction (LER) (or leukoerythroblastosis) refers to the presence of immature white blood cells (WBCs) and nucleated red blood cells (nRBCs) in the circulation (i.e., nRBCs and a left shift). In these cases the WBC count is usually high, but it can be normal or low.

As mentioned, cytopenias can develop as a result of decreased production or increased peripheral destruction of the affected cell line(s). In general, bicytopenias and pancytopenias result from primary bone marrow disorders (i.e., there is a problem in the "cell factory") (Box 86-1), although they may also result from peripheral blood cell destruction, such as what occurs in sepsis, disseminated intravascular coagulation (DIC), and some immune-mediated blood disorders.

LERs result from a variety of mechanisms (Box 86-2), but in general the presence of immature blood cells in the circulation is secondary to their premature release from the bone marrow or from other hematopoietic organs (spleen, liver). This premature release can result from (1) an increased demand for blood cells (e.g., hemolytic anemia, blood loss, peritonitis), resulting in a shorter transit time through the bone marrow compartments or extramedullary hematopoietic sites; or (2) the crowding out of normal bone marrow precursors (e.g., leukemia, bone marrow lymphoma). They may also be prematurely released from a site of extramedullary hematopoiesis (EMH) (i.e., spleen, liver) as a result of the absence of normal feedback mechanisms.

#### **CLINICOPATHOLOGIC FEATURES**

The clinical signs and physical examination findings in dogs and cats with combined cytopenias or LERs are usually related to the underlying disorder rather than the hematologic abnormalities per se, with the exception of pallor and spontaneous bleeding (petechiae, ecchymoses) secondary to anemia and thrombocytopenia, respectively. Pyrexia may be present if the patient is markedly neutropenic and is septic or bacteremic.

An important aspect of the clinical evaluation of these patients is the history. A detailed history should be obtained, with particular inquiries about the therapeutic use of drugs (e.g., estrogen or phenylbutazone in dogs, griseofulvin or chloramphenicol in cats), exposure to benzene derivatives (rare), travel history, vaccination status, and exposure to other animals, among others. Most drugs that cause anemia or neutropenia can also cause combined cytopenias (see Boxes 83-2 and 85-1).

The physical examination of dogs and cats with combined cytopenias may reveal the presence of spontaneous hemorrhages compatible with a primary hemostatic disorder (e.g., thrombocytopenia) or pallor secondary to the attendant anemia. Several physical examination findings may help the clinician establish a more presumptive or definitive diagnosis in patients with cytopenias or LER. Of particular interest is the finding of male-feminizing signs in a male dog (usually a cryptorchid) with pancytopenia, which may indicate the presence of a Sertoli cell tumor or, less frequently, an interstitial cell tumor or a seminoma with secondary hyperestrogenism. The finding of generalized

lymphadenopathy, hepatomegaly or splenomegaly, or intraabdominal or intrathoracic masses may direct the clinician toward a specific group of presumptive diagnoses. For example, the finding of a cranial or mid-abdominal mass in a dog with anemia, thrombocytopenia, and LER is highly suggestive of splenic hemangiosarcoma.

The presence of diffuse splenomegaly indicates that the spleen may be sequestering or destroying circulating blood cells or that EMH is occurring in response to a primary bone marrow disorder. Cytologic evaluation of spleen specimens obtained by percutaneous fine-needle aspiration is always indicated in dogs and cats with cytopenias and diffuse splenomegaly to determine whether the enlarged spleen is the cause or consequence of the cytopenia (see Chapter 88).

Serologic studies or polymerase chain reaction (PCR) for infectious diseases is usually indicated in dogs and cats with bicytopenias or pancytopenias. Infectious diseases associated with bicytopenias and pancytopenias commonly diagnosed on serologic PCR findings include monocytic ehrlichiosis in dogs, Babesia gibsoni infection in dogs (combined anemia and thrombocytopenia), and feline leukemia virus (FeLV) and feline immunodeficiency virus infections in cats. If the clinical and hematologic features of the case point toward an immune-mediated disease (e.g., presence of polyarthritis or proteinuria, spherocytosis) a direct Coombs' test and an antinuclear antibody test should be done (see Chapter 92). It is also helpful to submit fluid obtained from one or more joints for cytologic evaluation because the presence of suppurative nonseptic arthritis suggests an immune pathogenesis or a rickettsial disease.

Because establishing whether the cytopenia is the result of peripheral cell destruction or a bone marrow disorder is

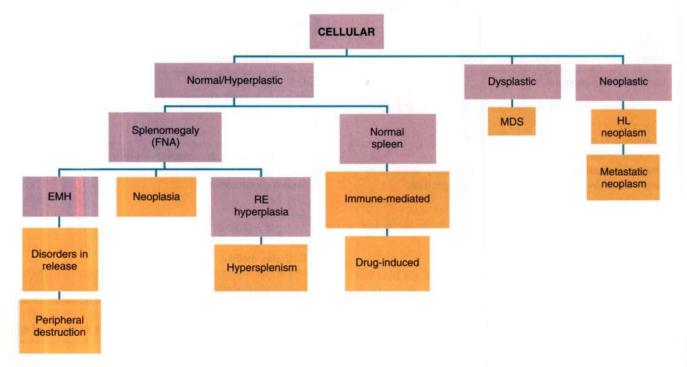

FIG 86-1

important, evaluation of the "cell factory" is logical if no evidence of RBC regeneration in the blood smear or CBC exists (see Chapter 85). Therefore bone marrow aspiration and, ideally, bone marrow core biopsy to obtain specimens for histopathologic studies should be performed in all dogs and cats with combined cytopenias, except for dogs with highly likely or confirmed Evans syndrome and dogs and cats with DIC (i.e., the anemia is regenerative; thus it is assumed that the factory is working properly). Algorithms for the evaluation of bone marrow findings in dogs and cats with bicytopenia and pancytopenia are shown in Figs. 86-1 and 86-2. In private practice obtaining a bone marrow aspirate is usually easier; bone marrow core biopsies are usually performed at referral practices.

A bone marrow evaluation should also be part of the clinical workup in animals with LERs to determine whether the immature WBCs and RBCs in the circulation are secondary to a primary bone marrow disorder or a disorder such as EMH. Because abdominal neoplasms, particularly hemangiosarcoma, are commonly associated with LERs in dogs, abdominal ultrasonography should be done. If diffuse splenomegaly is detected, percutaneous fine-needle aspiration of the spleen should be performed. If splenic or hepatic masses or both are present, the patient should be evaluated as described in Chapter 90.

Weiss (2006) recently reviewed bone marrow aspirates, core biopsies, and medical records of 717 dogs evaluated for presumptive bone marrow disorders. Approximately 2% of

the specimens evaluated were nondiagnostic, 22% were normal, 26% had changes secondary to another primary disease, 24% had nondysplastic and nonneoplastic conditions, 9% had dysplasia, and 18% had neoplasia. Less than 5% of the specimens evaluated had bone marrow hypoplasia and approximately 20% were hyperplastic; acute leukemias were more common than chronic leukemias.

#### **Bone Marrow Aplasia-Hypoplasia**

Bone marrow aplasia-hypoplasia is a disorder characterized by peripheral blood cytopenias and a paucity or absence of hematopoietic precursors in the bone marrow. As previously discussed, bone marrow aplasia-hypoplasia is commonly associated with the administration of certain drugs, such as griseofulvin or chloramphenicol in cats and phenylbutazone or estrogen in dogs. It is also commonly associated with infectious diseases, such as canine monocytic ehrlichiosis and FeLV infection. A corticosteroid-responsive syndrome of combined cytopenias or pancytopenia has been recognized in dogs and cats in the author's clinic. Some patients with pancytopenia have hypercellular bone marrow (see below), suggesting that the cells are destroyed peripherally or at the late stages of bone marrow production.

Bone marrow aspirates from dogs and cats with bone marrow aplasia or hypoplasia typically show hypocellularity or acellularity, and a bone marrow biopsy is frequently necessary to obtain specimens for histopathologic analysis so that a definitive diagnosis can be made. Once infectious

diseases (e.g., Ehrlichia canis titer, SNAP test [IDEXX, Westbrook, Maine], or PCR; FeLV p27 determination) and drug exposure have been ruled out, a therapeutic trial of immunosuppressive doses of corticosteroids (with or without other immunosuppressive drugs; see Chapter 93) may be warranted. Anabolic steroids and erythropoietin do not appear to be beneficial in these patients.

**Myelophthisis.** Infiltration of the bone marrow with neoplastic or inflammatory cells can lead to the crowding out of normal hematopoietic precursors and therefore the development of peripheral blood cytopenias. Disorders resulting in myelophthisis are listed in Box 86-1. Often these animals are evaluated because of anemia, although fever and bleeding caused by neutropenia and thrombocytopenia, respectively, can also be presenting complaints. The presence of hepatomegaly, splenomegaly, or lymphadenopathy in a dog or cat with anemia or combined cytopenias is highly suggestive of some of the neoplastic or infectious disorders listed in Box 86-1.

A definitive diagnosis in dogs and cats with myelophthisis is obtained by evaluating the cytologic or histopathologic characteristics of a bone marrow specimen. Given the fact that certain neoplastic or granulomatous disorders can show a patchy or multifocal distribution, the findings yielded by a bone marrow core biopsy specimen are usually more reliable than those yielded by an aspirate. Once a cytologic or histopathologic diagnosis is obtained, treatment is aimed at the

primary neoplasm (i.e., with chemotherapy) or infectious agent (see specific sections for detailed discussion).

#### Myelodysplastic Syndromes

Myelodysplastic syndromes include a host of hematologic and cytomorphologic changes that may precede the development of acute leukemias by months or years. In addition to the morphologic abnormalities in blood and bone marrow, functional abnormalities of granulocytes and platelets have been well documented in human beings with MDS. Therefore recurrent infections, spontaneous bleeding tendencies, or both are common in such patients, even when the neutrophil and platelet counts are within normal limits. These abnormalities have also been observed in cats with MDS.

MDS has been recognized in both dogs and cats but appears to be more common in retrovirus-infected cats. All dogs are lethargic, depressed, and anorectic. Physical examination findings include hepatosplenomegaly, pallor, and pyrexia; hematologic changes include pancytopenia or bicytopenia, macrocytosis, metarubricytosis, and reticulocytopenia. acute myelogenous leukemia (AML) subsequently developed 3 months after the initial diagnosis of MDS in one of the author's patients (Couto et al., 1984). The cytologic bone marrow abnormalities were similar to those described in cats and are discussed below. Some authors have proposed classifying dogs with primary myelodysplastic syndromes into those with refractory anemia and those with true myelo-

dysplasia, following similar classification schemes used in human beings (Weiss et al., 2000). However, because almost no clinical information was provided for the dogs evaluated, that classification scheme is of questionable clinical relevance.

Several reports of MDS in cats have appeared in the literature. More than 80% of cats in whom the FeLV status was investigated were found to be viremic. Most cats were evaluated because of nonspecific clinical signs such as lethargy, weight loss, and anorexia. Other signs, such as dyspnea, recurrent infections, and spontaneous bleeding, were observed in a few cats. Physical examination revealed hepatosplenomegaly in more than half of the cats; generalized lymphadenopathy and pyrexia were detected in approximately one third.

Hematologic abnormalities in cats with MDS are similar to those seen in dogs; they include isolated or combined cytopenias, macrocytosis, reticulocytopenia, metarubricytosis, and macrothrombocytosis. Morphologic changes in the bone marrow include a normal to increased cellularity, less than 30% blasts, an increased myeloid/erythroid ratio, dyserythropoiesis, dysmyelopoiesis, and dysthrombopoiesis. Megaloblastic RBC precursors are common, with occasional binucleated, trinucleated, or tetranucleated rubricytes or metarubricytes. The morphologic abnormalities in the myeloid cell line include giant metamyelocytes and asynchronous nuclear-cytoplasmic maturation.

Acute leukemia subsequently developed within weeks to months of the diagnosis in approximately one third of cats with MDS described in the literature. MDS commonly progresses to AML in human beings, with only isolated reports of progression to acute lymphocytic leukemia (ALL). However, according to Maggio and colleagues (1978), in one series of 12 cats with MDS, ALL subsequently developed in nine. This may reflect the fact that cytochemical staining was not done to classify the leukemic cells, and cells were thus morphologically classified as lymphoid when they were myeloid. However, because all the cats that showed progression to ALL were also viremic with FeLV, the hematologic changes preceding the development of leukemia did not reflect a "spontaneous" hematologic disorder (as seen in human beings and dogs) but were rather a manifestation of the morphologic and functional changes induced by FeLV.

The management of dogs and cats with MDS is still controversial. A variety of treatments have been used in human beings with MDS; however, none has proved effective. Chemotherapy, supportive therapy, anabolic steroids, inductors of differentiation, hematopoietic growth factors, and androgenic steroids, among others, have been reported to be of benefit in some human beings with MDS. Currently the preferred approach in human beings is treatment with supportive therapy and inductors of differentiation or hematopoietic growth factors. Because most patients are older, chemotherapy does not constitute the first treatment option, given its toxicity. The author recommends supportive therapy (e.g., fluids, blood components, antibiotics) and low-dose cytosine arabinoside as an inductor of differentiation (see Box 81-3). Aclarubicin (5 mg/m² IV q24h for 5 days), a drug

not currently available in the United States, was reported to be of benefit in a Shih Tzu with myelodysplasia (Miyamoto et al., 1999). Novel therapeutic approaches in human beings with MDS have been discussed by Warlick and Smith (2007).

# Myelofibrosis, Osteosclerosis, and Osteopetrosis

Fibroblasts or osteoblasts within the bone marrow can proliferate in response to retroviral infections, chronic noxious stimuli, or unknown causes, leading to fibrous or osseous replacement of the bone marrow cavity, thereby displacing the hematopoietic precursors. These syndromes are termed myelofibrosis and osteosclerosis-osteopetrosis, respectively. Although both syndromes are rare, they have been observed in FeLV-infected cats and in dogs with chronic hemolytic disorders, such as the pyruvate kinase deficiency anemia that occurs in Basenjis and Beagles. Peripheral blood elliptocytosis and dacryocytosis appear to be a common feature in dogs with myelofibrosis. A limited number of dogs and cats with idiopathic myelofibrosis have been reported; in some of these cases, previous exposure to drugs (e.g., phenobarbital, phenytoin, phenylbutazone, colchicine) was documented. In the author's experience, the clinical and hematologic features associated with myelofibrosis in dogs frequently resolve after immunosuppressive treatment with a combination of corticosteroids and azathioprine (see Chapter 93); the author has limited experience with myelofibrosis in FeLV-negative cats.

A presumptive diagnosis of osteosclerosis/osteopetrosis is made on the basis of the presence of combined cytopenias together with increased osseous radiographic density and can be confirmed by a core biopsy of the bone marrow. Unfortunately, no effective treatment is available.

#### CHAPTER OUTLINE

GENERAL CONSIDERATIONS PHYSIOLOGY OF HEMOSTASIS CLINICAL MANIFESTATIONS OF SPONTANEOUS **BLEEDING DISORDERS** CLINICOPATHOLOGIC EVALUATION OF THE **BLEEDING PATIENT** MANAGEMENT OF THE BLEEDING PATIENT PRIMARY HEMOSTATIC DEFECTS Thrombocytopenia Platelet Dysfunction SECONDARY HEMOSTATIC DEFECTS Congenital Clotting Factor Deficiencies Vitamin K Deficiency MIXED (COMBINED) HEMOSTATIC DEFECTS Disseminated Intravascular Coagulation THROMBOSIS

**GENERAL CONSIDERATIONS** 

Spontaneous or excessive bleeding is relatively common in small animals, particularly in dogs. As a general rule, a systemic hemostatic abnormality is the underlying cause of excessive bleeding in dogs and cats that have sustained trauma or are undergoing a surgical procedure and in dogs evaluated because of spontaneous bleeding tendencies (spontaneous bleeding is rare in cats with hemostatic abnormalities). Approaching these patients' bleeding in a logical and systematic fashion allows the clinician to confirm the presumptive diagnosis in most cases.

In addition to bleeding, abnormal hemostatic mechanisms can also cause thrombosis and thromboembolism, potentially leading to organ failure. Spontaneous bleeding disorders are extremely common in dogs evaluated at our clinic but are rare in cats. Thromboembolic disorders are rare in both dogs and cats without underlying cardiovascular disorders (e.g., cats with hypertrophic cardiomyopathy and

aortic thromboembolism; see Chapter 12). The most common disorder leading spontaneous bleeding in dogs seen at our clinic is thrombocytopenia, mainly of immune-mediated pathogenesis. Other common hemostatic disorders leading to spontaneous bleeding in dogs evaluated at our hospital include disseminated intravascular coagulation (DIC) and rodenticide poisoning. Congenital clotting factor deficiencies resulting in spontaneous bleeding are rare. Although von Willebrand disease (vWD) is common in certain breeds (see p. 1251), it is not a common cause of spontaneous bleeding. Abnormalities in hemostasis screens are frequently noted in cats with liver disease, feline infectious peritonitis (FIP), or neoplasia; however, spontaneous bleeding tendencies are extremely rare in these patients. Decreased production of platelets (thrombocytopenia) or virus-induced thrombocytopathia resulting in spontaneous bleeding is occasionally seen in cats with retrovirus-induced bone marrow disorders.

#### PHYSIOLOGY OF HEMOSTASIS

Under normal conditions, injury to a blood vessel leads to immediate vascular changes (e.g., vasoconstriction) and rapid activation of the hemostatic system. Changes in axial blood flow lead to exposure of circulating blood to subendothelial collagen, resulting in rapid adhesion of platelets to the affected area. The adhesion of platelets to the subendothelium is mediated by adhesive proteins, such as von Willebrand factor (vWF) and fibrinogen. After adhering to the area of endothelial damage, platelets aggregate and form the *primary hemostatic plug*, which is short lived (seconds) and unstable. The primary hemostatic plug serves as a framework in which secondary hemostasis occurs because most of the clotting factors "assemble" the thrombus or clot on the platelet plug.

Although the intrinsic, extrinsic, and common coagulation pathways have been well characterized and are still used to teach physiology of hemostasis, coagulation in vivo does not necessarily follow these distinct pathways. For example, factors XII and XI do not appear to be necessary for the

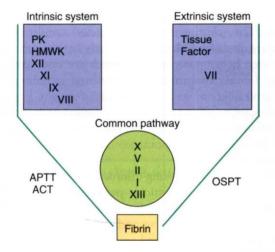

FIG 87-1
The traditional intrinsic, extrinsic, and common coagulation pathways. PK, Prekallikrein; HMWK, high-molecular-weight kininogen; APTT, activated partial thromboplastin time; ACT, activated coagulation time; OSPT, one-stage prothrom bin time.

initiation of coagulation (e.g., dogs and cats with factor XII deficiency do not have spontaneous bleeding tendencies). In the past 2 decades the traditional coagulation cascade has been thought of as a common pathway from early in the process; the traditional intrinsic, extrinsic, and common pathways are now known to be interrelated (Schenone et al., 2004)

In the traditional scheme, activation of the contact phase of the coagulation cascade occurs almost simultaneously with platelet adhesion and aggregation (Fig. 87-1) and leads to the formation of fibrin through the intrinsic coagulation cascade. A good mnemonic is to refer to the intrinsic system as the "dime store" coagulation cascade: "it is not \$12, but \$11.98" (for factors XII, XI, IX, and VIII). Factor XII is activated by contact with the subendothelial collagen and by the platelet plug; once it has been activated, fibrin, or the secondary hemostatic plug, forms. Prekallikrein (Fletcher factor) and high-molecular-weight kiningeen are important cofactors for factor XII activation. The role of the contact phase of coagulation in vivo is questionable. The secondary hemostatic plug is stable and long lasting. In addition, whenever tissue trauma occurs, the release of tissue procoagulants (collectively referred to as tissue factor) results in activation of the extrinsic coagulation cascade, also leading to the formation of fibrin (see Fig. 87-1). Tissue factor is ubiquitous and is present on the membrane of most cells, with the exception of normal endothelium.

The stimuli that activate the contact phase of coagulation also activate the fibrinolytic and kinin pathways. Fibrinolysis is extremely important as a safeguard mechanism because it prevents excessive clot or thrombus formation. When plasmin lyses fibrinogen and fibrin, it generates fibrin degradation products (FDPs), which impair additional platelet adhesion and aggregation in the site of injury. Once fibrin

has been stabilized by complexing factor XIII, plasmin biodegradation generates D-dimers instead. The activation of plasminogen into plasmin results in the destruction (lysis) of an existing clot (or thrombus) and interferes with the normal clotting mechanisms (inhibition of platelet aggregation and clotting factor activation in the affected area). Therefore excessive fibrinolysis usually leads to spontaneous bleeding. Two molecules stimulate plasminogen activation into plasmin: tissue plasminogen activator (tPA) and urokinase-type plasminogen activator. Three plasminogen activator inhibitors (PAI) termed PAI-1, -2, and -3 inhibit fibrinolysis, thus leading to thrombosis.

Other systems that oppose blood coagulation also become operational once intravascular clotting has occurred. The best-characterized ones include antithrombin (AT), a protein synthesized by hepatocytes that acts as a co-factor for heparin and inhibits the activation of factors IX, X, and thrombin. AT also inhibits tPA. Proteins C and S are two vitamin K–dependent anticoagulants also produced by hepatocytes. These three factors are some of the natural anticoagulants that prevent excessive clot formation.

#### CLINICAL MANIFESTATIONS OF SPONTANEOUS BLEEDING DISORDERS

In the evaluation of a cat or dog with spontaneous or excessive bleeding, the clinician should ask the owners the following questions, which may provide additional clues to the pathogenesis of the coagulopathy:

- Is this the first bleeding episode? If it is occurring in a mature animal, an acquired coagulopathy is suspected.
- Has the animal had any surgeries before this and, if so, did it bleed excessively? If the pet has had previous bleeding episodes during elective surgeries, a congenital coagulopathy is suspected.
- Do any litter mates have similar clinical signs? Did the litter have an increased perinatal mortality rate? These findings also support a congenital coagulopathy.
- Has the animal recently been vaccinated with modified-live vaccines? Modified-live vaccines can cause thrombocytopenia, platelet dysfunction, or both.
- Is the animal currently receiving any medication that may cause thrombocytopenia or platelet dysfunction (e.g., nonsteroidal antiinflammatories [NSAIDs], sulfas, antibiotics, phenobarbital)?
- Does the animal have access to rodenticides or does it roam freely? This may indicate rodenticide toxicity.

The clinical manifestations of primary hemostatic abnormalities are quite different from those of secondary hemostatic abnormalities (Box 87-1). Indeed, the clinician should be able to classify the type of coagulopathy on the basis of the physical examination findings before submitting any samples for laboratory evaluation. This is rather easy to

BOX 87-1

Clinical Manifestations of Primary and Secondary Hemostatic Defects

Bleeding into muscles, joints,
and body cavities
Delayed bleeding after
venipuncture

conceptualize by thinking about the normal coagulation mechanisms. For example, a primary hemostatic plug cannot form in a cat or dog with severe thrombocytopenia or platelet dysfunction. Because this plug is short lived and eventually covered with fibrin (generated through the secondary hemostatic mechanisms), multiple, short-lived bleeds occur that are arrested as soon as fibrin is formed, resulting in multiple small and superficial hemorrhages. This is analogous to turning on and off a faucet connected to a garden hose with multiple perforations (i.e., an irrigator); multiple spurts of water (i.e., blood) form adjacent to the hose (i.e., the vessel). On the other hand, a short-lived primary hemostatic plug can form in a cat or dog with severe clotting factor deficiencies (e.g., hemophilia, rodenticide poisoning); enough functional platelets are present, but fibrin cannot be generated. The result of this is a delayed, continuous, longlasting bleed, leading to hematoma formation or bleeding into a body cavity. This is analogous to turning on a faucet connected to a regular garden hose with a single large opening; in this situation, water (i.e., blood) continues to flow and collect in large amounts next to the opening in the hose (i.e., vessel).

Spontaneous bleeding infrequently occurs in cats and dogs with excessive fibrinolysis. I have evaluated four dogs with protein-losing nephropathy and nephrotic syndrome in which spontaneous bleeding (i.e., petechiae and ecchymoses) appeared to result from enhanced fibrinolysis. We have recently documented delayed postoperative bleeding in retired racing Greyhounds that may be associated with hyperfibrinolysis (Lara et al., 2007).

Cats and dogs with primary hemostatic defects (i.e., platelet disorders) therefore have typical manifestations of superficial bleeding, consisting of petechiae, ecchymoses, bleeding from mucosal surfaces (e.g., melena, hematochezia, epistaxis, hematuria), and prolonged bleeding immediately after venipuncture. In clinical practice, the majority of primary hemostatic disorders are caused by decreased numbers of circulating platelets (thrombocytopenia). Primary hemostatic defects occasionally result from platelet dysfunction (e.g., uremia, von Willebrand disease [vWD], monoclonal gammopathies, vector-borne diseases). Primary hemostatic defects caused by vascular disorders are extremely rare in cats and dogs and are not discussed here.

Clinical signs in cats and dogs with secondary hemostatic defects (i.e., clotting factor deficiencies) consist of deep bleeding, including bleeding into body cavities and joints, and deep hematomas, most of which are discovered as a lump. Certain congenital coagulopathies, including factor XII, prekallikrein, and high-molecular-weight kininogen deficiencies, result in a marked prolongation of the activated coagulation time (ACT) or activated partial thromboplastin time (APTT) without spontaneous or prolonged bleeding (see below).

Most secondary bleeding disorders seen in clinical practice are caused by rodenticide poisoning or liver disease; selective congenital clotting factor deficiencies occasionally can lead to spontaneous secondary bleeding disorders. A combination of primary and secondary bleeding disorders (mixed disorders) is seen almost exclusively in dogs and cats with DIC.

#### CLINICOPATHOLOGIC EVALUATION OF THE BLEEDING PATIENT

Clinicopathologic evaluation of the hemostatic system is indicated primarily in two subsets of patients: in those with spontaneous or prolonged bleeding and before surgery in patients with disorders commonly associated with bleeding tendencies (e.g., splenic hemangiosarcoma [HSA] and DIC in dogs; liver disease and clotting factor deficiency) or a suspected congenital coagulopathy (e.g., before ovariohysterectomy in a Doberman Pinscher suspected of having subclinical vWD).

When evaluating a cat or dog with a spontaneous bleeding disorder, the clinician should keep in mind that the preliminary clinical diagnosis can usually be confirmed by performing a handful of simple cage-side tests. If these tests do not yield a definitive answer or if a more specific diagnosis is desirable (e.g., the identification of specific clotting factor deficiencies), a plasma sample can be submitted to a referral veterinary diagnostic laboratory or a specialized coagulation laboratory (e.g., New York State Diagnostic Laboratory, Cornell University, Ithaca).

Some simple cage-side tests include evaluation of a blood smear; determination of the ACT, one-stage prothrombin time (OSPT), and APTT; quantification of FDP concentration or D-dimer assays; and the buccal mucosa bleeding time (BMBT) (Table 87-1). Examination of a good-quality, well-stained blood smear (e.g., Diff-Quik, Medion GmbH, Düdingen, Switzerland) provides important clues regarding platelet numbers and morphology. The first aspect of this examination should be to scan the smear at low power to identify platelet clumps; platelet clumping commonly results in pseudothrombocytopenia. Next, the oil immersion lens should be used to examine several representative monolayer fields (i.e., where approximately 50% of the red blood cells [RBCs] touch each other), and the number of platelets in five fields should be averaged. In dogs, 12 to 15 platelets should be present in each oil immersion field; in normal cats,

TABLE 87-1

Simple Cage-Side Tests for the Rapid Classification of Hemostatic Disorders

TEST	RESULTS	MOST LIKELY DISORDER(S) IF PROLONGED (OR POSITIVE)
Platelet estimation in blood smear	low	Thrombocytopenia

Liver disease	N/↑	<b>↑</b>	N/T	<b>↑</b>	N/↓	N/↓	N

<sup>\*</sup>OSPT and APTT are considered prolonged if they are 25% or more than the concurrent controls.

10 to 12 platelets per field should be seen. As a general rule, each platelet in an oil immersion field represents 12,000 to 15,000 platelets/ $\mu$ L (i.e., number of platelets/oil immersion field  $\times$  15,000 = platelets/ $\mu$ L). Cats and dogs with platelet counts of more than 30,000/ $\mu$ L and normal platelet function do not bleed spontaneously. Therefore the cause of bleeding is usually not thrombocytopenia if more than two or three platelets are visualized in each oil immersion field. The evaluation of platelet numbers should also include evaluation of the morphology of individual platelets because abnormal platelet morphology may reflect impaired platelet function.

The second set of cage-side tests of hemostatic ability are the ACT, OSPT, and APTT. For the APTT, 2 mL of whole fresh blood is added to a tube containing diatomaceous earth; this activates the contact phase of coagulation, thus assessing the integrity of the intrinsic and common pathways (factors XII, XI, IX, VIII, X, V, II, and I) (see Fig. 87-1). If the activity of individual clotting factors involved in these pathways has decreased by more than 70% to 75%, the ACT is prolonged (normal, 60 to 90 seconds). Common coagulopathies associated with prolongation of the ACT are listed in Table 87-2. A cage-side instrument has recently been validated in dogs and cats (SCA 2000, Synbiotics Corp., San Diego, Calif.); a new easy-to-use instrument is now commercially available (CoagDx Analyzer, IDEXX, Westbrook,

Maine). These units perform evaluation of the APTT or OSPT with only a small volume of blood for each test. The reference ranges for the APTT with this instrument are different than for the APTT obtained in referral diagnostic laboratories.

The third cage-side test that can be easily performed in practice is the determination of the FDP concentration (or titer) with the commercially available Thrombo Wellcotest (Thermo Fisher Scientific, Lenexa, Kan.). This latex agglutination test can detect circulating FDPs, which are generated during the cleavage of fibrin and fibrinogen (i.e., fibrinolysis). This test is commonly positive in dogs and in some cats with DIC. The FDP test is also positive in more than half of dogs with bleeding caused by rodenticide poisoning (e.g., warfarin). The mechanism of the latter is unknown; however, these results cannot be reproduced by the intracavitary or intramuscular injection of anticoagulated blood in normal dogs. Vitamin K antagonists are believed to activate fibrinolysis by inhibiting the production of PAI-1. Recently a pointof-care D-dimer assay has been validated in the dog (Stokol, 2003).

A fourth cage-side test that can be performed primarily in dogs is the BMBT (Box 87-2), in which a template (Sim-Plate, IDEXX) is used to make an incision in the buccal mucosa and the time until bleeding completely ceases is

BT, Bleeding time; ACT, activated coagulation test; OSPT, one-stage prothrombin time; APTT, activated partial thromboplastin time; FDPs, fibrin degradation products; vWD, von Willebrand disease; DIC, disseminated intravascular coagulation; ↑, high or prolonged; N, normal or negative; ↓, decreased or shortened; ₹, questionable.

BOX 87-2

#### Procedure for Determining the BMBT in Dogs

- Position the animal in lateral recumbency with manual restraint.
- Place a 5-cm wide strip of gauze around the maxilla to fold up the upper lip, causing moderate engorgement of the mucosal surface.
- Position the SimPlate against the upper lip mucosa and push the trigger.
- 4. Start a stopwatch when the incisions are made.
- 8fot the blood with a gauze or blotting paper placed 1 to 3 mm ventral to the incision without dislodging the clot
- 6. Stop the stopwatch when the incision ceases to bleed.
- 7. Normal times are 2 to 3 minutes.

BMBT, Buccal mucosal bleeding time.

determined. The BMBT is abnormal in cats and dogs with thrombocytopenia or with platelet dysfunction. In an animal with clinical signs of a primary bleeding disorder (e.g., petechiae, ecchymoses, mucosal bleeding) and a normal platelet count, a prolonged bleeding time indicates an underlying platelet dysfunction (e.g., resulting from NSAID therapy or vWD) or, less likely, a vasculopathy. Unfortunately, the BMBT has high interoperator and intraoperator variability (as high as 80%), and the results are not reproducible, even by the same operator. The PFA-100 (see below) has replaced the BMBT in most veterinary teaching hospitals.

By performing these simple tests after evaluating the clinical features of the bleeding disorder, the clinician should be able to narrow down the number of differential diagnoses. For example, the blood smear evaluation reveals whether the patient is thrombocytopenic. If the patient is not thrombocytopenic but petechiae and ecchymoses are present, a prolonged bleeding time supports the existence of a platelet function defect. A prolonged ACT or APTT indicates that an abnormality in the intrinsic or common pathways; a prolonged OSPT documents a defect in the extrinsic pathway (i.e., factor VII); and a positive test result for FDPs supports the presence of primary or secondary fibrinolysis.

If further confirmation of a presumptive diagnosis is required, plasma can be submitted to a referral laboratory or a specialized coagulation laboratory (see p. 1244). Most commercial veterinary diagnostic laboratories routinely evaluate hemostatic profiles. Samples should be submitted in a purple-topped tube (sodium ethylene diamine tetraacetic acid) for platelet count, a blue-topped tube (sodium citrate) for coagulation studies (OSPT, APTT, fibrinogen concentration), and a special blue-topped tube (Thrombo Wellcotest) for FDP determination (the last tube is usually supplied by the diagnostic laboratory). The blue-topped tubes are now available in two different sodium citrate concentrations: 3.2% and 3.8%. The results of routine hemostasis assays are not affected by the concentration of citrate used

TABLE 87-3

Specimens Required for Laboratory Evaluation of Hemostasis

SAMPLE	TUBE TOP	TEST(S)
EDTA blood Citrated blood	Purple Blue	Platelet count OSPT, APTT, fibrinogen, AT, vWF, clotting factor assays, D-dimer, TEG, PFA-100
Thrombin	Blue	FDPs

EDTA, Ethylenediamine tetraacetic acid; OSPT, one-stage prothrombin time; APTT, activated partial thromboplastin time; AT, antithrombin, vWF, von Willebrand factor assay; TEG, Thromboelastograph; PFA-100, platelet function analyzer; FDP, fibrin degradation product.

(Morales et al., 2007). It is important to submit the right samples in the appropriate anticoagulant. The guidelines for sample submission to commercial laboratories are summarized in Table 87-3.

A routine coagulation screen (or hemostatic profile) usually contains the OSPT, APTT, platelet count, fibrinogen concentration, and FDP concentration (or titer). In some laboratories a D-dimer test and AT activity may also be included. The OSPT primarily evaluates the extrinsic pathway, whereas the APTT primarily evaluates the intrinsic pathway. Because the end product in these assays is always fibrin formation, both tests also evaluate the common pathway (see Fig. 87-1). The D-dimer assay evaluates for systemic fibrinolysis, as does the FDP test; however, the D-dimer is formed after fibrin as been stabilized by factor XIII. Thus it is more indicative of intravascular thrombus formation. The interpretation of routine hemostasis profiles is summarized in Table 87-2.

New instruments now allow evaluation of other aspects of hemostasis. For example, the platelet function analyzer PFA-100 (Siemens Healthcare Diagnostics, Deerfield, Ill.) is a simple, cage-side instrument to evaluate platelet adhesion and aggregation (Couto et al., 2006). This instrument is available in several specialized clinical hemostasis laboratories and has been extensively evaluated in dogs. The PFA-100 is quite sensitive in the diagnosis of vWD. The Thromboelastograph (TEG; Haemoscope, Niles, Ill.), also available in some specialized hemostasis laboratories, uses native or anticoagulated blood that is activated with a variety of agonists. This instruments evaluates global hemostasis, including platelet adhesion and aggregation, fibrin formation, fibrinolysis, and clot retraction. The TEG is ideal to monitor response to blood component therapy in patients with coagulopathies. I have found it to provide a wealth of information in patients with hypercoagulability and those with spontaneous bleeding and normal results of hemostasis profiles.

BOX 87-3

Congenital and Acquired Clotting Factor Defects

#### **Congenital Clotting Factor Defects**

Factor I, or hypofibrinogenemia and dysfibrinogenemia (St. Bernards and Borzois)

Factor II, or hypoprothrombinemia (Boxers, Otterhounds, English Cocker Spaniels)

Factor VII, or hypoproconvertinemia (Beagles, Malamutes, Boxers, Bulldogs, Miniature Schnauzers)

Factor VIII, or hemophilia A (many breeds but mainly German Shepherd dogs)

Factor IX, or hemophilia B (many breeds of dogs; domestic short-haired and British Shorthair cats)

Factor X, or Stuart-Prower trait (Cocker Spaniels, Jack Russell Terriers)

Factor XI, or hemophilia C (English Springer Spaniels, Great Pyrenees, Kerry Blue Terriers)

Factor XII, or Hageman factor (Miniature and Standard Poodles, Shar-Peis, German Shorthair Pointers; cats)

Prekallikrein (Fletcher factor) deficiency (various dog breeds

#### **Acquired Clotting Factor Defects** Liver disease

Decreased production of factors Qualitative disorders? Cholestasis

Vitamin K antagonists (rodenticides)

DIC, Disseminated intravascular coagulation.

As previously discussed, if an unusual coagulopathy or a specific clotting factor deficiency is suspected, blood should be submitted to a specialized veterinary coagulation laboratory (see p. 1244). Congenital and acquired clotting factor deficiencies that occur in cats and dogs are listed in Box 87-3.

Thrombocytopenia can be from either decreased production or increased destruction, consumption, or sequestration of platelets; therefore a bone marrow aspiration for cytologic evaluation is indicated in cats and dogs with thrombocytopenia of unknown cause. Other tests can also be performed in thrombocytopenic cats and dogs, including determinations of titers or polymerase chain reaction (PCR) for tickborne diseases, evaluation for retrovirus infection, radioactive platelet scanning, and antiplatelet antibody tests (see p. 1250).

Finally, clinicians occasionally encounter a patient with abnormal results of hemostasis profiles but without spontaneous bleeding. The most common "abnormality" in the hemostasis profile of a dog or cat without a tendency to bleed is a prolongation of the APTT. Quite frequently the prolongation is marked (more than 50% above the control or upper limit of the reference range for the laboratory). If this "abnormality" is found during a presurgical evaluation, the surgery

may be delayed needlessly if the clinician is not familiar with some of the following clinical conditions. As previously discussed, dogs and cats with factor XII deficiency do not bleed, yet they have a prolonged APTT; determination of factor XII activity will resolve this issue. Prekallikrein and high-molecular-weight kininogen (HMWK) are co-factors for contact activation of factor XII. Dogs with prekallikrein or HMWK deficiencies have prolonged APTT but do not bleed; incubation of the plasma samples for a few hours overrides the factor deficiency and corrects the APTT. Finally, the presence of circulating anticoagulants, also referred to as lupus anticoagulants, results in prolongation of the APTT without bleeding. A simple test to determine if the patient with a prolonged APTT has a clotting factor deficiency (e.g., factor XII) or circulating anticoagulants is to perform an APTT after diluting the patient's sample 50:50 with normal or pooled dog plasma (dilution assay). As previously discussed, the APTT becomes prolonged when the patient has less than 30% activity of an individual factor. If the patient has factor XII deficiency, for example, and 0% factor XII activity, mixing the sample 50:50 with normal dog plasma (with a factor XII activity of 100%), will result in a final factor XII activity of 50% and thus the APTT will be normal. Circulating anticoagulants also inhibit the clotting factors in the normal dog plasma, so when the samples are mixed 50:50 the APTT remains prolonged.

#### MANAGEMENT OF THE BLEEDING PATIENT

Several basic principles apply to the management of cats and dogs with spontaneous bleeding disorders. Specific principles are discussed in the following paragraphs. In general, a cat or dog with a spontaneous bleeding disorder should be managed aggressively because these disorders are potentially life threatening, but iatrogenic bleeding should be minimized. As a general rule, trauma should be minimized and the patient must be kept quiet, preferably confined to a cage and leash walked, if necessary. Exercise should be avoided or markedly restricted.

Venipunctures should be done with the smallest gauge needle possible, and pressure should be applied to the puncture site for a minimum of 5 minutes. A compressive bandage should also be applied to the area once pressure has been released. If repeated samples for packed cell volumes (PCVs) and plasma protein determinations are necessary, they should be obtained from a peripheral vein with a 25-gauge needle to fill one or two microhematocrit tubes by capillarity. A bandage should be applied after each venipuncture.

Invasive procedures should be minimized. For example, urine samples should never be collected by cystocentesis because of the risk of intraabdominal, intravesical, or intramural bladder bleeding. Certain invasive procedures, however, can be performed quite safely. These include bone marrow aspiration from the iliac crest or wing of the ilium,

fine-needle aspiration of lymph nodes or superficial masses, fine-needle aspiration of the spleen (the thick fibromuscular capsule of the carnivore spleen seals the needle hole as soon as the needle is removed), and intravenous catheter placement (although seepage from the catheter is common in thrombocytopenic patients).

Certain types of surgery can also be safely performed in some cats and dogs with coagulopathies. For example, pedicle surgery (e.g., splenectomy) can be performed with minimal bleeding (i.e., seepage from the abdominal wound) in dogs with marked thrombocytopenia (i.e., less than 25,000 platelets/ $\mu$ L).

A transfusion of blood or blood components is indicated in some dogs and cats with spontaneous bleeding disorders. Whole fresh blood (or a combination of packed RBCs and fresh frozen plasma) should be used if the animal is anemic and lacking one or more clotting factors; plasma transfusions are of no benefit in thrombocytopenic animals. Fresh frozen plasma can be used to replenish clotting factors in a cat or dog with a normal or mildly decreased packed cell volume (i.e., the animal is not symptomatic). Stored blood or frozen plasma is deficient in factors V and VIII. In general, whole fresh blood, platelet-rich plasma, and platelet transfusions rarely provide sufficient platelets to halt spontaneous bleeding in a cat or dog with thrombocytopenia, particularly if the bleeding is the result of platelet consumption. (Some guidelines for transfusion therapy are discussed in Chapter 83.)

#### PRIMARY HEMOSTATIC DEFECTS

Primary hemostatic defects are characterized by the presence of superficial and mucosal bleeding (e.g., petechiae, ecchymoses, hematuria, epistaxis) and are usually associated with thrombocytopenia. Platelet dysfunction is a rare cause of spontaneous bleeding in dogs and cats. Primary hemostatic defects caused by vascular problems are extremely rare and thus are not discussed here. Primary hemostatic defects are the most common cause of spontaneous bleeding in dogs seen at our hospital.

#### **THROMBOCYTOPENIA**

Thrombocytopenia represents the most common cause of spontaneous bleeding in dogs seen at our clinic. Decreased numbers of circulating platelets can be the result of one or more of the following abnormalities (Box 87-4):

- Decreased platelet production
- · Increased platelet destruction
- · Increased platelet consumption
- Increased platelet sequestration

Increased platelet destruction represents the most common cause of thrombocytopenia in dogs in our clinic, but it is rare in cats. Most commonly the peripheral destruction of platelets results from immune-mediated, drug-related

Causes of Thrombocytopenia in Dogs and Cats

#### **Decreased Platelet Production**

Immune-mediated megakaryocytic hypoplasia Idiopathic bone marrow aplasia

Drug-induced megakaryocytic hypoplasia (estrogens, phenylbutazone, melphalan, lomustine β-lactams)
Myelophthisis

Cyclic thrombocytopenia
Retroviral infection
Canine monocytic ehrlichiosis
Feline monocytic ehrlichiosis?

Increased Platelet Destruction, Sequestration, or Utilization

IMT

Infectious (Anaplasma spp., Bartonella spp., sepsis, etc.)
Live viral vaccine-induced thrombocytopenia

Drug-induced thrombocytopenia

Microangiopathy

DIC

Hemolytic uremic syndrome/thrombotic thrombocytopenic purpura

Vasculitis

Splenomegaly

Splenic torsion

Endotoxemia

Acute hepatic necrosis

Neoplasia (immune mediated, microangiopathy)

Common; relatively common; rare.

IMT, Immune-mediated thrombocytopenia; DIC, disseminated intravascular coagulation.

(including vaccination with modified-live viruses), and sepsis-related (see Box 87-4) mechanisms. Increased platelet consumption occurs most commonly in dogs and cats with DIC (see below), and sequestration is usually caused by splenomegaly or, rarely, hepatomegaly (see Box 87-4).

# Approach to the Patient with Thrombocytopenia

Before assessing a patient with primary hemostatic bleeding, the clinician must remember than in some breeds platelet counts below the reference range for dogs are common. Platelet counts in Greyhounds typically range between 80,000 and 120,000/µL, whereas in Cavalier King Charles Spaniels with macrothrombocytopenia platelet counts <50,000/µL are common. In the latter the global platelet function is normal. Once thrombocytopenia has been confirmed by a platelet count or evaluation of a blood smear, its pathogenesis should be identified. The absolute platelet count may offer clues to its cause; for example, platelet counts of less than 25,000/µL are common in dogs with immune-mediated thrombocytopenia (IMT), whereas

platelet counts of 50,000 to 75,000// $\mu$ L are more common in dogs with ehrlichiosis, lymphoma affecting the spleen, or rodenticide toxicity.

The patient's drug history should be obtained from the owner. If the animal is receiving any medication, the thrombocytopenia should be considered drug related until proven otherwise. The drug should be discontinued if possible and the platelet count reevaluated within 2 to 6 days. If the count returns to normal, a retrospective diagnosis of drug-associated thrombocytopenia is made. Drugs that have been associated with thrombocytopenia in cats and dogs can also cause anemia and neutropenia (see Boxes 83-2 and 85-1).

Because retroviral disorders commonly affect the bone marrow and may result in thrombocytopenia in cats, bone marrow aspiration is indicated in a thrombocytopenic cat with no history of previous medication. The risk of bleeding during or after bone marrow aspiration in a thrombocytopenic animal is minimal. Feline leukemia virus (FeLV) and feline immunodeficiency virus tests should also be performed. If determined by the laboratory, a mean platelet volume is high in most cats with FeLV infection (i.e., macrothrombocytosis); however, macrothrombocytes are also seen in cats and dogs with peripheral platelet destruction, consumption, or sequestration, in which they may be analogous to reticulocytes (young, immature, large platelets).

Bone marrow evaluation may also be indicated in dogs with thrombocytopenia. Given the high prevalence of IMT, at our clinic we usually elect to treat a dog with a presumed diagnosis of IMT. If the patient does not respond to immunosuppressive drugs within 2 to 3 days, a bone marrow aspiration may be performed.

Hyperplasia of megakaryocytes occurs in response to peripheral destruction, consumption, or sequestration of platelets. Occasionally dogs and cats with IMT have decreased numbers of megakaryocytes and abundant free megakaryocyte nuclei in the bone marrow. This is thought to be mediated by antibodies directed against platelets that also destroy the megakaryocytes. Infiltrative or dysplastic bone marrow disorders causing thrombocytopenia are easy to identify on a bone marrow smear.

Because IMT is a diagnosis of exclusion, tick-borne diseases (e.g., canine ehrlichiosis, Rocky Mountain spotted fever, cyclic thrombocytopenia, babesiosis, bartonellosis) should theoretically be ruled out by evaluating the appropriate serology or PCR and a blood smear. However, if the animal does not have clinical signs unrelated to the bleeding, the thrombocytopenia is not likely caused by sepsis or tick-borne diseases, although occasionally asymptomatic thrombocytopenic dogs have subclinical rickettsial diseases. If sepsis is suspected on the basis of clinical signs and clinicopathologic findings (e.g., fever, tachycardia, poor perfusion, degenerative left shift in the leukogram, hypoglycemia, hyperbilirubinemia), urine and blood should be obtained for bacterial cultures.

The presence of spherocytic hemolytic anemia or autoagglutination in a dog with thrombocytopenia is highly suggestive of Evans syndrome (combination of IMT and immune hemolytic anemia [IHA]). A direct Coombs test is usually positive in these cases. On rare occasions a direct Coombs test is positive in a dog with IMT and borderline anemia, further supporting a diagnosis of Evans syndrome.

A hemostasis screen should always be performed to rule out DIC in a thrombocytopenic animal found to have RBC fragments in a blood smear or evidence of secondary bleeding (e.g., hematomas, bleeding into body cavities). The remainder of the hemostasis screen is usually normal in dogs and cats with selective thrombocytopenia.

Several tests are available to evaluate antiplatelet antibodies, including direct immunofluorescence of bone marrow megakaryocytes and enzyme-linked immunosorbent assays for circulating or platelet-bound antibodies (see Chapter 92). However, most of these are not clinically reliable, and a diagnosis of IMT can be made only after other causes of thrombocytopenia have been excluded (i.e., regardless of the results of the antiplatelet antibody tests).

Abdominal radiographs and ultrasonograms may reveal an enlarged spleen not evident during physical examination. Diffuse splenomegaly (i.e., splenic sequestration of platelets) may be the cause of the thrombocytopenia, or it may reflect "work hypertrophy" (i.e., mononuclear phagocytic system hyperplasia) and extramedullary hematopoiesis in a dog with IMT. Splenic nodules are usually an incidental finding in dogs with thrombocytopenia, and they may represent extramedullary hematopoiesis or hyperplasia; fine-needle aspiration of the nodules should establish a cytologic diagnosis. Despite the low platelet counts, clinically relevant bleeding rarely occurs.

Often a specific diagnosis of IMT is obtained only after a therapeutic trial with corticosteroids (see later discussion) results in resolution of the thrombocytopenia. If the clinician is in doubt regarding whether the thrombocytopenia is caused by a rickettsial disease or IMT (in dogs), immunosuppressive doses of corticosteroids can be administered in conjunction with doxycycline (5 to 10 mg/kg PO q12-24h) until serologic or PCR test results become available. This combination of agents has no deleterious effects on dogs with rickettsial diseases.

Blood or blood products should be transfused as needed (see Chapter 83). However, the transfusion of whole fresh blood, platelet-rich plasma, or platelets rarely, if ever, results in normalization of the platelet count or even in increases in the platelet count to "safe" levels.

#### Immune-Mediated Thrombocytopenia

IMT is the most common cause of spontaneous bleeding in dogs but is rare in cats. It affects primarily middle-aged, female dogs, and Cocker Spaniels and Old English Sheep-dogs are overrepresented. The clinical signs are those of a primary hemostatic defect and include petechiae, ecchymoses, and mucosal bleeding. Acute collapse may occur if bleeding is pronounced; if the anemia is mild, most dogs are fairly asymptomatic. IMT is acute or peracute in onset in most dogs. During physical examination, signs of primary

hemostatic bleeding (e.g., petechiae, ecchymoses, mucosal bleeding) with or without splenomegaly may be found.

The complete blood count in dogs with IMT is characterized by thrombocytopenia with or without anemia (depending on the degree of spontaneous bleeding and the presence or absence of concurrent IHA); leukocytosis with a left shift may also be present. As a general rule, hematologic changes are limited to the thrombocytopenia. If IHA is associated with IMT (i.e., Evans syndrome), a Coombs-positive, regenerative anemia with spherocytosis or autoagglutination is usually present. Bone marrow cytologic studies typically reveal megakaryocytic hyperplasia, although megakaryocytic hypoplasia with free megakaryocyte nuclei is occasionally present. In addition to the thrombocytopenia, the bleeding time is the only other abnormal test result (ACT, APTT, OSPT, FDP, and fibrinogen concentration are normal). An inverse linear correlation is usually present between the platelet count and the BMBT (i.e., a longer BMBT with lower platelet counts). Ideally, tick-borne diseases and druginduced thrombocytopenia should be ruled out before establishing a definitive diagnosis of IMT.

If the index of suspicion for IMT is high (i.e., a fairly asymptomatic dog with spontaneous primary hemostatic bleeding and thrombocytopenia as the sole hematologic abnormality), a therapeutic trial with immunosuppressive doses of corticosteroids (equivalent to 2 to 8 mg/kg/day of prednisone) should be instituted. Responses are usually seen within 24 to 96 hours. No clinical evidence exists that dexamethasone is more effective than prednisone in controlling IMT. Indeed, in my experience acute gastrointestinal tract ulceration is considerably more prevalent in dogs receiving dexamethasone than in those receiving prednisone. Because an acute upper gastrointestinal tract bleed is usually catastrophic in a dog with thrombocytopenia, prednisone is my drug of choice. H2-antihistamines, such as famotidine (0.5 mg/kg PO q24h), should be used in combination with the corticosteroids.

Fresh whole blood, stored blood, packed RBCs, or hemoglobin solutions should be administered as needed to maintain adequate oxygen-carrying capacity (see Transfusion Therapy in Chapter 83). In addition to immunosuppressive doses of corticosteroids, cyclophosphamide, given intravenously or orally in a single dose of 200 to 300 mg/m<sup>2</sup>, is effective for inducing remission. However, it should not be used as a maintenance agent because it usually causes sterile hemorrhagic cystitis when used on a long-term basis. Vincristine, at a dose of 0.5 mg/m<sup>2</sup> given intravenously, traditionally has been recommended for dogs with IMT. This drug stimulates megakaryocyte endomitosis, resulting in early platelet release from the bone marrow. However, because vinca alkaloids bind to tubulin, the platelets released prematurely are not fully functional (tubulin is responsible for platelet aggregation), and the patients may have further bleeding before the platelet count increases. As discussed in Chapters 85 and 93, human intravenous immunoglobulin (0.5 to 1 g/kg, single dose) can also be used successfully in dogs with refractory or life-threatening IMT.

Failure to induce remission (i.e., to normalize the platelet count) is usually the result of insufficient drug (low doses or the need for a second agent), insufficient duration of therapy (the drugs have not yet had time to become effective), or an incorrect diagnosis. In the event of one of these, the treatment protocol can easily be amended, with the thrombocytopenia usually resolving as a result. Azathioprine (50 mg/m<sup>2</sup> PO q24-48h) is effective in maintaining remission but is not a good agent for inducing remission. In some dogs azathioprine is better tolerated than long-term corticosteroid therapy, although close hematologic monitoring is recommended given its myelosuppressive properties and potential for hepatotoxicity. The androgenic steroid danazol or cyclosporine A may also be beneficial in dogs with IMT. (See Chapter 93 for additional information and drug dosages.)

The prognosis is good in most dogs with IMT, although they may require lifelong treatment. Dogs with refractory IMT can be successfully treated with vinca-loaded platelets, pulse-dose cyclophosphamide, human immunoglobulin, or splenectomy.

IMT has become more prevalent in cats over the past few years. The typical clinical presentation is different from dogs in that most cats have chronic thrombocytopenia that does not lead to spontaneous bleeding. A platelet count of 10,000 to 30,000/µL is relatively common in an otherwise healthy cat without spontaneous bleeding. I have followed up several of these cats for months to years, and their platelet counts do not increase markedly with treatment. Interestingly, a high proportion of these cats also have regenerative or nonregenerative anemia, neutropenia, lymphocytosis, or combinations thereof. The cytopenias may resolve for no apparent reason, only to have a decrease in another cell line months later. Because most of these cats do not bleed, the clinician should be aware that increasing drug dosages or adding drugs may cause more problems than monitoring the platelet count. My treatment of choice for cats with IMT or immune-mediated cytopenias is a combination of dexamethasone (4 mg q1-2wk) and chlorambucil (20-30 mg/m<sup>2</sup> PO q2wk). I have also successfully used human intravenous immunoglobulin G in a limited number of cats with immune-mediated cytopenias.

#### PLATELET DYSFUNCTION

The presence of primary hemostatic bleeding in a patient with a normal platelet count is highly suggestive of a platelet dysfunction syndrome, although vasculopathies and enhanced fibrinolysis should also be considered. Platelet dysfunction syndromes can be congenital or acquired (Box 87-5); however, they rarely result in spontaneous bleeding. More often a prolonged BMBT is noted preoperatively in an otherwise healthy animal, or the animal has a history of pronounced bleeding during a previous surgery. Congenital platelet dysfunction syndromes are rare, with the notable exception of vWD. Some authors classify vWD among the congenital clotting factor deficiencies; however, because its clinical manifestations are those of a primary hemostatic

mal recessive trait (see later discussion). This disorder has

been reported to occur in more than 50 breeds of dogs but

is more common in Doberman Pinschers, German Shepherd

dogs, Poodles, Golden Retrievers, and Shetland Sheepdogs. In these breeds the defect is inherited as an autosomal dom-

inant trait with incomplete penetrance. In Scottish Terriers and Shetland Sheepdogs, it can be inherited as an autosomal

recessive trait; homozygous dogs have no detectable vWF

concentrations and are usually severely affected. Type 1 vWD

may purportedly occur in association with clinical hypothyroidism in dogs; however, most scientifically controlled

studies have failed to prove an association between vWD and

hypothyroidism. Type 2 vWD was recently reported in dogs

with aortic valvular disease; in those dogs, the high shear

associated with turbulent flow across the valve resulted in

selective depletion of high-molecular-weight VWF multim-

In human beings vWF is produced by megakaryocytes and endothelial cells, circulates in plasma complexed to factor VIII coagulant (factor VIII: C), and is one of the major

adhesive proteins in the body. In the dog, platelets do not contribute as much vWF to plasma as in human beings, vWF

is mainly responsible for causing platelets to adhere to the subendothelial structures (e.g., collagen) in areas of high

shear once endothelial cell damage has occurred, thus initiat-

ing the formation of the primary hemostatic plug (Fig.

87-2). The vWF molecule circulates coiled; it uncoils at the

site of endothelial damage, binds to the subendothelium and

then to the platelet receptors, and the platelets are "reeled"

in to the site of injury. As a consequence, vWD is usually

characterized by primary hemostatic defects (e.g., petechiae,

ecchymoses, mucosal bleeding). However, most dogs with vWD do not bleed spontaneously but rather bleed exces-

sively during or after surgery; excessive bleeding during

teething or estrus can also occur, but petechiae and ecchymoses are rarer. Most dogs with vWD and spontaneous

bleeding seen at our clinic are brought in for evaluation of

diffuse oropharyngeal or vaginal bleeding. People with vWD

can also have low circulating concentrations of factor VIII leading to spontaneous secondary hemostatic bleeding

ers (Tarnow et al., 2005).

defect, I include it in this section. Acquired platelet function disorders are more common; clinically they are mainly secondary to uremia, monoclonal gammopathies, ehrlichiosis, retroviral infections, or drug therapy.

#### von Willebrand Disease

vWD is the most common inherited bleeding disorder in human beings and dogs but is rare in cats. The term *von Willebrand syndrome* is reserved for an acquired vWF deficiency. vWD can be classified into three types (Table 87-4). Dogs with the disease typically have a decreased concentration or activity (type 1 vWD), absence of circulating vWF (type 3 vWD), or low to normal concentrations of an abnormal vWF (type 2 vWD), which result in mild (if any) spontaneous bleeding or, more likely, prolonged surgical bleeding. In dogs vWD can be inherited as an autosomal dominant trait with incomplete penetrance or, more rarely, an autoso-

(i.e., the clinical findings of hemophilia A); however, this is extremely rare in dogs. Perinatal death or abortions/stillbirths are common in litters with vWD.

The hemostasis screen results are normal in most dogs with vWD. The platelet counts in dogs with vWD are also normal. However, the results of a PFA-100 or BMBT usually inversely correlate with the degree of vWF deficiency (i.e., the PFA-100 closure time or the BMBT is prolonged if the vWF concentration or activity is low). Indeed, the BMBT may be the most cost-effective method for screening dogs for vWD, although its results are not foolproof. It can be done before surgery in breeds at risk or if the owner or breeder is interested in determining whether the dog is likely to have this disorder. However, a normal bleeding time does not necessarily rule out vWD. At our clinic we routinely use the PFA-100 before surgery in dogs at high risk for vWD so that appropriate therapy can be instituted before or during surgery. A diagnosis of vWD can be confirmed by quantifying vWF in specialized veterinary coagulation laboratories. Genetic testing for vWD in specific breeds is available through commercial diagnostic laboratories.

Most dogs with type 1 vWD can be successfully treated before surgery or during a bleeding episode with desmopressin acetate (DDAVP), which causes a massive release of vWF from the endothelial cells and results in shortening of the BMBT and the PFA-100 closure times within 30 minutes of administration. A single 1 µg/kg dose of DDAVP (intranasal preparation) given subcutaneously consistently lessens bleeding in dogs with type 1 vWD despite modest increases in vWF concentration. DDAVP is not effective in dogs with types 2 or 3 vWD because these dogs either lack or have an abnormal (i.e., nonfunctional) vWF. Cryoprecipitate is the blood component of choice for dogs with vWD; a unit of cryoprecipitate is defined as the volume obtained from a unit of fresh frozen plasma. We dose it at 1 U cryoprecipitate per 10 kg of body weight; therefore, a Doberman Pinscher typically receives 3 U. If cryoprecipitate is not available, fresh frozen plasma or whole fresh blood can be used. DDAVP can

also be administered to the blood donor dog 1 hour before blood is collected to maximize the yield of vWF. The use of topical hemostatic agents such as fibrin, collagen, or methacrylate is also indicated to control the local bleeding. As is the case in dogs with other inheritable disorders, dogs with congenital vWD should not be bred.

#### **Other Congenital Platelet Function Defects**

Platelet function defects leading to spontaneous primary hemostatic bleeding have been reported in at least three breeds of dogs (Otterhounds, Foxhounds, and Basset Hounds). The clinical signs and clinicopathologic abnormalities are similar to those seen in dogs with vWD, but the vWF concentrations are normal or high. A syndrome of spontaneous and postoperative bleeding resembling Scott syndrome in human beings from a lack of platelet procoagulant activity was described in German Shepherd dogs (Brooks et al., 2002).

#### SECONDARY HEMOSTATIC DEFECTS

Dogs with secondary hemostatic defects are usually evaluated because of collapse, exercise intolerance, dyspnea, abdominal distention, lameness, or masses. The collapse and exercise intolerance are usually caused by anemia resulting from intracavitary bleeding, as is the dyspnea and abdominal distention. The lameness is usually caused by hemarthrosis, and the masses or lumps usually represent hematomas. Cats and dogs with secondary hemostatic disorders do not have petechiae or ecchymoses, and mucosal bleeding (e.g., melena, epistaxis) is rarely seen. In general the severity of the bleeding is directly related to the severity of the deficiency of the clotting factor(s). Liver disease and rodenticide poisoning leading to vitamin K deficiency are the two most common causes of secondary hemostatic defects seen at our clinic. As previously noted, these disorders are more common in dogs than in cats.

### CONGENITAL CLOTTING FACTOR DEFICIENCIES

Congenital clotting factor deficiencies, as well as the breeds affected, are listed in Box 87-3. They are relatively common in dogs but are rare in cats. Most genetic mutations leading to these defects have been well characterized, and some laboratories now offer genetic testing for congenital coagulopathies. Hemophilia A and B are sex-linked traits; the modes of inheritance of other coagulopathies vary. In affected animals the severity of the bleeding is usually inversely proportional to the concentration of the individual clotting factor affected (e.g., bleeding is more severe in association with a very low factor activity). Clinical signs usually include spontaneous hematoma formation, which the owners may describe as "lumps," and bleeding into body cavities as well as signs compatible with "fading puppy syndrome" and protracted umbilical cord bleeding after birth. Abortions or stillbirths in the litter are common. Petechiae and ecchymoses are not present in dogs with congenital clotting factor deficiencies. Cats with congenital clotting factor deficiency usually do not bleed spontaneously, but rather have intraoperative or delayed postoperative bleeding.

Carriers of the defect may be asymptomatic but usually have prolonged clotting times in vitro. Certain factor deficiencies (so-called "contact factors"), including factors XII and XI, Fletcher factor (prekallikrein), and HMWK, are also found in otherwise asymptomatic animals (i.e., no excessive  $bleeding) with {\it markedly prolonged APTTs}. However, massive$ and often life-threatening postoperative bleeding starting 24 to 36 hours after surgery is common in dogs with factor XI deficiency.

Most dogs and cats with congenital coagulopathies are treated with supportive and transfusion therapies; no other treatments appear to be beneficial. As with animals with other congenital defects, dogs and cats with coagulopathies should not be bred.

#### VITAMIN K DEFICIENCY

Vitamin K deficiency in small animals usually results from the ingestion of vitamin K antagonists (warfarin, diphacinone, or their derivatives, brodifacoum and bromadiolone), although it can also occur as a consequence of malabsorption in dogs and cats with obstructive cholestasis, infiltrative bowel disease, or liver disease. Four clotting factors are vitamin K dependent: factors II, VII, IX, and X. Proteins C and S, two natural anticoagulants, are also vitamin K dependent. Because of its clinical relevance, the following discussion focuses only on rodenticide poisoning, which is more common in dogs and extremely rare in cats.

Most dogs with toxicity are evaluated because of acute collapse and a possible history of rodenticide ingestion. Coughing, thoracic pain, and dyspnea are also common. These dogs usually have clinical signs compatible with secondary bleeding, such as hematomas and bleeding into body cavities. The most common site of bleeding in dogs evaluated at our clinic is the thorax; some dogs have superficial skin bruising in areas of friction, such as the axilla or the groin. Other abnormalities include pale mucous membranes, anemia (usually regenerative if sufficient time has elapsed since the acute bleeding episode), and hypoproteinemia. Sudden death may occur as a result of central nervous system or pericardial hemorrhage.

If the rodenticide has been ingested minutes to hours before presentation, induced vomiting and the administration of activated charcoal may eliminate or neutralize most of it. If the ingestion is questionable and no clinical signs of coagulopathy are present (e.g., hemothorax, hemoabdomen, bruising), determination of the OSPT is recommended. Because factor VII is the shortest lived vitamin K-dependent protein (circulating half-life of 4 to 6 hours), the OSPT is usually prolonged before spontaneous bleeding becomes evident. Newer tests for proteins induced by vitamin K absence may also aid in the early diagnosis of rodenticide toxicity, but they are not used in our clinic because they seem to lack clinical relevance.

The typical hemostasis screen in a dog with symptomatic vitamin K deficiency reveals marked prolongation of the OSPT and APTT; this is one of the few clinical situations where the OSPT is typically longer than the APTT. The FDP test is positive in more than half of affected dogs and mild thrombocytopenia is present (70,000 to 125,000/μL), which is likely caused by an excessive consumption of platelets from protracted bleeding.

These animals usually require immediate transfusions of whole fresh blood or fresh frozen plasma (or cryo-poor plasma) to replenish the coagulation factors (and packed RBCs if the animal is anemic). From 8 to 12 hours may elapse before vitamin K therapy appreciably shortens the OSPT and subsequently decreases bleeding.

Vitamin K is available in several forms, but vitamin  $K_1$  is the most effective. It is available for oral or parenteral use. Intravenous administration of vitamin K is not recommended because of the risk of anaphylactic reactions or Heinz body formation; intramuscular injections in a dog with a coagulopathy usually result in hematoma formation. Subcutaneous administration of vitamin K<sub>1</sub> with a 25-gauge needle (loading dose of 5 mg/kg, followed in 8 hours by 2.5 mg/kg SQ divided q8h) is preferred if the patient is properly hydrated. Administration of oral loading doses of vitamin K1 has been advocated for the treatment of dogs with rodenticide poisoning (5 mg/kg with a fatty meal, then 2.5 mg/kg divided q8-12h); this is the treatment used in our clinic. Because vitamin K is lipid soluble, its absorption is enhanced if it is given with fatty meals. Animals with cholestatic or malabsorptive syndromes may require continued subcutaneous injections of vitamin K. In critical cases the OSPT should be monitored every 8 hours until it normalizes.

If the anticoagulant is known to be warfarin or another first-generation hydroxycoumarin, 1 week of oral vitamin K<sub>1</sub> is usually sufficient to reverse the coagulopathy. However, if it is indanedione or any of the second- or third-generation anticoagulants, oral vitamin K1 therapy must be maintained for at least 3 weeks and possibly as long as 6 weeks. Most currently available rodenticides contain second- and thirdgeneration anticoagulants. If the rodenticide ingested is unknown, the animal should be treated for 1 week, at which time vitamin K treatment is discontinued. An OSPT is then determined within 24 to 48 hours of the last dose. If the OSPT is prolonged, therapy should be reinstituted and maintained for 2 more weeks and the OSPT reevaluated at the end of this period.

#### MIXED (COMBINED) HEMOSTATIC DEFECTS

#### DISSEMINATED INTRAVASCULAR COAGULATION

DIC, previously called consumptive coagulopathy or defibrination syndrome, is a complex syndrome in which excessive intravascular coagulation leads to multiple-organ microthrombosis (multiple organ failure [MOF]) and paradoxic bleeding caused by the inactivation or excessive consumption of platelets and clotting factors as a result of enhanced fibrinolysis. DIC is not a specific disorder but rather a common pathway in a variety of disorders. Moreover, DIC constitutes a dynamic phenomenon in which the patient's status and the results of coagulation tests change markedly, rapidly, and repeatedly during treatment. This syndrome is relatively common in dogs and cats.

#### **Pathogenesis**

Several general mechanisms can lead to activation of intravascular coagulation and therefore to the development of DIC, including the following:

- · Endothelial damage
- Platelet activation
- · Release of tissue "procoagulants"

Endothelial damage commonly results from electrocution or heat stroke, although it may also play a role in sepsis-associated DIC. Platelets can be activated by a variety of stimuli, but mainly they are activated by viral infections (e.g., FIP in cats) or sepsis. Tissue procoagulants (likely tissue factor) are released in several common clinical conditions, including trauma, hemolysis, pancreatitis, bacterial infections, acute hepatitis, and possibly some neoplasms (e.g., HSA).

The best way to understand the pathophysiologic process of DIC is to think of the entire vascular system as a single, giant blood vessel and the pathogenesis of the disorder as an exaggeration of the normal hemostatic mechanisms. Once the coagulation cascade has been activated in this "giant vessel" (i.e., it is widespread within the microvasculature in the body), several events take place. Although they are described sequentially, most of them actually occur simultaneously, and the intensity of each varies with time, thus making for an extremely dynamic process.

First, the primary and secondary hemostatic plugs are formed (see p. 1242). Because this is happening in thousands or tens of thousands of small vessels simultaneously, multiple thrombi form in the microcirculation. If this process is left unchecked, ischemia (resulting in MOF) eventually develops. During this excessive intravascular coagulation, platelets are consumed and destroyed in large quantities, leading to thrombocytopenia. Second, the fibrinolytic system is activated systemically, resulting in clot lysis and the inactivation (or lysis) of clotting factors and impaired platelet function. Third, AT and possibly proteins C and S are consumed in an attempt to halt intravascular coagulation, leading to "exhaustion" of the natural anticoagulants. Fourth, the formation of fibrin within the microcirculation leads to the development of hemolytic anemia and further compounds the thrombocytopenia as the RBCs are sheared by these fibrin strands (i.e., fragmented RBCs or schistocytes).

When all these events are considered, it is easy to understand (1) why an animal with multiple organ thrombosis

(caused by excessive intravascular coagulation and the depletion of natural anticoagulants) is bleeding spontaneously (as a result of thrombocytopenia, impaired platelet function, and inactivation of clotting factors) and (2) why one of the therapeutic approaches that appears to be beneficial in halting the bleeding in dogs and cats with DIC is to paradoxically administer heparin or other anticoagulants (i.e., if sufficient AT is available, heparin halts intravascular coagulation, which in turn decreases activation of the fibrinolytic system, thus releasing its inhibitory effect on the clotting factors and platelet function).

In addition to the events just described, impaired tissue perfusion results in the development of secondary "enhancers" of DIC, including hypoxia; acidosis; and hepatic, renal, and pulmonary dysfunction; and the release of myocardial depressant factor. The function of the mononuclear-phagocytic system also is impaired so that FDPs and other byproducts, as well as bacteria absorbed from the intestine, cannot be cleared from the circulation. These factors also must be dealt with therapeutically (see p. 1256).

The prevalence of primary disorders associated with DIC in 50 dogs and 21 cats recently evaluated at The Ohio State University Veterinary Teaching Hospital (OSU-VTH) is depicted in Table 87-5. Neoplasia (primarily HSA), liver disease, and immune-mediated blood diseases were the most common disorders associated with DIC in dogs; liver disease (primarily hepatic lipidosis), neoplasia (mainly lymphoma), and FIP were the disorders most frequently associated with DIC in cats.

At our clinic, symptomatic DIC in dogs (i.e., that associated with bleeding) is most commonly associated with HSA, followed by sepsis, pancreatitis, hemolytic anemia, gastric dilation-volvulus, and liver disease. Symptomatic DIC is extremely rare in cats but hemostatic evidence of DIC is common, accounting for approximately two thirds of the abnormal hemostatic profiles in this species in our clinic. As previously discussed, DIC is common in cats with liver disease, malignant neoplasms, or FIP. We have also observed symptomatic DIC in two cats receiving methimazole. The pathogenesis of DIC in dogs with HSA appears to be complex and multifactorial; the major mechanism triggering intravascular coagulation in dogs with this neoplasm was believed to be the abnormal irregular endothelium in the neoplasm (i.e., exposure to subendothelial collagen and the activation of coagulation). However, some canine HSAs appear to synthesize a cancer procoagulant because dogs with small HSAs can have severe DIC, whereas some dogs with widely disseminated HSA have normal hemostasis.

#### **Clinical Features**

Dogs with DIC can have several clinical presentations; the two common forms are chronic silent (subclinical) and acute (fulminant) DIC. In the chronic silent form, the patient does not have evidence of spontaneous bleeding, but clinicopathologic evaluation of the hemostatic system reveals abnormalities compatible with this syndrome (see the next page). This form of DIC appears to be common in dogs with

malignancy and other chronic disorders. The acute form may represent a true acute phenomenon (e.g., after heatstroke, electrocution, or acute pancreatitis) or, more commonly, it represents acute decompensation of a chronic, silent process (e.g., HSA). Acute DIC is extremely rare in cats. Regardless of the pathogenesis, dogs with acute DIC often are brought in because of profuse spontaneous bleeding and constitutional signs attributable to anemia or parenchymal organ thrombosis (i.e., MOF). The clinical signs of bleeding indicate both primary bleeding (e.g., petechiae, ecchymoses, mucosal bleeding) and secondary bleeding (blood in body cavities). Clinical and clinicopathologic evidence of organ

dysfunction is also present. Most cats with DIC seen at our clinic do not have evidence of spontaneous bleeding; clinical signs in these cats are those associated with the primary disease.

In a recent retrospective study of 50 dogs with DIC conducted in our clinic, only 26% had evidence of spontaneous bleeding, whereas only one of 21 cats with DIC had evidence of spontaneous bleeding. Most patients were presented for evaluation of their primary problem and were not bleeding spontaneously; DIC was diagnosed as part of the routine clinical evaluation.

#### **Diagnosis**

Because clinical DIC is uncommon in cats, the discussion on diagnosis and treatment focuses on dogs. Several hematologic findings help support a presumptive clinical diagnosis of DIC and include a regenerative hemolytic anemia (although occasionally, because the animal has a chronic disorder such as cancer, the anemia is nonregenerative), hemoglobinemia (caused by intravascular hemolysis), RBC fragments or schistocytes, thrombocytopenia, neutrophilia with a left shift, and rarely neutropenia. Most of these features are evident with evaluation of a spun hematocrit and a blood smear.

Serum biochemical abnormalities in dogs with DIC include hyperbilirubinemia from hemolysis or hepatic thrombosis, azotemia and hyperphosphatemia if severe renal microembolization has occurred, an increase in liver enzyme activities caused by hypoxia or hepatic microembolization, a decreased total carbon dioxide content caused by metabolic acidosis, and panhypoproteinemia if the bleeding is severe enough. Another manifestation of MOF is the development of multifocal ventricular premature contractions detected in an electrocardiogram.

Urinalysis usually reveals hemoglobinuria and bilirubinuria and occasionally proteinuria and cylindruria. Urine samples in dogs with acute DIC should not be obtained by cystocentesis because severe intravesical or intramural bleeding may result.

Hemostatic abnormalities in dogs with DIC include thrombocytopenia, a prolongation of the OSPT or APTT (more than 25% of the concurrent control), normal or low fibrinogen concentration, a positive FDP or D-dimer test, and a decreased AT concentration. Using a TEG, fibrinolysis can be enhanced in these animals. At our clinic, DIC is diagnosed if the patient has four or more of the hemostatic abnormalities just described, particularly if schistocytes are present.

The hemostatic abnormalities in 50 dogs and 21 cats with DIC evaluated in our clinic are listed in Table 87-6. In dogs thrombocytopenia, prolongation of the APTT, anemia, and schistocytosis were common; in contrast with previous descriptions of the syndrome in dogs, regenerative anemia, prolongation of the OSPT, and hypofibrinogenemia were not. In cats prolongation of the APTT and/or OSPT, schistocytosis, and thrombocytopenia were common, whereas the presence of FDPs and hypofibrinogenemia were rare.

BOX 87-6

Treatment of Dogs and Cats with DIC

- 1. Eliminate the precipitating cause
- 2. Halt intravascular coagulation:

Heparin

Mini dose: 5-10 IU/kg SQ q8h

- Low dose: 50-100 IU/kg SQ q8h
- Intermediate dose: 300-500 IU/kg SQ or IV q8h
- High dose: 750-1000 IU/kg SQ or IV q8h
   Blood or blood products (provide AT, other anticoagulants, and clotting factors)
- 3. Maintain parenchymal organ perfusion:

Aggressive fluid therapy

4. Prevent secondary complications:

Oxygen

Correct acid-base imbalance

Antiarrhythmics

**Antibiotics** 

DIC, Disseminated intravascular coagulation; AT, antithrombin.

#### **Treatment**

Once a diagnosis of DIC has been established (or even if the degree of suspicion is high that DIC is present), treatment should be instituted without delay. Unfortunately, no controlled clinical trials have been performed in veterinary medicine evaluating the effects of different treatments in dogs with DIC. Therefore the following discussion reflects my beliefs in the management of dogs with this disorder (Box 87-6).

Unquestionably, removing or eliminating the precipitating cause constitutes the main therapeutic goal in patients with DIC. However, this is not always possible. Conditions in which the precipitating causes can be eliminated include a primary HSA (surgical excision), disseminated or meta-

static HSA (chemotherapy), sepsis (appropriate antimicrobial treatment), and IHA (immunosuppressive treatment). In most other situations (e.g., electrocution, heatstroke, pancreatitis) the cause can rarely be eliminated within a short time. Therefore the treatment of dogs with DIC is aimed at the following:

- Halting intravascular coagulation
- · Maintaining good parenchymal organ perfusion
- · Preventing secondary complications

Of note, if blood and blood products were available in an unlimited supply (such as is the case in most human hospitals), dogs with DIC would not die of hypovolemic shock. Most dogs with DIC die of pulmonary or renal dysfunction. At our clinic, "DIC lungs" (i.e., intrapulmonary hemorrhages with alveolar septal microthrombi) appear to be a common cause of death in these patients.

Halting intravascular coagulation. I use a dual approach to halt intravascular coagulation: the administration of heparin and blood or blood products. As previously mentioned, heparin is a cofactor for AT and therefore is not effective in preventing the activation of coagulation unless AT activity in the plasma is sufficient. Because AT activity in animals with DIC is usually low as a result of consumption and possibly inactivation, the patient should be provided with sufficient quantities of this anticoagulant. The most cost-efficient way of achieving this is to administer fresh frozen plasma. The old adage that administering blood or blood products to a dog with DIC is analogous to "adding logs to a fire" has not been true in my experience. Therefore blood or blood products should never be withheld based solely on this belief.

Heparin has been used historically to treat DIC in human beings and dogs. However, controversy still exists regarding whether it is beneficial. At our clinic the survival rate in dogs with DIC has increased markedly since we routinely started using heparin and blood products. Although this can also be attributed to improvement in patient care, I believe that heparin is beneficial in such patients and indeed may be responsible for the increased survival rate.

Sodium heparin is given in a wide range of doses. Following are the four traditional dose ranges:

- · Mini dose: 5 to 10 IU/kg SQ q8h
- Low dose: 50 to 100 IU/kg SQ q8h
- Intermediate dose: 300 to 500 IU/kg SQ or IV q8h
- · High dose: 750 to 1000 IU/kg SQ or IV q8h

I routinely use low-dose heparin in combination with the transfusion of blood or blood components. The rationale for this is that this dose of heparin does not prolong the ACT or APTT in normal dogs (a minimum of 150 to 250 IU/kg q8h is required to prolong the APTT in normal dogs), and it appears to be biologically active in these animals given that some of the clinical signs and hemostatic abnormalities are reversed in animals receiving this dosage. The fact that it

does not prolong the APTT or ACT is extremely helpful in dogs with DIC. For example, if a dog with DIC is receiving intermediate-dose heparin, it is then impossible to predict, on the basis of hemostatic parameters, whether a prolongation of the APTT is caused by excessive heparin administration or progression of this syndrome. As laboratory heparin determinations become widely available, this may become a moot point. Until then, my clinical impression is that if an animal with DIC receiving mini- or low-dose heparin shows a prolonged ACT or APTT, the intravascular coagulation is deteriorating and a treatment change is necessary. The use of low-molecular-weight heparin in dogs with DIC is currently being investigated. In an experimental model of DIC in Beagles, high doses of low-molecular-weight heparin resulted in resolution of the clinicopathologic abnormalities associated with DIC (Mischke et al., 2005).

Lepirudin, a novel leech recombinant AT, recently proved beneficial in preventing MOF in an experimental model of sepsis with enteric organisms in Greyhounds. However, this treatment is currently cost prohibitive.

If evidence of severe microthrombosis is present (e.g., marked azotemia, increase in liver enzyme activity, ventricular premature contractions), dyspnea, or hypoxemia, intermediate- or high-dose heparin can be used, with the goal of prolonging the ACT to 2 to 2.5 times the baseline value, or normal if the baseline time was already prolonged. If overheparinization occurs, protamine sulfate can be administered by slow intravenous infusion (1 mg for each 100 IU of the last dose of heparin; 50% of the calculated dose is given I hour after the heparin and 25% 2 hours after the heparin). The remainder of the dose can be administered if clinically indicated. Protamine sulfate should be administered with caution because it can be associated with acute anaphylaxis in dogs. Once improvement in the clinical and clinicopathologic parameters has been achieved, the heparin dose should be tapered gradually (over 1 to 3 days) to prevent rebound hypercoagulability, a phenomenon commonly observed in human beings.

Aspirin and other antiplatelet agents can also be given to prevent platelet activation and thus halt intravascular coagulation. Doses of 0.5 to 10 mg/kg of aspirin given orally every 12 hours in dogs and every third day in cats have been recommended, although in my experience aspirin is rarely of clinical benefit. If it is used, the patient should be closely watched for severe gastrointestinal tract bleeding, because this NSAID can cause gastroduodenal ulceration, which could be catastrophic in a dog with a severe coagulopathy such as DIC.

#### Maintaining good parenchymal organ perfusion.

Good parenchymal organ perfusion is best achieved with aggressive fluid therapy consisting of crystalloids or plasma expanders such as dextran (see Table 87-6). The purpose of this therapy is to dilute out the clotting and fibrinolytic factors in the circulation, flush out microthrombi from the microcirculation, and maintain the precapillary arterioles patent so that blood is shunted to areas in which oxygen exchange is efficient. However, care should be taken not to

overhydrate an animal with compromised renal or pulmonary function.

Preventing secondary complications. As previously discussed, numerous complications occur in dogs with DIC. Attention should be directed toward maintaining oxygenation (by oxygen mask, cage, or nasopharyngeal catheter), correcting acidosis, eliminating cardiac arrhythmias, and preventing secondary bacterial infections (i.e., the ischemic gastrointestinal mucosa no longer functions as an effective barrier to microorganisms, bacteria are absorbed and cannot be cleared by the hepatic mononuclear-phagocytic system, and sepsis occurs).

Prognosis. The prognosis for dogs with DIC is still grave. Despite the numerous acronyms for DIC coined over the past few decades (e.g., "death is coming," "dead in cage," "dog in cooler"), if the inciting cause can be controlled most patients recover with appropriate treatment (see Fig. 87-2). In the retrospective study of DIC in dogs conducted at OSU-VTH the mortality rate was 54%; however, the mortality rate in dogs with minor changes in the hemostasis screen (i.e., fewer than three abnormalities) was 37%, whereas that in the dogs with severe hemostatic abnormalities (i.e., more than three hemostatic abnormalities) was 74%. In addition, marked prolongation of the APTT and marked thrombocytopenia were negative prognostic factors. The median APTT in dogs that survived was 46% over the controls, whereas it was 93% over the controls in dogs that did not survive. Likewise, the median platelet count in dogs that survived was 110,000/µL, and in dogs that did not survive it was 52,000/μL.

#### **THROMBOSIS**

Thrombotic and thromboembolic disorders appear to be considerably less common in cats and dogs than in human beings. Several situations can result in thrombosis or thromboembolism (TE), including stasis of blood, activation of intravascular coagulation in an area of abnormal or damaged endothelium, decreased activity of natural anticoagulants, and decreased or impaired fibrinolysis. Thrombosis has been recognized clinically as associated with cardiomyopathy, hyperadrenocorticism, protein-losing enteropathy and nephropathy, and IHA.

Diagnosing TE is not an easy task. Clinical signs are variable and include signs associated with parenchymal organ ischemia (e.g., dyspnea from pulmonary TE, high liver enzyme activities in patients with hepatic TE, intermittent rear limb claudication in dogs with aortic thrombosis). A positive D-dimer test has been reported to be associated with TE disease in dogs (Nelson & Andreasen, 2003). In our experience TEG is a rapid and sensitive test to diagnose TE disease in dogs (Fig. 87-3).

Stasis of blood and possibly an irregular endothelial surface appear to be the major causes in cats with aortic (iliac) TE secondary to hypertrophic cardiomyopathy. Decreased activity of the natural anticoagulant AT plays a major role in the thrombosis seen in dogs with

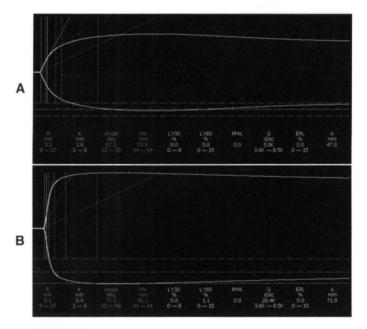

FIG 87-3

**A,** TEG (Haemoscope, Niles, Ill.) tracing in a normal dog; the MA (maximum amplitude) provides information on the strength of the clot and is within the reference range (53.9 mm). **B,** TEG tracing in a dog with hypercoagulability; notice that the MA is 80.3 mm.

protein-losing nephropathy or protein-losing enteropathy; in addition, human beings with hypertension frequently have high concentration of PAI-1, which in turns inhibits fibrinolysis, thus resulting in a net procoagulant effect. This mechanism may also be important in dogs with proteinlosing nephropathy and hypertension. The decreased AT activity stems from the fact that this is a relatively small molecule (approximately 60 kD) that is easily lost in the urine or gut contents in dogs with either of these two disorders. The thrombosis commonly seen in dogs with hyperadrenocorticism is likely related to the induction of PAI-1 synthesis by corticosteroids (corticosteroids inhibit fibrinolysis). An increased risk for TE has been recognized in dogs with IHA. Although the pathogenesis of these disorders is obscure, the release of procoagulants from the lysed RBCs has been postulated as a cause; sludging of autoagglutinated RBCs in the microcirculation is also likely to contribute to this procoagulant state.

Dogs and cats at high risk for thrombosis or TE should receive anticoagulants. The two drugs commonly used in cats and dogs at risk for this condition are aspirin and heparin. Coumarin derivatives are commonly used in human beings, but in dogs and cats they can result in excessive bleeding. In recent reports of human beings with AT deficiency, anabolic steroids such as stanozolol have been suggested to also decrease the risk of thrombotic disorders as a result of their stimulatory effect on the fibrinolytic system. The recognition and management of pulmonary TE are discussed in Chapter 22.

# CHAPTER Lymphadenopathy and Splenomegaly

#### CHAPTER OUTLINE

APPLIED ANATOMY AND HISTOLOGY
FUNCTION
LYMPHADENOPATHY
SPLENOMEGALY
APPROACH TO PATIENTS WITH
LYMPHADENOPATHY OR SPLENOMEGALY
MANAGEMENT OF PATIENTS WITH
LYMPHADENOPATHY OR SPLENOMEGALY

#### APPLIED ANATOMY AND HISTOLOGY

The lymph nodes and spleen constitute the main source of immunologic and mononuclear-phagocytic (MP) cells in the body. Because these lymphoid structures are in a constant dynamic state, they continuously reshape and change in size in response to antigenic stimuli. In general, the response of the cells within a lymph node to different stimuli is similar to that occurring in the spleen. However, the spleen responds primarily to blood-borne antigens (mainly nonopsonized organisms), whereas the lymph nodes respond to antigens arriving through the afferent lymphatics (i.e., local tissue response). The response of the lymph nodes and spleen to different stimuli is briefly reviewed in this chapter.

The canine and feline lymph nodes are reniform, encapsulated, well-developed structures responsible for filtering lymph and participating in immunologic reactions. Fig. 88-1 depicts the basic microscopic anatomy of a lymph node in a carnivore. It is composed of a capsule, subcapsular spaces, cortex, paracortex, and medulla. Each of these areas has specific functions. The capsule surrounds and supports all other structures within the node (stroma). The subcapsular spaces (or sinuses) contain mainly MP cells responsible for "filtering" particles arriving through the afferent lymphatics and presenting the antigens to the lymphoid cells. The cortex contains mainly B-cell areas in the germinal centers. The paracortex is composed primarily of T cells and is therefore involved in cell-mediated immunity. The medulla

contains the medullary cords, where the committed B cells persist and may expand to solid areas of plasma cells in response to antigenic stimulation. Between the medullary cords, the medullary sinuses form an endothelial sieve containing varying numbers of MP cells, which "screen" the efferent lymph. The lymph flows from the medulla to the efferent lymphatics in the hilus.

An understanding of the different histologic and functional characteristics of these anatomic areas aids in understanding the pathogenesis of lymphadenopathy. For example, a lymph node reacting to a bacterial infection has primarily B-cell hyperplasia characterized by increased numbers of secondary follicles. This histologic/functional compartmentalization should be kept in mind when interpreting cytologic or histopathologic lymph node specimens.

#### **FUNCTION**

The two main functions of the lymph nodes are to filter particulate material and participate in immunologic processes. Particulate material is filtered as lymph flows through the areas rich in MP cells while it moves from the afferent to the efferent lymphatics. During this transit, particulate material is taken up and processed by the MP or antigen processing (AP) cells and presented to the lymphoid cells to generate a humoral or cellular immune response.

The spleen has multiple functions, including hematopoiesis, filtration and phagocytosis, remodeling of red blood cells (RBCs), removal of intraerythrocytic inclusions, storage of RBCs and platelets, metabolizing of iron, and immunologic functions. Because of its nonsinusal nature, the feline spleen is less efficient at removing intracellular inclusions than its canine counterpart.

#### LYMPHADENOPATHY

#### **Etiology and Pathogenesis**

In this chapter lymphadenopathy is defined as lymph node enlargement. According to the distribution, the following

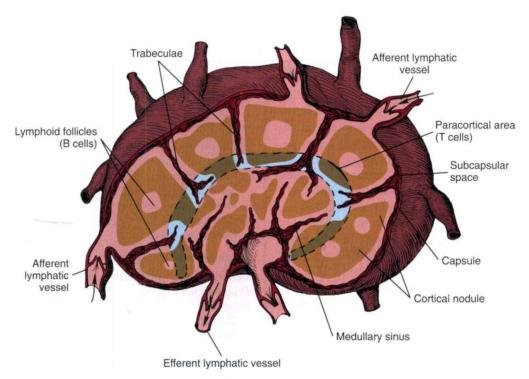

FIG 88-1
Microscopic anatomy of a typical lymph node in a carnivore. (Reprinted from Couto CG: Diseases of the lymph nodes and spleen. In Ettinger SJ, editor: Textbook of veterinary internal medicine—diseases of the dog and cat, ed 3, Philadelphia, 1989, WB Saunders.

terms are used to characterize lymphadenopathy. Solitary lymphadenopathy refers to the enlargement of a single lymph node. Regional lymphadenopathy is an enlargement of a chain of lymph nodes draining a specific anatomic area. Generalized lymphadenopathy is a multicentric lymph node enlargement affecting more than one anatomic area. Lymphadenopathies can also be classified as superficial or deep (or visceral) according to their anatomic location.

Lymph nodes enlarge as a consequence of the proliferation of normal cells that normally reside in the node, or infiltration with normal or abnormal cells. Rarely, lymph nodes enlarge as a result of vascular changes (e.g., hyperemia, congestion, neovascularization, edema).

When normal cells proliferate within a lymph node in response to antigenic stimuli (e.g., vaccination, infection), the term reactive lymphadenopathy (or lymph node hyperplasia) is used. Lymphoid and MP/AP cells proliferate in response to immunologic and infectious stimuli, although occasionally a clinician evaluates a dog or cat in which a cause for the reactive lymphadenopathy cannot be identified. Because these lymphoid structures are usually presented with many antigens simultaneously, the cell proliferation that occurs in reactive lymphadenopathies is polyclonal (i.e., a wide variety of morphologic types of lymphoid and MP/AP cell types are present in a cytologic or histopathologic specimen).

When polymorphonuclear leukocytes or macrophages predominate in the cellular infiltrate, the term *lymphadenitis* 

is used. This is usually, but not always, a result of infectious processes. Depending on the predominant cell type in the infiltrate, lymphadenitides are classified as *suppurative* (neutrophils predominate), *granulomatous* (macrophages predominate), *pyogranulomatous* (macrophages and neutrophils predominate), or *eosinophilic* (eosinophils predominate). A focal area of suppurative inflammation with marked liquefaction (i.e., pus) is referred to as a *lymph node abscess*. The etiologic agents that commonly cause the different types of lymphadenitis are listed in Table 88-1.

Infiltrative lymphadenopathies usually result from the displacement of normal lymph node structures by neoplastic cells and, more rarely, from extramedullary hematopoiesis. Neoplasms affecting the lymph nodes can be either *primary* hematopoietic tumors or *secondary* (metastatic) neoplasms. Lymph node infiltration by hematopoietic malignancies (i.e., lymphoma) constitutes one of the most common causes of generalized lymphadenopathy in dogs.

#### **Clinical Features**

From the clinical standpoint, familiarization with the location and palpation characteristics of normal lymph nodes, which should always be evaluated during a routine physical examination, is important. The following lymph nodes are palpable in normal dogs and cats: the mandibular, prescapular (or superficial cervical), axillary (in approximately half of animals), superficial inguinal, and popliteal (Fig. 88-2). Lymph nodes that are palpable only when markedly enlarged

include the facial, retropharyngeal, mesenteric, and iliac (sublumbar) lymph nodes.

When evaluating dogs and cats with lymphadenopathy or diffuse splenomegaly, the clinician can glean important information from the history. Certain diseases have a defined geographic or seasonal prevalence, including leishmaniasis in the Mediterranean region of Europe, salmon poisoning in the Pacific Northwest, and some systemic mycoses, such as histoplasmosis in the Ohio River Valley. Systemic (constitutional) clinical signs are usually present in dogs with systemic mycoses, salmon poisoning, Rocky Mountain spotted fever (RMSF), ehrlichiosis, bartonellosis, leishmaniasis, and acute

D, Dogs; C, cats; RMSF, Rocky Mountain spotted fever.

leukemia. Clinical signs are rare or absent in dogs and cats with chronic leukemias, anaplasmosis, most lymphomas, and reactive lymphadenopathies occurring after vaccination; cats with idiopathic reactive lymphadenopathy (see the following section) are usually asymptomatic.

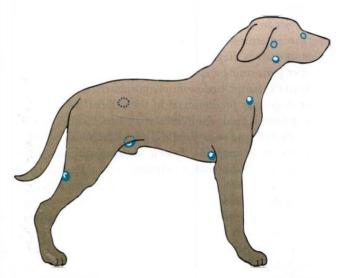

FIG 88-2

Anatomic distribution of clinically relevant lymph nodes in a dog. The nodes are in the same general location in cats. The lymph nodes depicted by the darkened circles include, from cranial to caudal, the mandibular, prescapular, axillary, superficial inguinal, and popliteal lymph nodes. The lymph nodes depicted by the open circles include, from cranial to caudal, the facial, retropharyngeal, and iliac or sublumbar lymph nodes. (Reprinted from Couto CG: Diseases of the lymph nodes and spleen. In Ettinger SJ, editor: Textbook of veterinary internal medicine—diseases of the dog and cat, ed 3, Philadelphia, 1989, WB Saunders.)

Clinical signs in dogs and cats with lymphadenopathy or splenomegaly are vague and nonspecific and are usually related to the primary disease rather than the organ enlargement; they include anorexia, weight loss, weakness, abdominal distention, vomiting, diarrhea, polyuria-polydipsia (PU/PD) (the latter in dogs with lymphoma-associated hypercalcemia), or a combination of these. Enlarged lymph nodes can occasionally result in obstructive or compressive signs (e.g., dysphagia resulting from enlarged retropharyngeal nodes, coughing resulting from enlarged tracheobronchial nodes, edema).

The distribution of the lymphadenopathy is also of diagnostic relevance. In patients with solitary or regional lymphadenopathy, the area drained by the lymph node(s) should be examined meticulously because the primary lesion is generally found there. Most cases of superficial solitary or regional lymphadenopathy in dogs and cats result from localized inflammatory or infectious processes or from metastatic neoplasia (less commonly), whereas most cases of deep (i.e., intraabdominal, intrathoracic) solitary or regional lymphadenopathy result from metastatic neoplasia or systemic infectious diseases (e.g., systemic mycoses). Most cases of generalized lymphadenopathy are caused by systemic fungal or bacterial infections (dogs), nonspecific hyperplasia (mainly cats), or lymphoma (dogs) (Table 88-2).

The characteristics of the lymph nodes on palpation are also important. In most dogs and cats with lymphadenopathy, regardless of the distribution, the lymph nodes are firm, irregular, and painless; their temperature is normal to the touch (cold lymphadenopathies); and they do not adhere to the surrounding structures. However, in patients with lymphadenitis the lymph nodes may be softer than usual and more tender and warmer than normal; they may also adhere to surrounding structures (fixed lymphadenopathy). Fixed

lymphadenopathies may also be the presenting feature in dogs and cats with metastatic lesions, lymphomas with extracapsular invasion, or ceratin infectious diseases (e.g., mycobacteriosis).

The size of the affected lymph nodes is also important. Massive lymphadenopathy-lymph node size five to 10 times normal—occurs almost exclusively in dogs with lymphoma or lymphadenitis (lymph node abscess formation). In cats the syndrome of distinctive lymph node hyperplasia usually results in massive lymphadenopathy. Rarely, metastatic lymph nodes exhibit this degree of enlargement; the main example of massive metastatic lymphadenopathy is the apocrine gland adenocarcinoma metastases to the sublumbar lymph nodes. Recognizing that lymph nodes of normal size may contain metastatic neoplasia is important. Dogs with salmon poisoning may also have marked generalized lymphadenopathy as the presenting feature, preceded by or in conjunction with bloody diarrhea. Mild to moderate lymph node enlargement (two to four times the normal size) occurs mostly in a variety of reactive and inflammatory lymphadenopathies (e.g., ehrlichiosis, bartonellosis, anaplasmosis, RMSF, systemic mycoses, leishmaniasis, immunemediated diseases, skin diseases) and in leukemias.

As previously discussed, the area draining the enlarged lymph node(s) should always be thoroughly examined, paying particular attention to the skin, subcutis, and bone. In dogs and cats with generalized lymphadenopathy, evaluation of other hemolymphatic organs is important, including the spleen, liver, and bone marrow.

#### **SPLENOMEGALY**

#### **Etiology and Pathogenesis**

Splenomegaly is defined as a localized or diffuse splenic enlargement. The term *localized splenomegaly* (or splenic mass) refers to a localized, palpable enlargement of the spleen. Diffuse splenic enlargement occurs as a consequence of either the proliferation of normal cells or infiltration with normal or abnormal cells. Rarely, diffuse splenic enlargement can occur as a result of vascular changes (e.g., hyperemia, congestion). Focal splenomegaly is more common in dogs, and diffuse splenomegaly is more common in cats.

Diffuse splenomegaly is classified into four major categories in terms of its pathogenesis: lymphoreticular hyperplasia, inflammatory changes (i.e., splenitis), infiltration with abnormal cells (e.g., lymphoma) or substances (e.g., amyloidosis), and congestion (Table 88-3).

The spleen commonly reacts to blood-borne antigens and RBC destruction with hyperplasia of the MP/AP and lymphoid components. This hyperplasia has been referred to as work hypertrophy because it usually results in varying degrees of splenic enlargement. Hyperplastic splenomegaly is relatively common in dogs with ehrlichiosis, bacterial endocarditis, systemic lupus erythematosus, or chronic bacteremic disorders such as discospondylitis and brucellosis, and in cats with mycoplasmosis or immune-mediated cytopenias.

RBC phagocytosis by the splenic MP system in human beings has been recognized to lead to hyperplasia of this cell population, resulting in splenomegaly. The same seems to occur in dogs and cats with certain hemolytic disorders, including immune-mediated hemolytic anemia, druginduced hemolysis, pyruvate kinase deficiency anemia, phosphofructokinase deficiency anemia, familial nonspherocytic hemolysis in Poodles and Beagles, Heinz body hemolysis, and mycoplasmosis (see Chapter 83). Rarely, an area of focal splenomegaly is diagnosed histopathologically as hyperplasia after performing a splenectomy.

As in the lymph nodes, if polymorphonuclear leukocytes or macrophages predominate in the cellular infiltrate, the term *splenitis* is used. The infiltrates are also classified according to the cell type as *suppurative*, *granulomatous*, *pyogranulomatous*, or *eosinophilic*. *Splenic abscesses* can also form, often in association with a perforation by a foreign body. *Necrotizing splenitis* caused by gas-forming anaerobes can occur in dogs in association with splenic torsion or neoplasia. *Lymphoplasmacytic splenitis* cannot be distinguished cytologically from splenic hyperplasia. The etiologic agents for different types of splenitis are listed in Table 88-3.

Infiltrative splenomegalies are also common in small animals. Marked splenomegaly is a common finding in dogs and cats with acute and chronic leukemias (although it is more common in dogs), in dogs and cats with systemic mastocytosis, and in dogs with malignant histiocytosis. In addition, diffuse neoplastic infiltration of the spleen commonly occurs in dogs and cats with lymphoma and multiple myeloma. Diffuse splenomegaly may be the only physical examination and imaging finding in cats with monoclonal gammopathies; fine-needle aspiration (FNA) of the spleen reveals diffuse infiltration with plasma cells and is a common presentation for myeloma in this species. Metastatic splenic neoplasms usually result in focal splenomegaly but are rare.

Nonneoplastic causes of infiltrative splenomegaly are uncommon, with the exception of extramedullary hematopoiesis (EMH), which is more common in dogs than in cats. Because the spleen retains its fetal hematopoietic potential during adult life, a variety of stimuli-such as anemia, severe splenic or extrasplenic inflammation, neoplastic infiltration of the spleen, bone marrow hypoplasia, and splenic congestion-may cause the spleen to resume its fetal hematopoietic function and produce RBCs, white blood cells, and platelets. Finding EMH in percutaneous FNA of the spleen is extremely common in dogs and cats with diffuse or focal splenomegaly; the presence of hematopoietic blasts may lead to an erroneous diagnosis of lymphoma in some of these patients. I have also observed splenic EMH in dogs with pyometra, immune-mediated hemolysis, immune-mediated thrombocytopenia, several infectious diseases, and a variety of malignant neoplasms as well as in seemingly healthy dogs. Another disorder that commonly results in prominent infiltrative splenomegaly is the hypereosinophilic syndrome of cats (and some dogs, such as Rottweilers), a disease characterized by peripheral blood eosinophilia, bone marrow hyperplasia

of the eosinophil precursors, and multiple-organ infiltration by mature eosinophils (see Chapter 85).

The canine and feline spleens have a great capacity to store blood, and under normal circumstances they store between 10% and 20% of the total blood volume. However, tranquilizers and barbiturates can cause splenic blood pooling to increase by relaxing the smooth muscle of the splenic capsule, leading to congestive splenomegaly. The blood that has pooled in an enlarged spleen can account for up to 30% of the total blood volume. Anesthetics such as halothane also may result in marked decreases of 10% to 20% in the packed cell volume and plasma protein concentrations in dogs as a result of the same mechanism.

Portal hypertension can lead to congestive splenomegaly; however, such splenic congestion does not appear to be as common in dogs and cats as it is in human beings. Causes of portal hypertension that may lead to splenomegaly in small animals include right-sided congestive heart failure; obstruction of the caudal vena cava as a result of congenital malformations, neoplasia, or heartworm disease; and intrahepatic obstruction of the venae cavae. Splenic vein thrombosis is a common incidental finding in dogs; it is usually associated with administration of corticosteroids and is typically of no clinical relevance. Ultrasonographic evaluation in these patients usually reveals markedly distended splenic, portal, or hepatic veins or thrombi.

A relatively common cause of congestive splenomegaly in dogs is *splenic torsion*. Torsion of the spleen, either by itself or in association with gastric dilation-volvulus syndrome, commonly results in marked splenomegaly caused by

D, Dogs; C, cats; EMH, extramedullary hematopoiesis.

congestion. Splenic torsion can occur independently of gastric dilation-volvulus syndrome. Most affected dogs are of large, deep-chested breeds, primarily Great Danes and German Shepherd dogs. Clinical signs can be either acute or chronic. Dogs with acute splenic torsion are usually evaluated because of acute abdominal pain and distention, vomiting, depression, and anorexia. Dogs with chronic splenic torsion display a wide variety of clinical signs, including anorexia, weight loss, intermittent vomiting, abdominal distention, PU/PD, hemoglobinuria, and abdominal pain. Physical examination usually reveals marked splenomegaly, and radiographs typically reveal a C-shaped spleen. Ultrasonography of the abdomen in these patients may show greatly distended splenic veins. Hematologic abnormalities usually include regenerative anemia, leukocytosis with a regenerative left shift, and leukoerythroblastosis. Disseminated intravascular coagulation appears to be a common complication in dogs with torsion of the spleen. A high percentage of dogs with splenic torsion have hemoglobinuria, possibly as a consequence of intravascular or intrasplenic hemolysis. Dogs with splenic torsion and hemoglobinuria seen at our clinic occasionally have a positive direct Coombs tests. The treatment of choice for dogs with splenic torsion is splenectomy.

Splenic masses are more common than diffuse splenomegaly in dogs, whereas the opposite is true for cats. Most splenectomies in dogs are done to remove splenic masses. Because splenic masses in cats are extremely uncommon, the following discussion pertains primarily to localized splenomegaly in dogs.

Splenic masses can be classified according to their histopathologic features and biologic behavior as either neoplastic or nonneoplastic. Neoplastic splenic masses can be benign or malignant and mainly include hemangiomas (HAs) and hemangiosarcomas (HSAs), although the former are less common than the latter. Other neoplastic splenic masses that are occasionally found are leiomyosarcomas, fibrosarcomas, leiomyomas, myelolipomas, metastatic carcinomas or sarcomas, malignant histiocytic tumors, and occasionally lymphomas. Nonneoplastic splenic masses include primarily hematomas and abscesses, although splenic infarcts are occasionally described as splenic masses in dogs. As previously discussed, a splenic mass is occasionally diagnosed as a hyperplastic nodule on histopathology after splenectomy.

HSAs are malignant vascular tumors of the spleen; they are extremely common in dogs, constituting the most common primary neoplasm in surgically collected splenic tissues (i.e., splenectomy). These neoplasms are extremely rare in cats.

#### **Clinical Features**

The history-taking and physical examination in dogs with splenomegaly are similar to those in dogs with lymphade-nopathy. The clinical signs in dogs with splenomegaly are vague and nonspecific and include anorexia, weight loss, weakness, abdominal distention, vomiting, diarrhea, PU/PD, or a combination of these. PU/PD is relatively common in dogs with marked splenomegaly, particularly in those with

splenic torsion. Although the pathogenesis of the PU/PD is unclear, psychogenic polydipsia provoked by abdominal pain and distention of the splenic stretch receptors may be a contributory mechanism. Splenectomy in these dogs usually results in prompt resolution of the signs. Other signs associated with splenomegaly result from the hematologic consequences of the splenic enlargement and include spontaneous bleeding caused by thrombocytopenia, pallor caused by anemia, and fever caused by neutropenia or the primary disorder.

During a routine physical examination in pups and cats, the normal spleen is easily palpated as a flat structure oriented dorsoventrally in the left anterior abdominal quadrant. In some deep-chested dogs (e.g., Irish Setters, German Shepherd dogs), the normal spleen is also easily palpated during routine examination, either in the ventral midabdomen or in the left anterior quadrant. This is also the case in Miniature Schnauzers and in some Cocker Spaniels. The fullness of the stomach determines to what extent a normal spleen is palpable in other breeds of dogs. It is easily palpated postprandially because its contour conforms to the greater curvature of the stomach, such that it lies parallel to the last rib. However, not all enlarged spleens are palpable, and not every palpable spleen is abnormal. The characteristics of the spleen on palpation vary. In dogs an enlarged spleen can be either smooth or irregular ("lumpy-bumpy"). In most cats with marked splenomegaly, the surface of the organ is smooth; a diffusely enlarged, lumpy spleen in a cat suggests systemic mast cell disease. As previously discussed, animals with hematologic abnormalities secondary to splenomegaly may also have pallor, petechiae, or ecchymoses.

# APPROACH TO PATIENTS WITH LYMPHADENOPATHY OR SPLENOMEGALY

#### **Clinicopathologic Features**

A complete blood count (CBC) and a serum biochemistry profile should be obtained, particularly in dogs and cats with generalized or regional lymphadenopathies and those with diffuse splenomegaly. Changes in the CBC may indicate a systemic inflammatory process (e.g., leukocytosis with neutrophilia, left shift, monocytosis) or hemolymphatic neoplasia (e.g., circulating blasts in acute leukemia or lymphoma, marked lymphocytosis suggestive of chronic lymphocytic leukemia or ehrlichiosis). Occasionally the etiologic agent may be identified during examination of a blood smear (e.g., histoplasmosis, mycoplasmosis, trypanosomiasis, babesiosis). Polymerase chain reaction for clonality and immunophenotyping with flow cytometry are commonly used in our clinic in patients with lymphadenopathy or splenomegaly and circulating abnormal cells or lymphocytosis.

The spleen exerts a marked influence on the CBC, resulting in two patterns of hematologic changes in dogs and cats with splenomegaly: hypersplenism and hyposplenism, or

asplenia. Hypersplenism results from increased MP activity, is rare, and is characterized by cytopenias in the presence of a hypercellular bone marrow; these changes resolve after splenectomy. Hyposplenism is more common and results in hematologic changes similar to those seen in splenectomized animals, such as thrombocytosis, schistocytosis, acanthocytosis, Howell-Jolly bodies, and increased numbers of reticulocytes and nucleated RBCs.

Anemia in dogs and cats with lymphadenopathy or splenomegaly can occur as a result of the several mechanisms already mentioned. In brief, anemia of chronic disease can be seen in inflammatory, infectious, or neoplastic disorders; hemolytic anemia is usually present in patients with hemoparasitic lymphadenopathies or splenomegaly and in some dogs with malignant histiocytosis or hemophagocytic syndrome. Severe nonregenerative anemia may be seen in dogs with chronic ehrlichiosis, in cats with feline leukemia virusrelated disorders or feline immunodeficiency virus-related disorders, and in dogs and cats with primary bone marrow neoplasms (e.g., leukemias, multiple myeloma).

Thrombocytopenia is a common finding in patients with ehrlichiosis, RMSF, anaplasmosis, sepsis, lymphomas, leukemias, multiple myeloma, systemic mastocytosis, or some immune-mediated disorders. Pancytopenia is common in dogs with chronic ehrlichiosis or systemic immunemediated disorders; in dogs and cats with lymphoma or leukemia; and in cats with disorders associated with retroviral infections.

Two major serum biochemical abnormalities are of diagnostic value in dogs and cats with lymphadenopathy or diffuse splenomegaly: hypercalcemia and hyperglobulinemia. Hypercalcemia is a paraneoplastic syndrome that occurs in approximately 10% to 20% of dogs with lymphoma and multiple myeloma, although it may also occur in dogs with blastomycosis. It is extremely rare in cats with these diseases. Monoclonal hyperglobulinemia commonly occurs in dogs and cats with multiple myeloma and occasionally in dogs with lymphoma, ehrlichiosis, or leishmaniasis (see Chapter 89). Polyclonal hyperglobulinemia commonly occurs in dogs and cats with systemic mycoses; in cats with feline infectious peritonitis; and in dogs with ehrlichiosis, anaplasmosis, or leishmaniasis (see Chapter 89).

Serologic and microbiologic studies should always be conducted in dogs and cats with suspected infectious lymphadenopathy-splenomegaly. Serologic tests or polymerase chain reaction for canine ehrlichiosis, RMSF, brucellosis, and systemic mycoses may help diagnose regional or systemic lymphadenopathies. Lymph node specimens for bacterial and fungal cultures should also be obtained if necessary.

#### **Imaging**

Radiographic abnormalities in dogs with lymphadenopathy can be related to the primary disorder, or they can reflect the location and degree of lymphadenopathy. In general, plain radiographs or computed tomography (CT) are beneficial in dogs and cats with solitary lymphadenopathy to search for primary bone inflammation or neoplasia, in those with generalized peripheral (superficial) lymphadenopathy to detect intrathoracic or intraabdominal lymph node enlargement, and in those with deep regional lymphadenopathy involving the thoracic cavity to determine the distribution and size of the affected nodes and the changes in the pulmonary parenchyma and pleural space.

The spleen is normally well visualized on plain abdominal radiographs, but its appearance can vary widely. On dorsoventral or ventrodorsal views, the spleen is seen between the gastric fundus and the left kidney. The size and location of the spleen are more variable on lateral radiographs than on ventrodorsal or dorsoventral projections. In some breeds, such as Greyhounds, the spleen appears to be large on plain radiographs and ultrasonography. On plain radiographs, large splenic masses usually appear in the caudal abdomen or the midabdomen. Tranquilization or anesthesia usually results in a diffuse congestive splenomegaly, making radiographic interpretation of splenic size extremely difficult. CT is a useful diagnostic tool in dogs with focal or diffuse splenomegaly.

Ultrasonography is the noninvasive procedure of choice to evaluate intraabdominal lymphadenopathy and splenomegaly because it can accurately image and show the size of both enlarged lymph nodes and the spleen so that the patient's response to therapy can be monitored. In addition, ultrasound-guided FNA or biopsies can be performed with minimal complications. Abdominal ultrasonography can reveal diffuse splenomegaly, splenic masses, splenic congestion, hepatic nodules, or other changes; in addition, colorflow Doppler allows evaluation of splenic blood flow. A major issue a clinician frequently must deal with is the incidental splenic nodule in an older dog; these lesions are common and usually clinically irrelevant, but they tend to cloud the clinical picture in a patient with intraabdominal neoplasia. If possible, splenic nodules should be aspirated and evaluated cytologically. Of note, however, is that the presence of hepatic nodules in a dog with a splenic mass does not constitute a valid reason for an owner to decline treatment or request euthanasia because regenerative liver nodules are indistinguishable from metastatic lesions. Moreover, hypoechoic splenic nodules are frequently found in normal dogs.

Radionuclide imaging of the spleen (and less commonly of lymph nodes) using technetium-99m-labeled sulfur colloid has become an accepted method of splenic imaging in human beings and small animals. However, this technique only evaluates the spleen's ability to clear particulate matter and rarely provides a morphologic diagnosis.

#### **Additional Diagnostics**

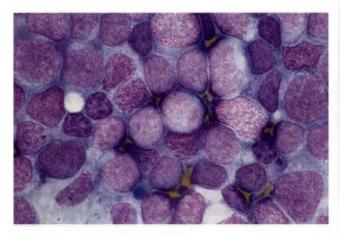

Evaluation of bone marrow aspirates or core biopsy specimens may be beneficial in dogs and cats with generalized lymphadenopathy or splenomegaly caused by hemolymphatic neoplasia or systemic infectious diseases. For example, acute or chronic leukemia in dogs may be difficult to diagnose on the basis of lymph node cytologic findings alone because the diagnosis is usually that of lymphoma (with the presence of well-differentiated or poorly differentiated lymphoid cells). In those cases, the combination of hematologic and bone marrow findings is usually diagnostic. Bone marrow evaluation should always be done before splenectomy in patients with cytopenias because the spleen may assume the primary hematopoietic function in dogs and cats with primary bone marrow disorders such as hypoplasia or aplasia. Splenectomy in these animals could remove the sole source of circulating blood cells, leading to death.

Cytologic evaluation of lymph node and splenic aspirates provides the clinician with a wealth of information and often constitutes the definitive diagnostic procedure in animals with lymphadenopathy or diffuse splenomegaly. In my experience, cytologic evaluation of appropriately collected specimens yields diagnostic findings in approximately 80% to 90% of dogs and 70% to 75% of cats with lymphadenopathy and in approximately 80% of dogs and cats with diffuse splenomegaly.

Although superficial lymph nodes can be aspirated with minimal difficulty, the successful aspiration of intrathoracic or intraabdominal lymph nodes or spleen requires some expertise and occasionally must be done under the guidance of imaging techniques (e.g., fluoroscopy, ultrasonography, CT) (see Chapter 75). To obtain an FNA of a superficial node, the area does not have to be surgically prepared. However, the aspiration of intrathoracic and intraabdominal structures (e.g., spleen) requires surgical preparation of the area and adequate restraint of the animal. Certain intraabdominal lymph nodes (e.g., markedly enlarged mesenteric or iliac nodes) are easily aspirated transabdominally by using manual isolation of the mass. Iliac lymph nodes can also be aspirated transrectally with a 2- to 3-inch (5 to 7.5 cm) needle. Splenic aspirates are obtained with the animal in right lateral or dorsal recumbency with manual restraint or mild sedation. Transabdominal splenic FNA in dogs or cats chemically restrained with phenothiazine tranquilizers or barbiturates usually yields blood-diluted specimens as a result of splenic congestion.

In a patient with generalized lymphadenopathy, the clinician must decide which lymph node to aspirate. Obviously aspiration of a node in which the tissue changes are representative of the ongoing disease is important. Therefore do not obtain a specimen from the largest lymph node because the central necrosis in such a node usually precludes a definitive diagnosis. Because clinical and subclinical gingivitis are common in older dogs and cats, mandibular lymph nodes should not be routinely aspirated because they are usually reactive and findings may obscure the primary diagnosis. The techniques of FNA are described in Chapter 75.

Several reviews of the cytologic evaluation of lymphoid tissues have appeared in the veterinary literature (see Suggested Readings). In brief, *normal lymph nodes* are composed primarily of small lymphocytes (80% to 90% of all cells); a low number of macrophages, medium or large lymphocytes,

Cytologic characteristics of a lymph node aspirate from a dog with massive generalized lymphadenopathy (lymphoma). Note a monomorphic population of large, round cells with a lacy chromatin pattern (neoplastic cells) intermixed with small, darker, normal lymphocytes. (Wright-Giemsa stain, ×1000.)

plasma cells, and mast cells can also be found. Normal spleens are similar except that RBCs are in high concentration given this organ's vascularity. Reactive lymph nodes and hyperplastic spleens are characterized by variable numbers of lymphoid cells in different stages of development (small, medium, and large lymphocytes; plasma cells); hematopoietic precursors are common in dogs and cats with splenic hyperplasia. The cytologic features of lymphadenitis-splenitis vary with the etiologic agent and the type of reaction elicited. Etiologic agents can frequently be identified in cytologic specimens from nodes with lymphadenitis. Metastatic neoplasms have different cytologic features depending on the degree of involvement and the cell type. Carcinomas, adenocarcinomas, melanomas, and mast cell tumors are easily diagnosed on the basis of cytologic findings. However, the cytologic diagnosis of sarcomas may be difficult because the neoplastic cells that comprise this tumor do not exfoliate easily. Primary lymphoid neoplasms (lymphomas) are characterized by a monomorphic population of lymphoid cells, which are usually immature (showing a fine chromatin pattern, one or more nucleoli, basophilic cytoplasm, vacuolation) (Fig. 88-3). For a more detailed description of cytologic changes, see Chapter 75.

When the cytologic examination of an enlarged lymph node or spleen does not yield a definitive diagnosis, excision of the affected node or incisional or even excisional splenic biopsy to obtain a specimen for histopathologic examination is indicated. Excision of the whole node is preferable because core biopsy specimens are difficult to interpret because the lymph node architecture is often poorly preserved. A wedge of tissue can be obtained during a splenic biopsy or, if the surgeon deems it necessary, a splenectomy can be performed. Care should be taken in handling the tissues during surgical manipulation because trauma may induce considerable artifactual changes, which would preclude interpretation of the

specimen. The popliteal lymph nodes are easily accessible and are the ones usually excised in dogs and cats with generalized lymphadenopathy.

Once a node is excised, it should be sectioned in half lengthwise, impression smears made for cytologic analysis, and the node fixed in 10% buffered formalin in a proportion of one part of tissue to nine parts of fixative. The specimen is then ready to be sent to a laboratory for evaluation. Samples can also be saved for cytochemical or immuno-histochemical evaluation, ultrastructural studies, or microbiologic evaluation, including polymerase chain reaction. The same guidelines apply to the preparation of splenic specimens.

# MANAGEMENT OF PATIENTS WITH LYMPHADENOPATHY OR SPLENOMEGALY

As previously discussed, no specific treatment exists for dogs or cats with local, regional, or generalized lymphadenopathy or diffuse splenomegaly. Treatment should be directed at the cause(s) of the lymphadenopathy or splenomegaly rather than at the enlarged lymph nodes or spleen. Exploratory celiotomies provide considerable information regarding the gross morphologic characteristics of an enlarged spleen and adjacent organs and tissues. However, direct visualization of these structures may be misleading because differentiation of some benign splenic masses (e.g., hematoma, HA) from their malignant counterpart (e.g., HSA) on the basis of gross morphology alone may be impossible. As discussed in the section on imaging, the surgeon may recommend to the owners that the animal be euthanized on the operating table because it has a splenic mass and nodules in the liver, only to find out that the hepatic nodules represent nodular hyperplasia or EMH and the primary mass was benign (e.g., HA or hematoma).

Splenectomy is indicated in the event of splenic torsion, splenic rupture, symptomatic splenomegaly, or splenic masses. The value of splenectomy is questionable in dogs with immune-mediated blood disorders, dogs and cats with splenomegaly caused by lymphoma in which chemotherapy has not induced splenic remission, and dogs and cats with leukemias. Splenectomy is contraindicated in patients with bone marrow hypoplasia in which the spleen is the main site of hematopoiesis.

Although rare, a syndrome of postsplenectomy sepsis has been documented in approximately 3% of dogs that undergo this surgical procedure in our clinic. The syndrome is similar to its human counterpart. Most dogs with postsplenectomy sepsis evaluated at our clinic were undergoing immunosuppressive therapy at the time of surgery or had undergone splenectomy for a neoplasm. This sepsis is usually rapid in onset (hours to days), so prophylactic bactericidal antibiotic therapy is recommended postoperatively. We routinely use cephalothin (20 mg/kg intravenously [IV] q8h) with or without enrofloxacin (5-10 mg/kg IV q24h) for 2 to 3 days

postoperatively. All dogs with clinically recognized postsplenectomy sepsis at our clinic have died within 12 hours of onset despite aggressive treatment.

The clinician occasionally encounters a patient in which the enlarged lymph node mechanically compresses or occludes a viscus, airway, or vessel. This may result in marked clinical abnormalities, such as intractable coughing, caused by tracheobronchial lymphadenopathy; colonic obstruction, caused by iliac lymphadenopathy; or anterior vena cava syndrome, caused by cranial vena cava and thoracic duct obstruction. Several treatment options are available for these situations. If the lymph node is surgically resectable, excision or drainage should be attempted. If the node is not surgically resectable or if surgery or anesthesia poses a high risk for the animal, one or more of the following can be used:

- Irradiation can shrink the lymph node and ameliorate the signs in animals with primary or metastatic neoplastic lesions. This can be accomplished by using intraoperative irradiation or external-beam fractionated therapy.
- Antiinflammatory doses of corticosteroids can be used (0.5 mg/kg PO q24h) in animals with fungal lesions such as *Histoplasma*-induced tracheobronchial lymphadenopathy.
- 3. Intralesional injections of corticosteroids (prednisolone, 50 to 60 mg/m²) can be successful in dogs and cats with solitary lymphomas or metastatic mast cell tumors if irradiation is not feasible.
- 4. Systemic antibiotic therapy may be beneficial in animals with solitary suppurative lymphadenitis.

The plasma protein fraction is composed mainly of albumin, globulins, and fibrinogen; fibrinogen is absent in serum as a result of clotting and conversion into fibrin. In some breeds, such as the Greyhound, serum protein concentrations are below the reference ranges for most laboratories (Fayos et al., 2005). *Hyperproteinemia* is the term given to an absolute or relative increase in the serum or plasma protein concentration. Before further evaluating a cat or dog with hyperproteinemia, the clinician should make sure that the condition is not attributable to a laboratory artifact (e.g., interference of other substances in protein determination), which constitutes one of the most common causes of "hyperproteinemia." Lipemia and, to a lesser degree, hemolysis typically result in artifactual increases in the plasma or serum protein concentration.

Once true hyperproteinemia has been established, the clinician should determine whether it is relative or absolute. Relative hyperproteinemia is usually accompanied by erythrocytosis and caused by hemoconcentration (i.e., dehydration). However, in an anemic cat or dog, relative hyperproteinemia may be present in association with a normal packed cell volume (i.e., the volume is low but hemoconcentration results in an artifactual increase). The relative proportions (ratio) of albumin and globulin provide considerable information regarding the pathogenesis of hyperproteinemia. This information is usually contained in reports of serum biochemistry profiles from most referral diagnostic laboratories and in-house analyzers. Occasionally only the total serum protein and serum albumin concentrations are reported. In this event, the total globulin concentration can be determined by simply subtracting the albumin concentration from the total protein concentration.

In dogs and cats with *relative hyperproteinemia* (i.e., hemoconcentration), both the albumin and globulin concentrations are increased above the reference values, whereas in those with *absolute hyperproteinemia* only the globulin concentration is increased, usually in association with a mild or marked decrease in the albumin concentration. Hyperalbuminemia does not occur because the liver is already at its maximal synthetic capacity. The finding of "hyperalbuminemia" and hyperglobulinemia indicates either the presence

of dehydration or a laboratory error. Rehydration results in resolution of relative hyperproteinemia.

When exposed to an electrical field (i.e., protein electrophoresis), the protein molecules migrate according to their shape, charge, and molecular weight. Staining of the electrophoresis gel after migration usually reveals six distinct protein bands: albumin (closer to the anode or negative electrode),  $\alpha_1$ -globulin,  $\alpha_2$ -globulin,  $\beta_1$ -globulin,  $\beta_2$ -globulin, and globulin (closer to the cathode or positive electrode) (Fig. 89-1, A). The albumin fraction is responsible for conferring oncotic properties on body fluids. Acute phase reactants (APRs), also referred to as acute phase proteins, migrate in the  $\alpha_2$  and  $\alpha_1$  regions, whereas immunoglobulins (Igs) and complement usually migrate in the and regions. Igs migrate in the following order (from anode to cathode and beginning in the  $\alpha_2$  region): IgA, IgM, and IgG. By evaluating a protein electrophoretogram, the clinician can gain insight into the pathogenesis of the hyperglobulinemia.

Increased production of globulins occurs in a variety of clinical situations, but mainly in two groups of disorders: inflammatory-infectious and neoplastic. In inflammation and infection the hepatocytes elaborate a variety of globulins, collectively termed APRs, which result in increases in the  $\alpha_2$ - and  $\alpha_1$ -globulin fractions. Because the hepatocytes are "reprogrammed" to produce APRs, the albumin production is "switched off," resulting in hypoalbuminemia. In conjunction with these changes, the immune system produces a variety of immune proteins (mainly Igs), which result in increases in the  $\alpha_2$ ,  $\beta$ , or  $\gamma$  regions or a combination of these.

Because the immune system reacts against an organism (e.g., a bacterium) by producing antibodies against each somatic antigen, several clones of lymphocytes—plasma cells are "instructed" to simultaneously produce specific antibody molecules (i.e., each clone is programmed to produce one specific antibody type against a specific antigen). As a consequence, immune stimulation leads to the appearance of a polyclonal band in the or regions or both. This polyclonal band is broad based and irregular and contains most of the Igs and complement generated by the immune cells. A typical inflammatory-infectious electrophoretogram therefore

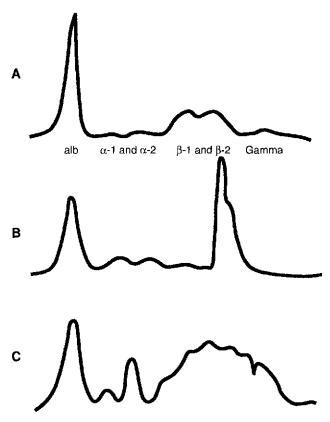

FIG 89-1

**A**, A normal canine or feline serum protein electrophoretogram. **B**, Electrophoretogram from a dog with multiple myeloma and a monoclonal gammopathy in the  $\beta_2\gamma$  region. Note the narrow spike approximately the same width as the albumin band. **C**, Electrophoretogram from a cat with feline infectious peritonitis and a typical polyclonal gammopathy. consists of a normal to mildly decreased albumin concentration and hyperglobulinemia resulting from increased  $\alpha_2$ -(i.e., APR) and  $\beta\gamma$ -globulins (polyclonal gammopathy) (Fig. 89-1, C).

Typical inflammatory-infectious electrophoretograms are seen in several common disorders, including chronic pyoderma, pyometra, and other chronic suppurative processes; feline infectious peritonitis; feline and canine hemobartonellosis and other hemoparasite infections; canine ehrlichiosis, anaplasmosis, and leishmaniasis; chronic autoimmune disorders (e.g., systemic lupus erythematosus, immune polyarthritis); and some neoplastic diseases, although they are rare (Box 89-1). Polyclonal gammopathies are also common in otherwise healthy old cats.

Monoclonal gammopathies occur when one clone of immune cells produces the same type and subtype of Ig molecule. Because these molecules are identical, they migrate in a narrow band (monoclonal spike, or M-component) located typically in the  $\beta$  or  $\gamma$  regions (Fig. 89-1, B). Monoclonal gammopathies occur in dogs with chronic multiple myeloma, lymphocytic leukemia, and lymphoma. They are

also present in dogs with ehrlichiosis and occasionally in dogs with leishmaniasis and other chronic inflammatory disorders (Box 89-2). In most cats monoclonal gammopathies occur in association with multiple myeloma or lymphoma, but they can occur in cats with feline infectious peritonitis. Occasionally an M-component is detected in an otherwise asymptomatic cat or dog but additional evaluation fails to reveal a source for the monoclonal gammopathy. Although this likely represents the counterpart of human idiopathic monoclonal gammopathy, the patient should be reevaluated frequently for a clinically emerging malignancy. In cats the source of the M-component is usually the spleen, where a neoplastic population of well-differentiated plasma cells is frequently identified in asymptomatic cats with a monoclonal gammopathy.

The treatment of dogs and cats with monoclonal or polyclonal gammopathies is aimed at the primary disease. Refer to specific sections throughout this text for discussion of these treatments.

#### CHAPTER

# Fever of Undetermined Origin

#### CHAPTER OUTLINE

FEVER OF UNDETERMINED ORIGIN

Disorders Associated with Fever of Undetermined Origin

Diagnostic Approach to the Patient with Fever of Undetermined Origin

#### **FEVER**

The term *fever* refers to a syndrome of malaise or nonspecific systemic clinical signs and pyrexia or hyperthermia. In this chapter, however, the terms *fever* and *pyrexia* are used interchangeably. Fever constitutes a protective physiologic response to both infectious and noninfectious causes of inflammation that enhances the host's ability to eliminate a noxious agent.

A variety of stimuli—including bacteria, endotoxins, viruses, immune complexes, activated complement, and necrotic tissue—trigger the release of endogenous pyrogens by the phagocytic system, mainly the mononuclear cells, or macrophages. These endogenous pyrogens include interleukin-1, tumor necrosis factor, and interleukin-6, among others. They activate the preoptic nucleus of the hypothalamus, raising the set point of the thermostat by generating heat through muscle contraction and shivering and conserving heat through vasoconstriction.

In human beings several patterns of fever have been associated with specific disorders; however, this does not appear to be the case in dogs and cats. In people with *continuous fever*, the pyrexia is maintained for several days or weeks. This type of fever is associated with bacterial endocarditis, central nervous system lesions, tuberculosis, and some malignancies. In people with *intermittent fever*, the body temperature decreases to normal but rises again for periods of 1 to 2 days; this is seen in brucellosis and some malignancies. In *remittent fever* the temperature varies markedly each

day but is always above normal (39.2° C); this type of fever is associated with bacterial infections. The term *relapsing* fever is used to refer to febrile periods that alternate with variable periods of normal body temperature, as seen in human beings with malaria.

#### FEVER OF UNDETERMINED ORIGIN

The term fever of undetermined (or unknown) origin (FUO) is used liberally in veterinary medicine to refer to a febrile syndrome for which a diagnosis is not evident. In human medicine, FUO refers to a febrile syndrome of more than 3 weeks' duration that remains undiagnosed after 1 week of thorough in-hospital evaluation. If the term FUO were to be used in the same way in animals as is recommended in human beings, few dogs and cats would actually have it. Therefore in this chapter the discussion focuses on the approach to a dog or cat with fever that does not respond to antibacterial antibiotic treatment and for which a diagnosis is not obvious after a minimal workup has been performed (e.g., complete blood count [CBC], serum biochemistry profile, urinalysis).

As a general rule, the clinician typically presumes that a dog or cat with fever has an infection until proved otherwise. This appears to be true in reality, as shown by the fact that a large proportion of dogs and cats with fever respond to nonspecific antibacterial treatment. No clinicopathologic evaluation is performed in most of these animals because the fever responds promptly to treatment.

## DISORDERS ASSOCIATED WITH FEVER OF UNDETERMINED ORIGIN

In human beings, certain infectious, neoplastic, and immunemediated disorders are commonly associated with FUO. Approximately one third of patients have infectious diseases; one third have cancer (mainly hematologic malignancies, such as lymphoma and leukemia); and the remaining third have immune-mediated, granulomatous, or miscellaneous disorders. In 10% to 15% of the patients with FUO, the underlying disorder remains undiagnosed despite intensive

FUO, Fever of undetermined origin; D, dog; C, cat.

efforts. However, most of the review articles describing dogs and cats with FUO that have appeared in the literature extrapolate data from human papers.

On the basis of observations made in dogs and cats evaluated at our clinic and case reports in the literature, the most common cause of FUO appears to be infectious diseases, followed by immune-mediated, neoplastic disorders and miscellaneous (Table 90-1). However, despite aggressive evaluation, the cause of the fever cannot be determined in approximately 10% to 15% of small animals.

# DIAGNOSTIC APPROACH TO THE PATIENT WITH FEVER OF UNDETERMINED ORIGIN

A dog or cat with FUO should be evaluated in a systematic fashion. In general, a three-stage approach is used at our clinic (Box 90-1). The first stage consists of a thorough history-taking and physical examination as well as a minimal database. The second stage consists of additional noninvasive and invasive diagnostic tests. The third stage consists of a therapeutic trial, which is instituted if no diagnosis can be obtained after completion of the second stage.

# History and Physical Examination

When a febrile patient does not respond to antibacterial treatment, a course of action must be formulated. A thorough history should be obtained and a complete physical examination performed. The history rarely provides clues to the cause of the fever. However, a history of ticks may indicate a rickettsial or hemoparasitic disorder, previous administration of tetracycline (mainly to cats) may indicate a drug-induced fever, and travel to areas where systemic mycoses are endemic should prompt further investigation consisting of cytologic or serologic studies or fungal cultures.

During a physical examination the lymphoreticular organs should be evaluated because numerous infectious diseases affecting these organs (e.g., ehrlichiosis, Rocky Mountain spotted fever, bartonellosis, leukemia, systemic mycoses) may cause fever. An enlarged lymph node or spleen should be evaluated cytologically by using specimens

BOX 90-1

Diagnostic Evaluation of the Dog or Cat with FUO

#### First Stage

CBC

Serum biochemistry profile and thyroxine concentration Urinalysis

Urine bacterial culture and susceptibility

FNA of enlarged organs, masses, or swellings

#### Second Stage

Thoracic and abdominal imaging Echocardiography

Serial bacterial blood cultures

Immune tests (antinuclear antibody, rheumatoid factor)

Serum protein electrophoresis

Serologic tests or PCR (see Table 90-1)

Arthrocentesis (cytologic studies and culture)

Biopsy of any lesion or enlarged argan

Bone marrow aspiration (for cytologic studies and bacterial/fungal culture)

Cerebrospinal fluid analysis

Leukocyte or ciprofloxacin scanning

Exploratory celiotomy

#### Third Stage

Therapeutic trial (antipyretics, antibiotics, corticosteroids)

FUO, Fever of undetermined origin; CBC, complete blood count; FNA, fine-needle aspiration; PCR, polymerase chain reaction.

obtained by fine-needle aspiration (FNA). An FNA sample can also be obtained for bacterial and fungal culture and susceptibility testing if the cytologic studies reveal evidence of infection or inflammation. Any palpable mass or swelling should also be evaluated by using specimens obtained by FNA to rule out granulomatous, pyogranulomatous, and suppurative inflammation as well as neoplasia (see Chapter 75).

The clinician should thoroughly inspect and palpate the oropharynx, searching for signs of pharyngitis, stomatitis, or tooth root abscesses. The bones should also be thoroughly palpated, particularly in young dogs, because metabolic bone disorders such as hypertrophic osteodystrophy can cause fever associated with bone pain. Palpation and passive motion of all joints is also indicated in search of monoarthritis, oligoarthritis, or polyarthritis. A neurologic examination should be conducted to detect signs of meningitis or other central nervous system lesions. In older cats the ventral cervical region should be palpated to detect thyroid enlargement or nodules.

The thorax should be auscultated carefully in search of a murmur, which could indicate bacterial endocarditis. A thorough ocular examination may reveal changes suggestive of a specific cause (e.g., chorioretinitis in cats with feline infectious peritonitis or in dogs with monocytic ehrlichiosis).

# Clinicopathologic Evaluation

A minimum database consisting of a CBC, serum biochemistry profile, urinalysis, and urine bacterial culture and susceptibility testing should always be carried out in dogs and cats with persistent fever. The CBC may provide important clues regarding the cause of the fever (Table 90-2). A serum biochemistry profile rarely yields diagnostic information in dogs and cats with FUO, although it can provide indirect information on parenchymal organ function. However, the finding of hyperglobulinemia and hypoalbuminemia may indicate an infectious, immune-mediated, or neoplastic disorder (see Chapter 89). The finding of pyuria or white blood

TABLE 90-2

Hematologic Changes in Dogs and Cats with FUO

HEMATOLOGIC CHANGE	COMPATIBLE WITH
Regenerative anemia	Immune-mediated diseases, hemoparasites, drugs
Nonregenerative anemia	Infection, immune-mediated diseases, tissue necrosis, malignancy, endocarditis
Neutrophilia with left shift	Infection, immune-mediated diseases, tissue necrosis, malignancy, endocarditis
Neutropenia	Leukemia, immune-mediated diseases, pyogenic infection, bone marrow infiltrative disease drugs
Monocytosis	Infection, immune-mediated diseases, tissue necrosis, lymphoma, endocarditis, histiocytosis
Lymphocytosis	Ehrlichiosis, anaplasmosis, Chagas' disease, leishmaniasis, chronic lymphocytic leukemia
Éosinophilia	Hypereosinophilic syndrome, eosinophilic inflammation, lymphoma
Thrombocytopenia	Rickettsiae, leukemia, lymphoma, drugs, immune-mediated diseases
Thrombocytosis	Infections (chronic), immune-mediated diseases

cell casts in a urinalysis may indicate a urinary tract infection, which may be the cause of the FUO (i.e., pyelonephritis). Proteinuria associated with an inactive urine sediment should prompt the clinician to evaluate a urine protein/creatinine ratio to rule out glomerulonephritis or amyloidosis as the cause of the fever.

Other diagnostic tests that may be called for in patients with FUO are listed in Box 90-1. Echocardiography is indicated only if the patient has a heart murmur because it rarely detects a valvular lesion in dogs without murmurs. Some of the infectious diseases listed in Table 90-1 can be diagnosed on the basis of serologic findings or polymerase chain reaction testing.

Fluid from several joints should be aspirated for cytologic evaluation and possibly bacterial culture because polyarthritis may be the only manifestation of a widespread immunemediated disorder. Thoracic radiography and abdominal ultrasonography should be performed to search for a silent septic focus. In dogs and cats with neurologic signs associated with fever, a cerebrospinal fluid tap should be performed; in dogs, immune-mediated vasculitis or meningitis can cause marked temperature elevations. If a diagnosis has still not been reached, bone marrow aspirates for cytologic studies and bacterial and fungal culture should also be obtained. A leukocyte or ciprofloxacin scan may reveal a hidden septic focus. Finally, if a definitive diagnosis is ultimately not obtained, a therapeutic trial of specific antibacterial or antifungal agents or immunosuppressive doses of corticosteroids can be initiated.

# Treatment

If a definitive diagnosis is obtained, a specific treatment should be initiated.

The problem arises if the clinician cannot arrive at a definitive diagnosis. In these patients, changes in the CBC usually are the only clinicopathologic abnormality (see Table 90-2). That is, results of bacterial and fungal cultures, serologic tests, PCR, imaging studies, and FNAs are negative or normal. If the patient has already been treated with a broad-spectrum bactericidal antibiotic, a therapeutic trial of immunosuppressive doses of corticosteroids is warranted. However, before instituting immunosuppressive treatment, the owners should be informed of the potential consequences of this approach: primarily that a dog or cat with an undiagnosed

infectious disease may die as a result of systemic dissemination of the organism after the start of treatment. Dogs and cats undergoing a therapeutic trial of corticosteroids should be kept in the hospital and monitored frequently for worsening of clinical signs, in which case steroid therapy should be discontinued. In patients with immune-mediated (or steroid-responsive) FUO, the pyrexia and clinical signs usually resolve within 24 to 48 hours of the start of treatment.

If no response to corticosteroids is observed, two courses of action remain. In one, the patient can be released and given antipyretic drugs, such as aspirin (10 to 25 mg/kg PO q12h in dogs and 10 mg/kg PO q72h in cats) or other nonsteroidal antiinflammatories, and then returned to the clinic for a complete reevaluation in 1 to 2 weeks. Antipyretics should be used with caution, however, because fever is a protective mechanism and lowering the body temperature may be detrimental in an animal with an infectious disease. Moreover, drugs such as dipyrone and flunixin can result in marked hypothermia, which may have adverse effects. Also of note is that some nonsteroidal antiinflammatory drugs have ulcerogenic effects, can cause cytopenias, and may result in tubular nephropathy if the patient becomes dehydrated or receives other nephrotoxic drugs. The second course of action is to continue the trial of antibiotics by using a combination of bactericidal drugs (e.g., ampicillin and enrofloxacin) for a minimum of 5 to 7 days.

Recurrent or persistent infections usually result from congenital or acquired abnormalities of the immune system. Although veterinary clinical immunology is not yet a well-developed specialty, great progress has been made over the past decade in elucidating the underlying immunologic abnormalities in dogs with recurrent infections. Most often these principles also apply to cats; however, with the exception of retrovirus-induced immunodeficiency syndromes and Chediak-Higashi syndrome, little is known about recurrent infections in this species.

## **Classification and Clinical Features**

Congenital immunodeficiency syndromes can affect the humoral, cellular, or phagocytic systems, either singly or in combination, and appear to be more common in dogs than in cats (Table 91-1). The molecular defects leading to these syndromes have been extensively investigated, and genetic testing for some of these syndromes is available. Humoral immunodeficiency syndromes usually result in recurrent upper and lower respiratory tract infections, dermatitis, and enteritis. Some Beagles with a selective immunoglobulin A (IgA) deficiency also have grand mal seizures of unknown pathogenesis and may be more susceptible to immunemediated diseases. Cellular immunodeficiency syndromes are apparently less common; a T-cell abnormality has been documented in Weimaraners with pituitary dwarfism and in Bull Terriers with lethal acrodermatitis (see Table 91-1). The disease in Weimaraner pups is characterized by retarded growth and recurrent respiratory and gastrointestinal tract infections. Necropsy findings in affected dogs include hypoplastic thymuses with no thymic cortex. Related Bull Terriers with growth retardation, progressive acrodermatitis, chronic pyoderma and paronychia, pneumonia, and diarrhea have significantly decreased lymphocyte blastogenesis in response to phytohemagglutinin stimulation. Other diseases that involve inconsistent cell- mediated immunologic abnormalities include Pneumocystis carinii infection in Dachshunds and systemic aspergillosis, generalized demodicosis, and protothecosis in other breeds. Bassett Hounds and Miniature Schnauzers have increased susceptibility to mycobacteriosis. Birman cats with congenital hypotrichosis and thymic atrophy resemble nude mice in that they are born hairless and have severe cell-mediated immune deficiency.

Abnormalities in the phagocytic system have been well documented in dogs and cats (see Table 91-1). They may occur as a consequence of decreased numbers of circulating phagocytes (e.g., in Grey Collies with cyclic hematopoiesis) or as a consequence of abnormal phagocytic function (e.g., defective neutrophil adhesion in Irish Setters with leukocyte adhesion deficiency, defective bactericidal capacity in Doberman Pinschers with recurrent respiratory tract infections). Occasionally the affected neutrophils are morphologically abnormal (e.g., Chediak-Higashi syndrome in Persian cats). Setters with a deficiency of surface adhesion proteins have recurrent episodes of omphalophlebitis, gingivitis, lymphadenitis, pyoderma, respiratory tract infections, pyometra, and fulminant sepsis. Affected Dobermans exhibit recurrent episodes of rhinitis and pneumonia that respond transiently to antibiotic therapy.

Immunodeficiency syndromes affecting more than one arm of the immune system (X-linked severe combined immunodeficiency syndrome) have been documented in Basset Hounds and Cardigan Welsh Corgis; they are associated with severe growth retardation and early death. Low serum IgG and IgA concentrations and abnormal lymphocyte blastogenesis in response to phytohemagglutinin are common in affected dogs; the defect is caused by a mutation in the gene that encodes for the interleukin-2 receptor.

Acquired immunodeficiency syndromes include canine distemper virus, parvovirus, and ehrlichial and Bartonella infections as well as generalized demodicosis in dogs and feline leukemia virus and feline immunodeficiency virus infections in cats. In addition, anticancer chemotherapy may cause variable degrees of immunosuppression.

#### **Diagnosis**

The type of infectious agent and the pattern of infection are usually determined by the nature of the defect. For example, defects in humoral immunity usually result in infections with pyogenic organisms affecting one or more sites. Defects in T-cell function result in viral, fungal, or protozoal infections that are usually widespread, and abnormalities

in the phagocytic system may result in skin, respiratory tract, meningeal, or systemic infections with pyogenic or enteric organisms. Therefore the type and pattern of the infection dictate which tests should be performed in these animals.

Several diagnostic tests can be used to evaluate dogs and cats with a suspected immunodeficiency syndrome. Some of these tests (i.e., neutrophil function tests, lymphocyte blastogenesis) require fresh blood samples (i.e., must be performed within 4 hours of sampling) and specialized laboratory equipment. They are therefore of limited use to general practitioners because such equipment is only available at teaching or research institutions. However, other tests can be performed on serum samples mailed to referral laboratories. Tests that can be used to evaluate animals with recurrent infections are listed in Table 91-2.

#### Management

The clinical management of these animals includes appropriate antimicrobial drugs determined on the basis of the etiologic agent identified (i.e., bacterial or fungal culture and sensitivity testing). If an infectious agent cannot be isolated and the animal appears to have a bacterial infection, bactericidal antibiotics that attain high intraleukocyte concentrations (e.g., sulfa-trimethoprim, enrofloxacin) should be used. Dogs and cats with suspected or known immunodeficiencies should be current on their vaccinations. If a severe immunodeficiency is present, the use of modified-live vaccines should be avoided because they may induce disease. Bone marrow transplantation and gene therapy with retroviral vectors have been used successfully in experimental dogs.

Nonspecific immunomodulators may be of benefit in dogs and cats with immunodeficiency. We have used levamisole (3 mg/kg PO two or three times per week) successfully in a limited number of dogs with recurrent infections;

however, because of the potential for toxicity in cats, this drug should be used with caution in this species.

Culture Techniques
Immunologic Techniques
Polymerase Chain Reaction
Animal Inoculation
Electron Microscopy
ANTIBODY DETECTION

Serum Body Fluids

Clinical syndromes induced by infectious agents are common in small animal practice. The combination of signalment, history, and physical examination findings are used to develop a list of differential diagnoses ranking the most likely infectious agents involved. For example, young, unvaccinated cats with conjunctivitis generally are infected by herpesvirus type 1, Chlamydophila felis, or Mycoplasma felis; if a dendritic ulcer is present, herpesvirus type 1 is most likely. Results of a complete blood count, serum biochemical panel, urinalysis, radiographs, or ultrasonography can also suggest infectious diseases. For example, a dog with polyuria, polydipsia, neutrophilic leukocytosis, azotemia, pyuria, and an irregularly marginated kidney on radiographic examination likely has pyelonephritis. After making a tentative diagnosis, the clinician then must determine whether to "test or treat." Empiric treatment is often satisfactory in simple, first-time infections of dogs or cats without life-threatening disease (see Chapter 93). However, having a definitive diagnosis is usually preferred so that treatment, prevention, prognosis, and zoonotic issues can be addressed optimally.

Documenting that the infectious agent is still present is the best way to make a definitive diagnosis. However, with some infectious agents, organism demonstration techniques have low sensitivity, are expensive, are invasive, are not adequately validated, or require specialized equipment. Antibody detection is commonly used to aid in the diagnosis of specific infectious diseases in these situations. Antibody detection is generally inferior to organism demonstration for three reasons: (1) antibodies can persist long after an infectious disease has resolved, (2) positive antibody test results do not confirm clinical disease induced by the infectious agent, and (3) in peracute infections, results of serum antibody tests can be negative if the humoral immune responses have not had time to develop. This chapter discusses the common organism demonstration and antibody detection techniques used in small animal practice.

## **DEMONSTRATION OF THE ORGANISM**

#### FECAL EXAMINATION

Examination of feces can be used to help diagnose parasitic diseases of the gastrointestinal (Table 92-1; see Chapter 29) and respiratory tracts (Table 92-2; see Chapter 20). The techniques used most frequently include direct and saline smear, stained smear, fecal flotation, and Baermann technique; each procedure can easily be performed in a small animal practice.

#### **Direct Smear**

Fresh, liquid feces or feces that contain large quantities of mucus should be microscopically examined immediately for the presence of protozoal trophozoites, including those of *Giardia* spp. (small-bowel diarrhea), *Tritrichomonas foetus* (large-bowel diarrhea), and *Pentatrichomonas hominis* (large-bowel diarrhea). A direct saline smear can be made to potentiate observation of these motile organisms.

<sup>\*</sup>D, Dog; C, cat; B, dog and cat.

A 2 mm  $\times$  2 mm  $\times$  2 mm quantity of fresh feces is mixed thoroughly with 1 drop of 0.9% NaCl or water. The surface of the feces or mucus coating the feces should be used because the trophozoites are most common in these areas. After application of a coverslip, the smear is evaluated for motile organisms by examining it under × 100 magnification.

#### Stained Smear

A thin smear of feces should be made from all dogs and cats with diarrhea. Material should be collected by rectal swab, if possible, to increase the chances of finding white blood cells. A cotton swab is gently introduced 3 to 4 cm through the anus into the terminal rectum, directed to the wall of the rectum, and gently rotated several times. Placing 1 drop of 0.9% NaCl on the cotton swab will facilitate passage through the anus and not adversely affect cell morphology. The cotton swab is rolled on a microscope slide gently multiple times to give areas with varying smear thickness (Fig. 92-1). After air drying, the slide can be stained. White blood cells and bacteria morphologically consistent with Campylobacter spp. (spirochetes) or Clostridium perfringens (spore-forming

Diff-Quik-stained fecal smear showing appropriate smear thickness.

FIG 92-2 Wright's-stained, thin fecal smear. A neutrophil and sporeforming rods are present in the center of the field.

rods; Fig. 92-2) can be observed after staining with Diff-Quik (Medion GmbH, Dudingen, Switzerland) or Wright's or Giemsa stains (see Cytology section). Histoplasma capsulatum or Prototheca may be observed in the cytoplasm of mononuclear cells. Methylene blue in acetate buffer (pH 3.6) stains trophozoites of the enteric protozoans. Iodine and acid methyl green stains are also used for the demonstration of protozoans. Modified acid-fast staining of a thin fecal smear can be performed in dogs and cats with diarrhea to aid in the diagnosis of cryptosporidiosis. Cryptosporidium spp. are the only enteric organisms of approximately 4 to 6 um in diameter that will stain pink to red with acid-fast stain (Fig. 92-3). Presence of neutrophils on rectal cytology can suggest inflammation induced by Salmonella spp., Campylobacter spp., or Clostridium perfringens; fecal culture is indicated in these cases, particularly if the history supports these differentials.

# **Fecal Flotation**

Cysts, oocysts, and eggs in feces can be concentrated to increase the sensitivity of detection. A variety of techniques are available for use in veterinary clinics. Centrifugation techniques are more sensitive than passive flotation techniques. Most eggs, oocysts, and cysts are easily identified after centrifugation in zinc sulfate solution (Box 92-1) or Sheather's sugar solution. These procedures are particularly superior to passive flotation techniques for the demonstration of protozoan cysts (particularly Giardia spp.; Fig. 92-4). Fecal sedimentation recovers most cysts and ova but also contains debris.

# **Baermann Technique**

This technique is used to concentrate motile larvae from feces. Some respiratory parasites are passed as larvated eggs but release larvae shortly after being passed in feces. Eggs or larvae from respiratory parasites can also be detected by cytologic evaluation of airway washings (Fig. 92-5).

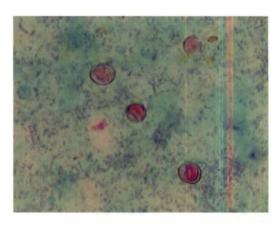

FIG 92-3 Cryptosporidium parvum oocysts stained with a modified acid-fast stain. The oocysts are approximately  $4 \times 6 \mu m$ .

BOX 92-1

# Zinc Sulfate Centrifugation Procedure

- Place 1 g fecal material in a 15-mL conical centrifuge tube.
- 2. Add 8 drops of Lugol iodine and mix well.
- Add 7 to 8 mL of zinc sulfate (1.18 specific gravity)\* and mix well.
- 4. Add zinc sulfate until there is a slight positive meniscus.
- 5. Cover the top of the tube with a coverslip.
- 6. Centrifuge at 1500-2000 rpm for 5 minutes.
- 7. Remove the coverslip and place on a clean microscope slide for microscopic examination.
- 8. Examine the entire area under the coverslip for the presence of ova, oocysts, or larvae at  $\times$  100.
- \* Add 330 g zinc sulfate to 670 mL distilled water.

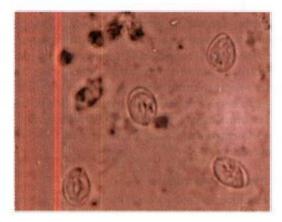

FIG 92-4 Giardia cysts after zinc sulfate flotation. The cysts are approximately  $10\times 8~\mu m$ .

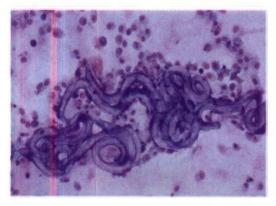

FIG 92-5
Aelurostrongylus abstrusus larvae in an airway washing collected by bronchoalveolar lavage. (Courtesy Dr. Timothy Hackett, Colorado State University, Fort Collins.)

#### **Preservation of Feces**

Feces should be refrigerated, not frozen, until assayed. If present, refrigerated *Toxoplasma gondii* oocysts will not likely sporulate and become infectious. In addition, refrigerated feces have less overgrowth of yeast, leading to fewer false-positive results. If a fecal sample is to be sent to a diagnostic laboratory for further analysis and will not be evaluated within 48 hours, it should be preserved. Polyvinyl alcohol, merthiolate-iodine-formalin, and 10% formalin preservation can be used. Ten percent formalin is commonly used because of its routine availability; the clinician should add 1 part feces to 9 parts formalin and mix well.

#### CYTOLOGY

Cytologic evaluation of exudates, bone marrow aspiration, blood smears, synovial fluid, gastric brushings, duodenal secretions, urine, prostatic washings, airway washings, fecal smears, tissue imprints, and aspiration biopsies is an inexpensive and extremely valuable tool for the documentation of infectious agents (Table 92-3). Cytologic demonstration of some infectious agents constitutes a definitive diagnosis. Morphologic appearance and Gram stain of bacteria aids in the selection of empiric antibiotics while waiting for results of culture and antimicrobial susceptibility testing (see Chapter 93).

For demonstration of most infectious agents, thin smears are preferred. Blood can be prepared as follows: 1 drop of blood approximately the size of a match head is placed at one end of a clean microscope slide. The short edge of another slide (i.e., spreader slide) is placed against the slide at a 30-degree angle and pulled back until the blood and the spreader slide make contact. After the blood spreads across the width of spreader slide, the slide is smoothly and quickly pushed away from the blood across the length of the slide ("push" smears). For materials other than blood, the spreader slide is laid gently on top of the material; the slides are then smoothly and rapidly pulled apart on parallel planes ("pull" smears). Cells in airway washings, prostatic washings, urine, aqueous humor, and cerebrospinal fluid (CSF) should be pelleted by centrifugation at 2000 g for 5 minutes before staining. For CSF the clinician should add 1 drop of 22% albumin or normal canine serum before centrifugation to help cells adhere to the slides. Multiple slides should always be made, if possible. After being placed on the microscope slide, the material is air dried at room temperature, fixed if indicated by the procedure used, and stained. Slides that are not stained immediately should be fixed by dipping in 100% methanol and air dried.

Cytologic specimens can be stained with routine stains; immunocytochemical techniques for certain pathogens are available (see Immunologic Techniques, p. 1287). Stains routinely used for the diagnosis of infectious diseases in small animal practice include Wright's-Giemsa stain, Diff-Quik, Gram stain, and acid-fast stain. Immunocytochemical techniques (e.g., fluorescent antibody staining of bone marrow cells for feline leukemia virus) are only performed in refer-

ence or research laboratories (see Immunologic Techniques, p. 1287). The laboratory should be contacted for specific specimen handling information.

## **Bacterial Diseases**

Neorickettsia risticii

If bacterial disease is suspected, materials are collected aseptically and handled initially for culture (see Culture Techniques, p. 1287). After slides are prepared for cytologic evaluation, one is generally stained initially with Wright's-Giemsa or Diff-Ouik stain. If bacteria are noted Gram stain of another slide is performed to differentiate gram-positive and gram-negative agents. This information can be used to aid in the empiric selection of antibiotics (see Chapter 93). If filamentous, gram-positive rods are noted, acid-fast staining can help differentiate Actinomyces (not acid fast) from Nocardia (generally acid fast). If macrophages or neutrophils are detected, acid-fast staining is indicated to assess for Mycobacterium spp. within the cytoplasm. Bacteria can be present in small numbers, so failure to document organisms cytologically does not totally exclude the diagnosis. Bacterial culture of all samples with increased numbers of neutrophils or macrophages should always be considered. Some organisms such as Mycoplasma are rarely documented cytologically, whereas other organisms require special stains for optimal visualization. For some bacteria culture has never been successful. For example, the hemoplasmas of dogs

and cats (previously called *Haemobartonella felis* and *H. canis*) can be detected on the surface of red blood cells (RBCs) but have never been successfully cultured. Until the advent of PCR (see p. 1288), documentation of infection was based on cytology; Wright's-Giemsa stain is the best stain to use in practice for these organisms. The duration of parasitemia is short lived, and the organism commonly leaves the surface of the RBC if the blood is placed into ethylenediamine tetraacetic acid (EDTA), making it difficult to document the presence of the organism. Making thin blood smears immediately with blood that has not been placed into anticoagulant, or collecting blood into a heparinized syringe may help determine canine or feline hemoplasmas.

#### **Rickettsial Diseases**

Clusters of gram-negative bacteria (morulae) in mononuclear cells

Ehrlichia spp., Anaplasma spp., and Neorickettsia risticii (atypical ehrlichiosis) are occasionally found within the cytoplasm of cells in the peripheral blood, lymph node aspirates, bone marrow aspirates, or synovial fluid (see Chapter 96). Morulae of these genera can be found in different cell types (see Table 92-3). Wright's-Giemsa stain is superior to Wright's or Diff-Quik stain for the demonstration of morulae. Rickettsia rickettsii in endothelial cells lining vessels can be documented by immunofluorescent antibody staining (see Immunologic Techniques, p. 1287).

<sup>\*</sup> Previously known as Haemobartonella felis and H. canis. RBCs, Red blood cells.

# **Fungal Diseases**

Arthrospores and conidia of dermatophytes can be identified cytologically. Hairs plucked from the periphery of a lesion are covered with 10% to 20% potassium hydroxide on a microscope slide to clear debris. The slide is then heated, but not boiled, and examined for dermatophytes. All cats with chronic, draining skin lesions should have imprints of the lesions made and stained with Wright's-Giemsa stain followed by microscopic examination for the characteristic round, oval, or cigar-shaped yeast phase of *Sporothrix schenckii* within the cytoplasm of mononuclear cells (see Chapter 98). Periodic acid—Schiff stain is superior to Wright's-Giemsa stain for the demonstration of fungi. The cytologic appearance of the systemic fungi is presented in Table 98-1.

#### **Cutaneous Parasitic Diseases**

Cheyletiella spp., Demodex spp., Sarcoptes scabiei, Notoedres cati, and Otodectes cynotis are the most common small animal cutaneous parasites. Definitive diagnosis is based on cytologic demonstration of the organisms. Cheyletiella is demonstrated by pressing a piece of transparent tape against areas with crusts, placing the tape on a microscope slide, and examining it microscopically. Demodex spp. are most commonly detected in deep skin scrapings and follicular exudates; Cheyletiella spp., Sarcoptes scabiei, and Notoedres cati are detected in wide, more superficial scrapings. Otodectes cynotis or its eggs are detected in ceruminous exudates from the ear canals.

# **Systemic Protozoal Diseases**

The most common systemic protozoal diseases and the cytologic appearance and location of these agents are summarized in Table 92-4. Cytologic demonstration of these agents leads to a presumptive or definitive diagnosis of the disease. Wright's-Giemsa or Giemsa staining of thin blood films

should be used to demonstrate Leishmania spp., Trypanosoma cruzi, Babesia spp., Hepatozoon americanum, and Cytauxzoon felis. Collection of blood from an ear margin vessel may increase the chances of demonstrating the protozoans found in blood, particularly Babesia spp. and Cytauxzoon felis. Toxoplasma gondii and Neospora caninum cause similar syndromes in dogs, but their tachyzoites are difficult to distinguish morphologically; immunocytochemical staining or PCR is required to differentiate these agents. These protozoans can also be distinguished by evaluating for seroconversion because antibodies are specific to each agent. With the exception of T. gondii and N. caninum, systemic protozoans are rare or regionally defined in the United States. See Chapter 99 for further discussion of these agents.

#### Viral Diseases

Rarely, viral inclusion bodies are detected cytologically after staining with Wright's-Giemsa. Distemper virus infection causes inclusions in circulating lymphocytes, neutrophils, and erythrocytes of some dogs. Rarely, feline infectious peritonitis virus results in intracytoplasmic inclusions in circulating neutrophils. Feline herpesvirus 1 (FHV-1) transiently results in intranuclear inclusion bodies in epithelial cells.

#### TISSUE TECHNIQUES

Tissues collected from animals with suspected infectious diseases can be evaluated by several different techniques. Tissue samples should be aseptically placed in appropriate transport media for culture procedures or inoculated into laboratory animals, if indicated, before further handling.

Gently blotting the cut edge of the tissue on a paper towel to remove excess blood and then lightly touching the tissue multiple times to a microscope slide make tissue impressions for cytologic examination. Tissue specimens can then be

**TABLE 92-4** 

Characteristic Cytologic Morphology of Small Animal Systemic Protozoal Agents

AGENT	MORPHOLOGIC CHARACTERISTICS
Babesia canis	Paired piroplasms (2.4 $\times$ 5.0 $\mu$ m) in circulating RBCs
Babesia gibsoni	Single piroplasms (1.0 $\times$ 3.2 $\mu$ m) in circulating RBCs
Cytauxzoon felis	Piroplasms (1.0 $\times$ 1.5 $\mu$ m "signet ring" form; 1.0 $\times$ 2.0 $\mu$ m oval form; 1.0 $\mu$ m round form) in circulating RBCs; macrophages or monocytes of lymph node aspirates, splenic aspirates, or bone marrow
Hepatozoon canis and H. americanum	Gamonts in circulating neutrophils and monocytes
Leishmania spp.	Ovoid to round amastigates (2.5-5.0 µm × 1.5-2.0 µm) in macrophages found on imprints of exudative skin lesions, lymph node aspirates, or bone marrow aspirates
Neospora caninum	Free or intracellular (macrophages or monocytes) tachyzoites (5-7 $\mu$ m $ imes$ 1-5 $\mu$ m) in CSF, airway washings, or imprints of cutaneous lesions
Toxoplasma gondii	Free or intracellular (macrophages or monocytes) tachyzoites (6 × 2 μm) in pleural effusions, peritoneal effusions, or airway washings
Trypanosoma cruzi	Flagellated trypomastigates (one flagellum; 15-20 μm long) free in whole blood, lymph node aspirates, and peritoneal fluid

frozen, placed into 10% buffered formalin solution, or placed into glutaraldehyde-containing solutions. Frozen specimens are generally superior for immunohistochemical staining and PCR. Routine histopathologic evaluation is performed on formalin-fixed tissues. Special stains can be used to maximize the identification of some infectious agents. The clinician should alert the histopathology laboratory to the infectious agents most suspected to allow for appropriate stain selection. Glutaraldehyde-containing fixatives are superior to other fixatives for electron microscopic examination of tissues; this technique can be more sensitive than other procedures for demonstration of viral particles.

#### **CULTURE TECHNIQUES**

Bacteria, fungi, viruses, and some protozoans can be cultured. In general, a positive culture can be used to establish a definitive diagnosis. Bacterial culture can be combined with antimicrobial susceptibility testing to determine optimal drug therapy. Successful culture depends on collecting the optimal materials without contamination, transporting the materials to the laboratory as quickly as possible in the most appropriate medium to minimize organism death or overgrowth of nonpathogens, and using the most appropriate culture materials.

Culture results of body systems with normal bacterial and fungal flora, including the skin, ears, mouth, nasal cavity, trachea, feces, and vagina, are the most difficult to interpret. Finding positive culture results and inflammatory cells cytologically suggests the organism is inducing disease. Culture of a single agent, particularly if the organism is relatively resistant to antimicrobials, is more consistent with a diseaseinducing infection than if multiple, antibiotic-susceptible bacteria are cultured. Materials for routine aerobic bacterial culture can be placed on sterile swabs if the swabs remain moist and are placed on appropriate culture media within 3 hours of collection. If a delay of greater than 3 hours is expected, swabs containing transport medium should be used. These swabs should be refrigerated or frozen to inhibit bacterial growth if cultures are not to be started within 4 hours; some bacteria will grow more rapidly than others, potentially masking fastidious organisms. Most aerobes will survive at 4° C (routine refrigeration temperature) in tissue or on media-containing swabs for 48 hours. Solid-phase transport media that will support the growth of most aerobes, anaerobes, Mycoplasma spp., and fungi for several days if refrigerated are also routinely available. Routine aerobic culture is generally successful on fluid samples (e.g., urine, airway washings) stored at 20° C for 1 to 2 hours, 4° C for 24 hours, or 4° C for 72 hours if placed in transport medium.

Anaerobes can be successfully cultured from fluid collected aseptically into a syringe and the needle covered with a rubber stopper if the material is to be placed on culture media within 10 minutes of collection. Because of time limitations, transport media is generally required for samples from animals with suspected anaerobic infections. These media will support the growth of most anaerobes for 48 hours if stored at 4° C.

Samples for blood culture should be collected aseptically from a large vein after surgical preparation of the skin. In general, three 5-mL samples are collected over a 24-hour period in stable patients or at 1- to 3-hour intervals in septic patients. Unclotted whole blood is placed directly into transport media that will support the growth of aerobic and anaerobic bacteria, and it is incubated at 20° C for 24 hours. Culture for *Bartonella* spp. from the blood of dogs or cats is generally performed on a 1.5-mL whole blood sample collected aseptically and placed in an EDTA-containing tube (see Chapter 95).

Culture of feces for Salmonella spp., Campylobacter spp., and Clostridium perfringens is occasionally indicated in small animal practice. Approximately 2 to 3 g of fresh feces should be submitted to the laboratory immediately for optimal results; however, Salmonella and Campylobacter are usually viable in refrigerated fecal specimens for 3 to 7 days. To increase the likelihood of achieving positive culture results, a transport medium should be used if a delay is expected. The laboratory should be notified of the suspected pathogen so that appropriate culture media can be used.

Mycoplasma and Ureaplasma cultures are most commonly performed on airway washings, synovial fluid, exudates from chronic draining tracts in cats, urine from animals with chronic urinary tract disease, and the vagina of animals with genital tract disease. Samples should be transported to the laboratory in Amies medium or modified Stuart bacterial transport medium. Mycoplasma spp. culture should be specifically requested.

Mycobacterium spp. grow very slowly, and culture is often limited by overgrowth of other bacteria. Special medium is required; therefore the laboratory should be specifically instructed to culture for Mycobacterium spp. Tissue samples or exudates from animals with suspected Mycobacterium spp. infection should be refrigerated immediately after collection and transported to the laboratory as soon as possible. Exudates should be placed in transport media.

Cutaneous fungal agents can be cultured in the small animal office by using routinely available culture media. Materials from dogs or cats with suspected systemic fungal infection can be transported to the laboratory as described for bacteria, and the laboratory can be told specifically that fungal culture is needed. The yeast phase of the systemic fungi occurs in vivo and is not zoonotic; the mycelial phase of *Blastomyces*, *Coccidioides*, and *Histoplasma* grows in culture and will infect human beings. Thus in-house culture for these agents is not recommended.

Viral agents can be isolated from tissues or secretions at some laboratories. Contact the laboratory before submitting samples. Samples should be collected aseptically as for bacteria, placed in transport media, and immediately refrigerated to inhibit bacterial growth. The samples should be transported to the laboratory on cold packs but not frozen.

#### IMMUNOLOGIC TECHNIQUES

Infectious agents or their antigens can be detected in body fluids, feces, cells, or tissues by using immunologic techniques. In general, polyclonal or monoclonal antibodies against the agent in question are used in a variety of different test methods, including direct fluorescent antibody assay with cells or tissue, agglutination assays, and enzyme-linked immunosorbent assay (ELISA). Sensitivities and specificities vary by test but are generally high for most assays. Positive results with these tests generally prove infection; this is in contrast to antibody detection procedures, which only document exposure to an infectious agent. Contact the laboratory for details concerning specimen transport before collection.

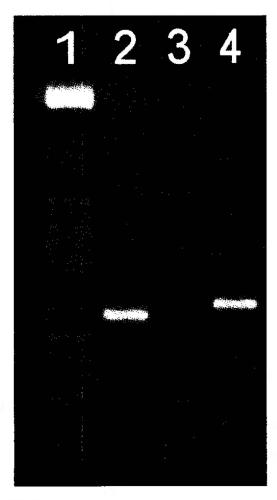

Commercially available assays are available for the detection of antigens of *Dirofilaria immitis*, *Cryptococcus neoformans*, *Blastomyces dermatitidis*, and FeLV in serum or plasma. The *Cryptococcus neoformans* latex agglutination procedure can also be performed on aqueous humor, vitreous humor, and CSF.

Parvovirus, *Cryptosporidium* spp., and *Giardia* spp. antigen detection procedures are available for use with feces. Parvovirus assays detect both canine and feline parvovirus antigen and may be affected transiently by administration of modified-live vaccines. Most *Giardia* antigen tests marketed for use with human feces and the test labeled for use with dog or cat feces detect the *Giardia* assemblages that infect dogs or cats. Samples are occasionally antigen positive but cyst negative on fecal flotation. In this situation whether the antigen test is falsely positive or the fecal flotation is falsely negative. None of the currently available *C. parvum* antigen tests marketed for use with human feces consistently detects *C. felis* or *C. canis* and should therefore not be used with feces from dogs and cats.

Immunocytochemistry and immunohistochemistry techniques are widely available for the documentation of a variety of infectious diseases. These procedures are particularly valuable for the detection of viral diseases, detection of agents present in small numbers, and for differentiation among agents with similar morphologic features. In general, these techniques are more sensitive and specific than histopathologic techniques and are comparable to culture. For example, focal feline infectious peritonitis granulomatous disease can be documented by immunohistochemical staining (see Chapter 97).

#### POLYMERASE CHAIN REACTION

PCR amplifies small quantities of DNA to detectable levels (Fig. 92-6). With a reverse transcriptase step, RNA is converted to DNA; therefore the technique can also be used to detect RNA (RT-PCR). In general PCR is much more sensitive than cytologic or histopathologic techniques and is comparable to culture and laboratory animal inoculation. PCR assays are of great benefit for documentation of infections, particularly if the organism in question is difficult to culture (e.g., Ehrlichia spp.) or cannot be cultured (e.g., hemoplasmas). Specificity can be quite high depending on the primers used in the reaction. For example, primers can be designed to detect one bacterial genus but not others. Primers can also be designed to identify only one species. For example, a PCR

Photograph of a PCR assay for hemoplasmas showing the two different band sizes that help differentiate species: Mycoplasma haemofelis (Lane 2) and Candidatus M. haemominutum (Lane 4). Lane 1 is a base pair ladder and Lane 3 is a negative sample. In this assay Candidatus M. turicensis is included in the M. haemofelis amplicon.

assay can be developed to detect all *Ehrlichia* spp. or just one species, such as *E. canis*.

Because of the inherent sensitivity of the reaction, PCR can give false-positive results if sample contamination occurs during collection or at the laboratory performing the procedure. False-negative results can occur if the sample is handled inappropriately; this is of particular importance for detection of RNA viruses by RT-PCR. Results may also be affected by treatment. Another potential problem is that no standardization exists among commercial laboratories offering PCR techniques; in addition, no external quality control exists (see Chapter 97).

Although PCR assays can be one of the most sensitive for documentation of infections, positive test results do not always prove that the infection is causing clinical illness. For example, because the technique detects DNA of both live and dead organisms, positive test results may be achieved even if the infection has been controlled. When the organism being

tested for commonly infects the background population of healthy pets, interpretation of results for a single animal can be difficult. For example, FHV-1 commonly infects cats and is commonly carried by healthy cats. Thus although PCR is the most sensitive way to document infection by FHV-1, the positive predictive value for disease of a FHV-1 PCR result is actually quite low. In one study more positive FHV-1 PCR results were detected in the healthy control group than in the group with conjunctivitis (Burgesser et al., 1999). In addition, the currently available PCR assays for FHV-1 also amplify modified-live vaccine strains, so a positive result does not even indicate presence of a pathogenic strain. Realtime PCR can be used to determine the amount of microbial DNA in a sample. The DNA load may correlate to the presence of disease for some agents. Because of these findings, small animal practitioners must carefully assess the predictive values of currently available PCR assays and the expertise and reliability of the laboratory that will be performing the assays. New PCR assays are being developed almost daily. See specific chapters for a discussion of the use of PCR for the detection of the agents.

## ANIMAL INOCULATION

Animal inoculation can be used to identify some infectious diseases. For example, oocysts of *Toxoplasma gondii* cannot be distinguished morphologically from those of *Hammondia hammondi* or *Besnoitia darlingi*; only *T. gondii* is infectious for human beings. *T. gondii* can be differentiated from the other coccidians by inoculation of sporulated oocysts into mice and monitoring for *T. gondii*—specific antibody production. However, because live animals are required, animal inoculation is rarely used in small animal practice.

#### **ELECTRON MICROSCOPY**

Flectron microscopy is a highly sensitive procedure for organism identification in body fluids and tissues. Glutaral-

dehyde-containing fixatives are used most commonly. One of the most clinically relevant uses of electron microscopy is for the detection of viral particles in feces of animals with gastrointestinal signs of diseases. Approximately 1 to 3 g of feces without fixative should be transported to the laboratory (e.g., Diagnostic Laboratory, Colorado State University, College of Veterinary Medicine and Biomedical Sciences, Fort Collins) by overnight mail on cold packs.

# ANTIBODY DETECTION

#### SERUM

A variety of different methods exists for detecting serum antibodies against infectious agents; complement fixation, hemagglutination inhibition, serum neutralization, agglutination assays, agar gel immunodiffusion, indirect fluorescent antibody assay (IFA), ELISA, and Western blot immunoassay are commonly used methods. Complement fixation, hemagglutination inhibition, serum neutralization, and agglutination assays generally detect all antibody classes in a serum sample. Western blot immunoassay, IFA, and ELISA can be adapted to detect specific immunoglobulin (Ig) M, IgG, or IgA responses.

Comparison of IgM, IgA, and IgG antibody responses against an infectious agent can be used to attempt to prove recent or active infection. In general, IgM is the first antibody produced after antigenic exposure (Fig. 92-7). Antibody class shift to IgG occurs in days to weeks. Serum and mucosal IgA immune responses have also been studied for some infectious agents, including *T. gondii*, feline coronaviruses, and *Helicobacter felis*.

Timing of antibody testing is important. In general, serum antibody tests in puppies and kittens cannot be interpreted as specific responses until at least 8 to 12 weeks of age because of the presence of antibodies from the dam passed to the

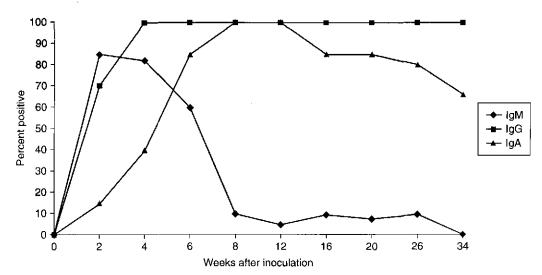

FIG 92-7
Serum Toxoplasma gondii lgM, lgG, and lgA immune responses after experimental inoculation in cats.

puppy or kitten in the colostrum. Most infectious agents can induce disease within 3 to 10 days after initial exposure; with many assays serum IgG antibodies are usually not detected until 1 to 2 weeks after initial exposure. On the basis of these facts, falsely negative serum antibody tests during acute disease can be common in small animal practice. If specific serum antibody testing is initially negative in an animal with acute disease, repeat antibody testing should be performed in 2 to 3 weeks to assess for seroconversion. Documentation of increasing antibody titers is consistent with recent or active infection. Assessment of both the acute and convalescent sera in the same assay on the same day is preferable to avoid interassay variation.

Sensitivity is the ability of an assay to detect a positive sample; specificity is the ability of an assay to detect a negative sample. Sensitivity and specificity vary with each assay. Positive predictive value is the ability of a test result to predict presence of disease; negative predictive value is the ability of a test result to predict absence of disease. Many of the infectious agents encountered in small animal practice infect a large percentage of the population, resulting in serum antibody production. However, they only induce disease in a small number of animals in the infected group. Examples include coronaviruses, canine distemper virus, T. gondii, Bartonella spp., and Borrelia burgdorferi. For these examples, even though assays with good sensitivity and specificity for the detection of serum antibodies are available, the predictive value of a positive test for presence of disease is extremely low. This is because antibodies are commonly detected in nondiseased animals. Diagnostic utility of some serologic tests is also limited because of the presence of antibodies induced by vaccination. Examples include feline coronaviruses, some B. burgdorferi assays, FHV-1, parvoviruses, FIV calicivirus, and canine distemper virus.

The clinician should interpret positive results in serum antibody tests only as evidence of present or prior infection by the agent in question. Recent or active infection is suggested by the presence of IgM, an increasing antibody titer over 2 to 3 weeks, or seroconversion (negative antibody result on the first test and positive antibody result on convalescent testing). However, detection of recent infection based on antibody testing does not always prove disease because of the agent in question. Conversely, failure to document recent or active infection based on serologic testing does not exclude a diagnosis of clinical disease. For example, many cats with toxoplasmosis develop clinical signs of disease after serum antibody titers have reached their plateau. The magnitude of antibody titer does not always correlate with active or clinical disease. For example, many cats with clinical toxoplasmosis have IgM and IgG titers that are at the low end of the titer scale; conversely, many healthy cats have IgG titers greater than 1:16,384 years after infection with T. gondii. The clinical diagnosis of an infectious disease usually includes the combination of the following:

- · Clinical signs referable to the agent
- · Serologic evidence of exposure to the agent

- · Exclusion of other causes of the clinical syndrome
- · Demonstration of the agent or response to treatment

#### **BODY FLUIDS**

Some infectious agents induce disease of the eyes or central nervous system (CNS). Documentation of agent-specific antibodies in aqueous humor, vitreous humor, or CSF can be used to support the diagnosis of infection of these tissues. Quantification of ocular and CSF antibodies is difficult to interpret if serum antibodies and inflammatory disease are present; serum antibodies leak into ocular fluids and CSF in the face of inflammation. Detection of local production of antibodies within the eye or CNS has been used to aid in the diagnosis of canine distemper virus infection, feline toxoplasmosis, and feline bartonellosis (see Chapters 95, 97, and 99). The following is a method to prove local antibody production by the eye or CNS:

Aqueous humor or CSF-specific antibody ×

Serum-specific antibody

Serum total antibody

Aqueous humor or CSF total antibody

A ratio greater than 1 suggests that the antibody in the aqueous humor or CSF was produced locally. This formula has been used extensively in the evaluation of cats with uveitis. Approximately 60% of cats with uveitis in the United States have *T. gondii*—specific IgM, IgA, or IgG values greater than 1 (see Chapter 99). The technique was also used to help prove that FHV-1 and *Bartonella henselae* are causes of uveitis in cats.

# CHAPTER OUTLINE

ANAEROBIC INFECTIONS
BACTEREMIA AND BACTERIAL ENDOCARDITIS
CENTRAL NERVOUS SYSTEM INFECTIONS
GASTROINTESTINAL TRACT AND HEPATIC
INFECTIONS
MUSCULOSKELETAL INFECTIONS
RESPIRATORY TRACT INFECTIONS
SKIN AND SOFT TISSUE INFECTIONS
UROGENITAL TRACT INFECTIONS

Antimicrobial drugs should only be administered if the index of suspicion for an infection exists. The prescribing veterinarian should also always be cognizant of the potential for development of antimicrobial resistance, particularly when prescribing drugs also used in human beings. Veterinarians should be familiar with judicious use of antimicrobial guidelines (http://www.aahanet.org/About\_aaha/AAFP\_AAHA\_AntimicrobialGuidelines.pdf).

In small animal practice, decisions to institute antimicrobial chemotherapy are almost always made without the benefit of results of culture and antimicrobial susceptibility testing. In simple, first-time infections, culture and antimicrobial susceptibility testing is often not performed. In life-threatening infections, decisions on the choice of antimicrobials must be made before obtaining the culture results; patient survival may depend on the selection of optimal treatment regimens. For some infectious agents such as *Ehrlichia* spp., *Borrelia burgdorferi*, *Rickettsia rickettsii*, and hemoplasmas, the organisms are not readily grown in culture and so empirical therapy is always used.

Recognition of the most common infectious agents (gram positive, gram negative, aerobic, or anaerobic) associated with infection of different organ systems or associated with different clinical syndromes is imperative in the empirical selection of antimicrobials. Cytologic findings and the results of a Gram stain can be used to identify microbes and

help choose appropriate antimicrobials. The antimicrobial selected must have an appropriate mechanism of action against the suspected pathogen and must achieve an adequate concentration in infected tissues. Bacteriostatic agents may be less effective for treatment of infections in immunosuppressed animals because normal immune responses are required for the drugs to have maximal effect (Table 93-1). The owner must be willing to administer the drug in the appropriate interval, and the drug must be affordable. Whether the antimicrobial has potential for toxicity is also an important consideration (Table 93-2). In animals with simple, first-time infections or when drugs with the potential for toxicity are used, the low end of the antimicrobial dose and the longest dosage interval should be used. Intracellular pathogens, anaerobic infections, and life-threatening infections, including bacteremia and central nervous system (CNS) infections, should be treated with the high end of the dose and the shortest dosage interval. In all animals with life-threatening infections, antibiotics should be administered parenterally for at least the first 3 to 5 days. Parenteral antibiotic administration is also indicated in animals with vomiting or regurgitation. Oral administration of antibiotics can be initiated when vomiting, regurgitation, or the lifethreatening condition have resolved.

Most simple, first-time infections in immunocompetent animals respond adequately to 7 to 10 days of antibiotic therapy. Therapy is generally continued for no more than 1 to 2 days past resolution of clinical signs. Chronic infections, bone infections, infections in immunosuppressed animals, infections resulting in granulomatous reactions, and those caused by intracellular pathogens are generally treated for a minimum of 1 to 2 weeks beyond resolution of clinical or radiographic signs of disease; the duration of therapy commonly exceeds 4 to 6 weeks.

When the results of antimicrobial susceptibility tests become available, the antibiotic choice is changed if indicated. If therapeutic response to an antibiotic in 72 hours is poor and an antibiotic-responsive infectious disease is still likely, an alternative treatment should be considered. Veterinarians should always know at least two classic drugs for each infectious agent (Tables 93-3 to 93-7).

Antibiotics Used for the Treatment of Bacterial Infections in Dogs and Cats and General Dosing Guidelines\*

Protein synthesis inhibition    DRUG	MECHANISM	BACTERIOSTATIC OR BACTERIOCIDAL	SPECIES	DOSAGE	ROUTE OF ADMINISTRATION

IM, Intramuscular; IV, intravenous; SC, subcutaneous; PO, oral; D, dog; C, cat; B, dog and cat.

<sup>\*</sup>The dose ranges and intervals in this table are general. Please see appropriate sections to determine the optimal dose for specific syndromes or infections.

<sup>†</sup> For parenterally administered aminoglycosides, giving the total daily dose at one time may lessen the potential for renal toxicity.

<sup>‡</sup> For simple infections azithromycin can be given daily for 3 days and then every third day.

<sup>§</sup>The maximal total daily dose should be 50 mg/kg.

<sup>¶</sup>The drug can be given once daily to cats for the treatment of simple infections.

**TABLE 93-2** 

#### Common Antibiotic Toxicities

TOXICITY	ANTIBIOTIC EXAMPLES
Aminoglycosides	Renal tubular disease
	Neuromuscular blockade
T:	Ototoxicity
Cephalosporins	Immune-mediated diseases
Chloramphenicol	Bone marrow/aplastic anemia
	(predominantly cats)
	Inhibition of drug metabolism
Doxycycline	Esophagitis or strictures in cats
	given tablets or capsules
Macrolides/	Vomiting or diarrhea
lincosamides	Cholestasis
	Esophagitis or strictures in cats
No. 1 1	given clindamycin capsules
Nitroimidazoles	Neutropenia (metronidazole)
	CNS toxicity (metronidazole and
Penicillins	ronidazole)
Quinolones	Immune-mediated diseases
Guinolones	Failure of cartilage development in young, growing animals
	Retinal dysfunction in some cats
	with some formulations
	Potentiation of seizures
Sulfonamides	Hepatic-cholestasis or acute hepatic
obilonamaes	necrosis (rare)
	Macrocytic anemia (long-term
	administration in cats)
	Thrombocytopenia
	Suppurative, nonseptic polyarthritis
	(predominantly Doberman)
	Keratoconjunctivitis sicca
	Renal crystalluria (rare)
Tetracyclines	Renal tubular disease
	Cholestasis
	Fever, particularly in cats
	Inhibition of drug metabolism

CNS, Central nervous system.

Conditions resulting in devitalized, granulomatous, or consolidated tissues, such as aspiration pneumonia, may not show radiographic signs of improvement before 7 days. Devitalized tissues should be debrided, if possible, to aid in the resolution of infection.

The following is a brief discussion of the empirical antimicrobial choices for treatment of infections of various body systems or types of infections. The reader is referred to individual chapters for further information concerning adjunct treatments.

# ANAEROBIC INFECTIONS

The anaerobic bacteria of clinical significance in dog and cats are Actinomyces spp., Bacteroides spp., Clostridium spp.,

	ormetoprim-sulfadimethoxine
	(superficial pyoderma)

Eubacterium spp., Fusobacterium spp., Peptostreptococcus spp., and Porphyromonas spp. Actinomyces is a facultative anaerobe; the other organisms are obligate anaerobes, which cannot use oxygen metabolically and die in its presence. Anaerobic bacteria are part of the normal flora in areas with low oxygen tension and low oxygen-reduction potential, such as the mucous membranes of the oral cavity and vagina. The origin of most anaerobic infections is the animal's own flora. Anaerobic infections are potentiated by poor blood supply, tissue necrosis, prior infection, or immunosuppression. Anaerobic bacteria produce a number of enzymes and factors that induce tissue injury and promote colonization.

<sup>\*</sup> Usually administered parenterally for the treatment of bacteremia.

Most infections involving anaerobes usually have coexisting aerobic bacterial infection, which should be considered when selecting antimicrobial agents.

Anaerobic infections are commonly associated with infections of the oropharynx, CNS, subcutaneous space, musculoskeletal system, gastrointestinal tract, liver, and female genital tract, and they are relatively common in animals with aspiration pneumonia or consolidated lung lobes (Fig. 93-1). Dogs and cats with gingivitis or stomatitis, rhinitis, retrobulbar abscesses, retropharyngeal abscesses, aspiration pneumonia, pyothorax, otitis media or interna, CNS infection, bite wounds, open wounds, open fractures, osteomyelitis, peritonitis, bacterial hepatitis, pyometra, vaginitis, bacteremia, and valvular endocarditis should be suspected to be infected with anaerobes. Anaerobic infections also should be considered in animals with a history of fighting, a foreign body, recent surgery, recent dental procedures, a history of immunosuppressive drugs or diseases, infections resistant to aminoglycosides or fluoroquinolones, lesions with a putrid

Empirical Antibiotic Choices for Dogs and Cats with Urogenital Infections

ORGAN SYSTEM OR INFECTIOUS AGENT	ANTIBIOTIC CHOICES
Aerobic urinary tract	1. Amoxicillin or amoxicillin-
infections	clavulanate
	2. First-generation
	cephalosporin
	3. Potentiated sulfas
	4. Quinolone
Brucella canis	1. Quinolone
	2. Minocycline or doxycycline
	cycled with a quinolone
Leptospira spp.	1. Penicillin G or ampicillin IV
	during acute phase and
	amoxicillin PO during
	chronic phase
	Doxycycline to eliminate
Mastitis	renal carriers
	1. First-generation
	cephalosporin  2. Amoxicillin or amoxicillin-
	clavulanate
Myconlasma	
Mycoplasma/ Ureaplasma	Doxycycline     Chloramphenicol
	3 Quinolone
Prostatitis	Potentiated sulfas
	Quinolone
	3. Chloramphenicol
	4. Erythromycin
	5. Clindamycin
Pyometra	Quinolone and amoxicillin
	2. Chloramphenicol
	3. Potentiated sulfas
	Amoxicillin-clavulanate

IV, Intravenous; PO, oral.

odor or black discharge, a painful lesion with a serosanguineous discharge, neutrophilic inflammation with cytologically evident bacteria but negative aerobic culture, and the presence of "sulfur granules" on cytology. The reader is referred to Chapter 92 for a discussion of the cytologic and cultural characteristics of anaerobic infections. Flaccid paralysis (Clostridium botulinum), rigid paralysis and trismus (Clostridium tetani) and subcutaneous gas production occur in association with some anaerobic infections.

Improving the blood supply and oxygenation of the infected area is the primary goal for treatment of anaerobic infections. Antibiotic therapy should be used concurrently with drainage or debridement. Parenteral antibiotics should be administered for several days in dogs or cats with pyothorax, pneumonia, peritonitis, or clinical signs consistent with bacteremia. Ampicillin, amoxicillin, amoxicillin-clavulanate, clindamycin, metronidazole, cephalosporins (first and second generation), potentiated sulfas, and chloramphenicol are

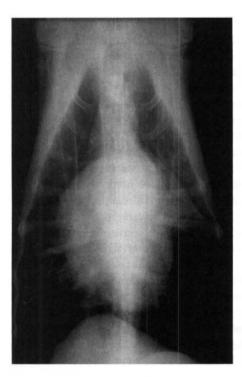

FIG 93-1
Consolidated lung lobe in a dog with aspiration pneumonia and anaerobic involvement.

commonly used for the treatment of anaerobic infections (see Table 93-3). *Bacteroides* spp. are commonly resistant to ampicillin and clindamycin, so if gram-negative coccobacilli are detected cytologically in a neutrophilic exudate—particularly if associated with the oral cavity—metronidazole, a first-generation cephalosporin, or amoxicillin-clavulanate should be administered instead of a penicillin derivative. Because concurrent anaerobic and aerobic infections occur frequently, combination antimicrobial treatment is often indicated, particularly if life-threatening signs of bacteremia exist.

# BACTEREMIA AND BACTERIAL ENDOCARDITIS

Bacteremia can be transient, intermittent, or continuous. Routine dentistry is a common cause of transient bacteremia. Immunosuppressed or critically ill animals commonly develop intermittent bacteremia; the source of infection is commonly the genitourinary or gastrointestinal systems. Continuous bacteremia occurs most frequently in association with bacterial endocarditis. Bacteremic animals have intermittent fever, depression, and clinical signs associated with the primary organ system infected. Sepsis is the systemic response to infection and is manifested by peripheral circulatory failure (septic shock).

Staphylococcus, Streptococcus, Enterococcus, Corynebacterium, Escherichia coli, Salmonella, Klebsiella, Enterobacter, Pseudomonas, Proteus, Pasteurella, Clostridium, Fusobacte-

rium, and Bacteroides organisms are commonly isolated from the blood of bacteremic animals. Bacterial endocarditis is often caused by Staphylococcus aureus, E. coli, or  $\beta$ -hemolytic Streptococcus infection. Bartonella vinsonii (dogs) and B. quintana (cats and dogs; see Chapter 95) have recently been associated with bacterial endocarditis (Sykes et al., 2006).

If the source of bacteremia or bacterial endocarditis is from an area with mixed flora, such as the gastrointestinal tract, or if the animal has life-threatening clinical signs of disease, an antibiotic or combination of antibiotics that is effective against gram-positive, gram-negative, aerobic, and anaerobic organisms should be used (a four-quadrant approach). An aminoglycoside or quinolone for gramnegative organisms combined with ampicillin, a firstgeneration cephalosporin, metronidazole, or clindamycin for gram-positive and anaerobic organisms is a commonly prescribed combination treatment (see Table 93-4). Secondand third-generation cephalosporins, ticarcillin combined with clavulanate, and imipenem are some of the agents with a four-quadrant spectrum. After parenteral treatment with these drugs for 5 to 7 days, oral treatment is selected on the basis of culture and antimicrobial susceptibility results. Optimal treatment for valvular endocarditis from bartonellosis in dogs has not be determined, but the combination of azithromycin and a fluoroquinolone or rifampin may be required in some cases (see Chapter 95). Oral treatment is continued for at least 4 to 6 weeks, particularly in dogs or cats with bacterial endocarditis. The blood culture should be rechecked 1 and 4 weeks after discontinuation of therapy to confirm control of the infection. The prognosis in dogs and cats with bacterial endocarditis is guarded to poor because of damage to the infected heart valves (see Chapter 6).

# CENTRAL NERVOUS SYSTEM INFECTIONS

Chloramphenicol, the sulfonamides, trimethoprim, metronidazole, and the quinolones penetrate the CNS and should be chosen for empirical treatment of suspected bacterial infections of this system (see Table 93-6). Anaerobic bacterial infection and rickettsial infections (*Ehrlichia* spp. and *R. rickettsii*) of the CNS occur in some cases, making chloramphenicol a logical first choice. Multiple other drugs, including penicillin derivatives, tetracyclines (doxycycline), and clindamycin, may cross into the cerebrospinal fluid when inflammation exists. Clindamycin achieves adequate brain tissue concentrations in normal cats for the treatment of toxoplasmosis. Potentiated sulfas are alternative anti-*Toxoplasma* drugs.

# GASTROINTESTINAL TRACT AND HEPATIC INFECTIONS

Oral administration of antibiotics is indicated for the treatment of small intestinal bacterial overgrowth, hepatic

encephalopathy, cholangiohepatitis, hepatic abscessation, and infection by *Helicobacter* spp., *Campylobacter* spp., *Clostridium perfringens, Giardia* spp., *Cryptosporidium* spp., *Cystoisospora* spp., *Tritrichomonas foetus*, and *Toxoplasma gondii* (see Table 93-5). Administration of parenteral antibiotics is indicated in dogs and cats with bacteremia from translocation of enteric flora or *Salmonella* infection.

Giardia spp. infections often respond clinically to the administration of metronidazole, but infection is usually not eliminated. Administration of metronidazole benzoate at 25 mg/kg q12h PO for 7 days was effective in suppressing cyst shedding to below detectable limits in 26 cats (Scorza et al., 2004). This is the maximal dose of metronidazole that should be used; CNS toxicity can be induced by overdosing or as a cumulative neurotoxin. Fenbendazole is the most commonly used alternate drug. Metronidazole also has the advantage of helping correct secondary small intestinal bacterial overgrowth. For T. foetus infections, ronidazole at 30 mg/kg PO q12h for 14 days eliminated clinical signs of disease and trophozoites from cats infected with one strain of the organism. In the United States this drug currently must be purchased from a custom pharmacy. CNS toxicity is also common with ronidazole.

Sequential administration of clindamycin followed by tylosin blocked oocyst shedding and resolved diarrhea in one cat with chronic clinical cryptosporidiosis. Tylosin (10-15 mg/kg q12h PO) has apparently been successful in lessening diarrhea and oocyst shedding in multiple other cats and dogs with diarrhea that were positive for Cryptosporidium. However, infection is not eliminated. Unfortunately, tylosin is quite bitter and usually has to be given to cats in capsules. Treatment duration may need to be weeks. Paromomycin can be effective for lessening diarrhea and oocyst shedding associated with cryptosporidiosis in cats and also is an alternate anti-Giardia drug. However, this orally administered aminoglycoside may cross the diseased intestinal wall and result in renal toxicity and should never be used in cats with bloody diarrhea. In cats with naturally occurring cryptosporidiosis, response to azithromycin has been variable (Lappin MR, unpublished data, 2005). If tried, use 10 mg/kg PO weekly for at least 10 days. If responding, continue treatment for at least 1 week past clinical resolution. The Toxoplasma gondii oocyst shedding period can be shortened by administration of clindamycin or sulfadimethoxine. Cystoisospora spp. generally respond to the administration of sulfadimethoxine or other sulfa-containing drugs.

Clostridium perfringens and bacterial overgrowth generally respond to treatment with tylosin, metronidazole, ampicillin, amoxicillin, or tetracyclines. The drug of choice for campylobacteriosis is erythromycin; however, oral administration of quinolones or chloramphenicol are often less likely to potentiate vomiting. Salmonellosis should only be treated parenterally because of rapid resistance that occurs after oral administration of antibiotics. Appropriate antibiotics for the empirical treatment of salmonellosis while awaiting susceptibility testing results include ampicillin and trimethoprim-sulfa; quinolones are also effective. Helico-

bacter spp. infections are usually treated with the combination of metronidazole and tetracycline or amoxicillin and clarithromycin. In cats the use of clarithromycin alone may be logical because the species is often difficult to treat with multiple drugs.

Dogs or cats with apparent bacteremia from enteric bacteria should be treated with parenteral antibiotics with a spectrum against anaerobic and gram-negative organisms. The combination of enrofloxacin with a penicillin or first-generation cephalosporin is generally effective. Intravenous metronidazole can also be used. Second-generation cephalosporins or imipenem is also an appropriate choice.

The most common bacteria in one study of hepatic infections were *E. coli, Enterococcus, Streptococcus, Clostridium*, and *Bacteroides* (Wagner et al., 2007). Dogs or cats with hepatic infections and signs of bacteremia should be treated with antibiotics that kill gram-positive, gram-negative, and anaerobic bacteria, as previously discussed. Nonbacteremic hepatic infections generally respond to amoxicillinclavulanate, first-generation cephalosporins, or metronidazole; a fluoroquinolone should be added if signs of sepsis are present. Decreasing numbers of enteric flora by oral administration of penicillins, metronidazole, or neomycin can lessen the clinical signs of hepatic encephalopathy.

## MUSCULOSKELETAL INFECTIONS

Osteomyelitis and discospondylitis are commonly associated with infections by *Staphylococcus*, *Streptococcus*, *Proteus*, *Pseudomonas* spp., *E. coli*, and anaerobes. First-generation cephalosporins, amoxicillin-clavulanate, and clindamycin are logical antibiotics for empirical therapy of these conditions because of their spectrum of activity against the grampositive organisms and anaerobic bacteria and their ability to achieve high concentrations in bone (see Table 93-6). Quinolones should be used if gram-negative organisms are suspected. Antibiotic treatment should be continued for a minimum of 2 weeks beyond resolution of radiographic changes.

Dogs and cats with septic polyarthritis should be treated in the same way as those with osteomyelitis. The source of infection should be removed if possible. Bartonella vinsonii, Ehrlichia spp., Rickettsia rickettsii, Borrelia burgdorferi, Mycoplasma organisms, and L-form bacteria can induce nonseptic, suppurative polyarthritis. Occasionally, morulae of Ehrlichia spp. are identified cytologically in the joint fluid. In general, the cytologic findings in joint fluid induced by these agents are similar to those of immune-mediated polyarthritis. For this reason doxycycline is a logical empirical antibiotic choice for dogs with nonseptic, suppurative polyarthritis pending the results of further diagnostic tests. Amoxicillin is an alternative drug for the treatment of B. burgdorferi infection. Fluoroquinolones can also be used for R. rickettsii, Mycoplasma, and l-form bacteria infections. B. vinsonii infection may require the administration of azithromycin, with or without concurrent fluoroquinolones.

Muscle disease from T. gondii infection often resolves during treatment with clindamycin hydrochloride. Although many dogs with neosporosis die, some have survived after treatment with trimethoprim-sulfadiazine combined with pyrimethamine; sequential treatment with clindamycin hydrochloride, trimethoprim-sulfadiazine, and pyrimethamine; or clindamycin alone. For treatment of acute Hepatozoon americanum infection, the combination of trimethoprim-sulfadiazine, pyrimethamine, and clindamycin for 14 days is highly successful; the use of decoquinate at 10 to 20 mg/kg q12h with food lessens the likelihood of recurrence of clinical disease and prolongs survival

# RESPIRATORY TRACT INFECTIONS

Most bacterial upper respiratory infections are secondary to other primary diseases, including foreign bodies, viral infections, tooth root abscesses, neoplasms, trauma, and fungal infections. After the epithelium of the nose and sinuses is inflamed, normal bacterial flora can colonize and perpetuate inflammation; deep infection can result in chondritis and osteomyelitis. Because the upper respiratory passageways have a normal flora, it is difficult to assess the results of culture and antimicrobial susceptibility testing in these tissues. The source of the primary insult should always be removed if possible. Broad-spectrum antibiotics with an anaerobic spectrum, including amoxicillin, amoxicillinclavulanate, potentiated sulfas, and first-generation cephalosporins, are commonly prescribed empirically to treat upper respiratory infections caused by normal flora overgrowth (see Table 93-4). Treatment duration is generally 1 to 2 weeks for acute, first-time infections. Dogs and cats with chronic rhinitis and suspected osteochondritis that respond to antibiotics should be treated for a minimum of 4 to 6 weeks or until clinical signs have been resolved for 2 weeks. Chronic rhinitis often responds to treatment with clindamycin because of the excellent anaerobic and gram-positive spectrum and its ability to penetrate cartilage and bone well. Bordetella bronchiseptica, Mycoplasma spp., and Chlamydophila felis infection of cats are primary bacterial pathogens that infect the upper respiratory tissues. If the animal responds poorly to broad-spectrum antibiotics, doxycycline, azithromycin, chloramphenicol, or quinolones can be administered; Chlamydophila, Bordetella, and Mycoplasma organisms generally respond to these drugs. Epistaxis can be caused by B. vinsonii, E. canis, and R. rickettsii. No evidence currently supports Bartonella spp. as a cause of rhinitis in cats. Canine bartonellosis often fails to respond to the administration of doxycycline but can be successfully treated with azithromycin. Canine kennel cough syndrome caused by Bordetella or Mycoplasma spp. is usually effectively treated with doxycycline, chloramphenicol, quinolones, or amoxicillinclavulanate. Bacterial bronchitis in cats generally responds to administration of amoxicillin-clavulanate. In dogs and cats with chronic bronchitis, doxycycline, chloramphenicol, quinolones, or amoxicillin-clavulanate are rational empirical antibiotic choices.

Common bacteria associated with pneumonia in dogs include E. coli, Klebsiella spp., Pasteurella spp., Pseudomonas spp., B. bronchiseptica, Streptococcus spp., Staphylococcus spp., and Mycoplasma spp. In cats, Bordetella, Pasteurella, and Mycoplasma organisms are commonly isolated. Aspiration of gastrointestinal contents is a common cause of bacterial pneumonia with a mixed population of bacteria. Multiple species of bacteria are typically cultured from dogs and cats with bronchopneumonia. B. bronchiseptica is the most important primary pathogen in dogs and cats; most other bacteria colonize after airways have been previously damaged. If consolidated lung lobes are detected radiographically, an anaerobic infection should be assumed. Whether species of Mycoplasma infecting dogs and cats are capable of being primary respiratory pathogens is unknown. Chlamydophila infection in cats is not a common cause of lower respiratory tract infection. Yersinia pestis causes pneumonia in cats in western states (see Chapter 100); aminoglycosides, tetracycline derivatives, and quinolones can be used successfully.

In dogs and cats with bacterial pneumonia, culture and antimicrobial susceptibility testing should be performed on secretions collected by transtracheal wash or bronchoalveolar lavage. If the animal shows signs of bacteremia or if radiographic evidence of consolidated lung lobes is present, parenteral administration of a four-quadrant antibiotic choice, as previously discussed for bacteremia, should be used initially. Quinolones combined with clindamycin or azithromycin or chloramphenicol alone is a good choice for animals with consolidated lung lobes because of their broad spectrum, excellent tissue penetration, and efficacy against B. bronchiseptica (see Table 93-5). In animals with pneumonia but without clinical signs of bacteremia or consolidated lung lobes, broad-spectrum antibiotics, including amoxicillin, amoxicillin-clavulanate, potentiated sulfas, and firstgeneration cephalosporins, may be effective. Surface-dwelling organisms such as B. bronchiseptica and Mycoplasma may respond to nebulization of gentamicin diluted in sterile saline (25 to 50 mg in 3 to 5 mL saline/nebulization). Treatment for bacterial pneumonia should be continued for at least 4 weeks or for 1 to 2 weeks beyond resolution of clinical and radiographic signs of disease.

T. gondii occasionally causes pneumonia in neonatally infected, transplacentally infected, and immunosuppressed cats and dogs (see Chapter 99). Clindamycin or potentiated sulfas should be used if toxoplasmosis is suspected. Azithromycin may also be effective for the treatment of toxoplasmosis. Neospora caninum has occasionally been associated with pneumonia in dogs and should be treated with a combination of clindamycin and potentiated sulfas.

If pyothorax is attributable to penetration of foreign material from an airway or esophagus into the pleural space, thoracotomy is usually required for removal of devitalized tissue and the foreign body (see Chapter 23). Pyothorax occasionally results from hematogenous spread of bacteria to the pleural space; this may be common in cats. Pleural lavage through chest tubes is the most effective treatment for patients with pyothorax and no obvious foreign material. Most dogs and cats with pyothorax have mixed aerobic and anaerobic bacterial infections. Animals with pyothorax and clinical signs of bacteremia should initially receive parenteral four-quadrant antibiotics, as previously discussed for bacteremia.

# SKIN AND SOFT TISSUE INFECTIONS

Staphylococcus pseudointermedius is the most common cause of pyoderma in dogs and cats. Deep pyoderma can be induced by any organism, including gram-negative types. Most soft tissue infections, including open wounds and abscesses, are infected with a mixed population of bacteria; the aerobic and anaerobic flora from the mouth are often involved. Recommended empirical antibiotic choices for routine cases of pyoderma and soft tissue infections are listed in Table 93-3. Antibiotics with a broad spectrum, such as first-generation cephalosporins and amoxicillin-clavulanate, are often first choices. Other β-lactamase-resistant penicillins, such as oxacillin, dicloxacillin, and cloxacillin, also can be used. Potentiated sulfas can be used to treat dogs and cats with superficial pyoderma but should be avoided if longterm treatment is needed because bacterial resistance occurs quickly. Cutaneous and soft tissue infections that do not respond to these antibiotics may be caused by gram-negative bacteria, L-form bacteria, Mycoplasma organisms, rapidly growing Mycobacterium spp., systemic fungi, or Sporothrix schenckii. Quinolones are the antibiotic class of choice for the treatment of gram-negative infections. Animals that do not respond to empirical antibiotic treatment should undergo further diagnostic testing or be treated with antibiotics known to have an effect against the less-common pathogens (see Table 93-3). If not previously done, microscopic examination of tissue or pustule aspirates should be performed for the presence of Sporothrix organisms and bacteria morphologically similar to Mycobacterium spp. After surgical preparation of the skin, deep tissues should be obtained for aerobic, anaerobic, Mycoplasma, fungal, and atypical Mycobacterium spp. culture (see Chapter 92).

#### UROGENITAL TRACT INFECTIONS

Microscopic examination and Gram stain of urine sediment aids in the empirical choice of an antibiotic in dogs and cats with signs of urinary tract infection. Culture and antimicrobial susceptibility testing should always be performed if possible. Approximately 75% of urinary tract infections in dogs are caused by gram-negative organisms; *E. coli, Proteus, Klebsiella, Pseudomonas,* and *Enterobacter* infections are common. In cats that have been previously catheterized, *E. coli* is most common; *Staphylococcus* and *Streptococcus* organisms are common after urethrostomy (see Chapter 45).

In bitches with simple, first-time urinary tract infections, amoxicillin or amoxicillin-clavulanate should be used if cocci are observed; potentiated sulfas or first-generation cephalosporins should be used if rods are observed. Quinolones should be reserved for life-threatening or resistant infections. Many antibiotics do not penetrate the prostate unless it is markedly inflamed. Because the prostate can be a source of recurrent urinary tract infection, all male dogs with urinary tract infection should be assumed to have prostatitis, and antibiotics that penetrate the prostate should be chosen (see Table 93-7). The majority of urinary tract infections in cats respond to amoxicillin. Administration of antibiotics for 10 to 14 days is generally sufficient for simple urinary tract infections. Urinalysis, culture, and antimicrobial susceptibility testing should be performed 7 days after finishing treatment if possible.

Mycoplasma and Ureaplasma infections have been documented in dogs with clinical signs of urinary tract infections. If poor response to penicillin derivatives, cephalosporins, or potentiated sulfas is observed, further diagnostics should be performed. If empirical therapy is deemed necessary, chloramphenicol, doxycycline, or quinolone treatment can be administered and may be more effective for Mycoplasma and Ureaplasma organisms.

All dogs and cats with urinary tract infection and azotemia should be assumed to have pyelonephritis and be treated accordingly, even if further diagnostic procedures are not performed. Treatment for pyelonephritis should be based on susceptibility results if possible; potentiated sulfa combinations or quinolones are good empirical choices. If Leptospira spp. infection is suspected, intravenous administration of ampicillin is indicated (see Chapter 95). If renal insufficiency exists, the tetracyclines (except doxycycline) and aminoglycosides should be avoided, and the dosage or dosing interval of quinolones and cephalosporins should be extended proportionally to the diminution in renal function. The new dosage can be calculated by multiplying the current dosage by the result obtained when the mean normal creatinine concentration is divided by the patient's creatinine concentration. The new dosing interval can be calculated by multiplying the current dosing interval by the result obtained when the patient's creatinine concentration is divided by the mean normal creatinine concentration. Treatment for pyelonephritis and other chronic, complicated urinary tract infections should be continued for at least 6 weeks. Urinalysis, culture, and antimicrobial susceptibility testing should be performed 7 and 28 days after treatment. Some infections cannot be eliminated and require administration of pulse antibiotic therapy.

Most bacterial prostatic infections involve gram-negative bacteria. During acute prostatitis almost all antibiotics penetrate the prostate well because of inflammation. After reestablishment of the blood-prostate barrier in dogs with chronic prostatitis, the acidic prostatic fluid allows only the basic antibiotics (pK<sub>a</sub> less than 7) to penetrate well (see Table 93-7). Chloramphenicol, because of its high lipid solubility, also penetrates prostatic tissue well. In acute prostatitis

administration of acidic antibiotics, including penicillins and first-generation cephalosporins, may initially penetrate well, lessening clinical signs of disease but not eliminating the infection. This predisposes to chronic bacterial prostatitis and prostatic abscessation. For this reason the use of penicillins and first-generation cephalosporins is contraindicated for the treatment of urinary tract infections in male dogs. In dogs with chronic prostatitis antimicrobial therapy should be continued for at least 6 weeks. Urine and prostatic fluid should be cultured 7 days and 28 days after therapy.

Brucella canis causes a number of clinical syndromes in dogs, including epididymitis, orchitis, endometritis, still-births, abortion, discospondylitis, and uveitis. Ovariohyster-ectomy or neutering lessens contamination of the human environment. (See Chapter 100 for a discussion of the zoonotic potential.) Long-term antibiotic administration usually does not lead to a complete cure (Wanke et al., 2006). Some dogs become antibody-negative, but the organism can still be cultured from tissues. Several antibiotic protocols have been suggested for dogs with brucellosis (see Table 93-7). However, owners should be carefully counseled concerning zoonotic risks before initiating treatment.

Vaginitis generally results from overgrowth of normal flora secondary to primary diseases, including herpesvirus infection, urinary tract infection, foreign bodies, vulvar or vaginal anomalies, vaginal or vulvar masses, or urinary incontinence. In dogs and cats with bacterial vaginitis from overgrowth of flora and resolution of the primary insult, broad-spectrum antibiotics, including amoxicillin, potentiated sulfas, first-generation cephalosporins, tetracycline derivatives, and chloramphenicol, are typically successful. Because *Mycoplasma* and *Ureaplasma* organisms are part of the normal vaginal flora, providing a clinical disease association is virtually impossible; positive cultures do not confirm disease because of the organism (see Chapter 95). Hence a positive vaginal culture from an asymptomatic dog (excluding *B. canis*) is meaningless.

In all dogs and cats with pyometra, ovariohysterectomy or medically induced drainage of the uterus is imperative. Antibiotic treatment is for the bacteremia that commonly occurs concurrently (i.e., *E. coli* and anaerobes). Animals with clinical signs of bacteremia or sepsis should be treated with a four-quadrant antibiotic choice (see Table 93-5). Broad-spectrum antibiotics with efficacy against *E. coli*, such as potentiated sulfas or amoxicillin-clavulanate, are appropriate empirical choices pending the results of culture and antimicrobial susceptibility testing. Potentiated sulfas and the quinolones commonly are effective for *E. coli* but are not

as effective as other drugs for the treatment of anaerobic infections in vivo,

Ampicillin, amoxicillin, and first-generation cephalosporins achieve good concentrations in milk and are relatively safe for the neonate; therefore they can be used in the empirical treatment of mastitis. Chloramphenicol, quinolones, and tetracycline derivatives should be avoided because of potential adverse effects on the neonate.

# CHAPTER OUTLINE

BIOSECURITY PROCEDURES FOR SMALL ANIMAL HOSPITALS

General Biosecurity Guidelines
Patient Evaluation
Hospitalized Patients
Basic Disinfection Protocols
BIOSECURITY PROCEDURES FOR CLIENTS
VACCINATION PROTOCOLS

Vaccine Types Vaccine Selection Vaccination Protocols for Cats Vaccination Protocols for Dogs

Preventing infections is always preferred over treating infections. Avoiding exposure is the most effective way to prevent infections. Most infectious agents of dogs and cats are transmitted in fecal material, respiratory secretions, reproductive tract secretions, or urine; by bites or scratches; or by contact with vectors or reservoirs. Some infectious agents such as FHV-1, Bordetella bronchiseptica, and canine influenza virus can be transmitted by direct contact with clinically normal, infected animals. Many infectious agents are environmentally resistant and can be transmitted by contact with a contaminated environment (fomites). The avoidance of zoonotic transfer of infectious agents is extremely important because some zoonotic diseases, such as plague and rabies, are life threatening (see Chapter 100). Recognition of risk factors associated with infectious agents is the initial step in the prevention of infectious diseases. Veterinarians should strive to understand the biology of each infectious agent so they can counsel clients and staff on the best strategies for prevention.

Vaccines available for some infectious agents can prevent infection or lessen clinical illness when infection occurs. However, vaccines are not uniformly effective, are not available for all pathogens, and sometimes induce serious adverse effects. Therefore the development of sound biosecurity procedures is paramount to avoid exposure to infectious agents when developing a preventive medicine program.

# BIOSECURITY PROCEDURES FOR SMALL ANIMAL HOSPITALS

Most hospital-borne infections (nosocomial) can be prevented by following simple biosecurity guidelines (Box 94-1). The following are some general guidelines to consider that were adapted from those used at the Veterinary Medical Center at Colorado State University (http://csuvets.colostate.edu/biosecurity).

#### **GENERAL BIOSECURITY GUIDELINES**

Contaminated hands are the most common source of infectious agent transmission in the hospital environment. Fingernails of personnel having patient contact should be cut short. Hands should be washed before and after attending to each individual animal as follows. Collect clean paper towels and use to turn on water faucets, wash hands for 30 seconds with antiseptic soap being sure to clean under fingernails, rinse hands thoroughly, use the paper towel to dry hands, and use the paper towel to turn off the water faucets. Use of antiseptic lotion should be encouraged. Personnel should not touch patients, clients, food, doorknobs, drawer or cabinet handles or contents, equipment, or medical records with soiled hands or gloves.

All employees should wear an outer garment, such as a smock or scrub suit, when attending to patients. Footwear should be protective, clean, and cleanable. A minimum of two sets of outer garments should always be available, and they should be changed immediately after contamination with feces, secretions, or exudates. Equipment such as stethoscopes, pen lights, thermometers, bandage scissors, lead ropes, percussion hammers, and clipper blades can be fomites and should be cleaned and disinfected after each use with animals likely to have a transmissible infectious disease. Disposable thermometer covers or thermometers should be used.

BOX 94-1

#### General Hospital Biosecurity Guidelines

- Wash hands before and after each patient contact.
- Wear gloves when handling patients when zoonotic diseases are on the list of differential diagnoses.
- Minimize contact with hospital materials (instruments, records, door handles, etc.) while hands or gloves are contaminated.
- Always wear an outer garment, such as a smock or scrub shirt, when handling patients.
- Change outer garments when soiled by feces, secretions, or exudates.
- Clean and disinfect equipment (stethoscopes, thermometers, bandage scissors, etc.) after each use with animals likely to have an infectious disease.
- Examination tables, cages, and runs should be cleaned and disinfected after each use.
- Litter boxes and dishes should be cleaned and disinfected after each use.
- · Place animals with suspected infectious diseases into an examination room or an isolation area immediately on admission into the hospital.
- Treat animals with suspected infectious diseases as outpatients if possible.
- Procedures that use general hospital facilities, such as surgery and radiology, should be postponed until the end of the day if possible.
- Do not consume fluids or drink in areas where patient care is provided.

To avoid zoonotic transfer of infectious diseases, food or drink should not be consumed in areas where animal care is provided. All areas where animals are examined or treated should be cleaned and disinfected immediately after use, irrespective of infectious disease status of the individual animal.

#### PATIENT EVALUATION

Prevention of infectious diseases starts with the front desk personnel. Staff should be trained to recognize the presenting complaints for the infectious agents in the geographic area of the hospital. Animals with gastrointestinal or respiratory diseases are the most likely to be contagious. Infectious gastrointestinal disease should be suspected in all dogs and cats with small- or large-bowel diarrhea whether the syndrome is acute or chronic. Infectious respiratory disease should be suspected in all dogs and cats with sneezing (especially those with purulent oculonasal discharge) or coughing (especially if productive). The index of suspicion for infectious diseases is increased for dogs or cats with acute disease and fever, particularly if the animal is from a crowded environment such as a breeding facility, boarding facility, or shelter.

Front desk personnel should indicate clearly on the hospital record that gastrointestinal or respiratory disease is present. If the presenting complaint is known before admission into the hospital, an optimal method would be to meet the client in the parking area to determine the infectious disease risk before the pet enters the hospital. If an infectious gastrointestinal or respiratory disease is suspected, the animal should be transported (i.e., not allowed to walk on the premises) to an examination room or the isolation facility. If a patient with acute gastrointestinal or respiratory disease is presented directly to the reception desk, the receptionist should contact the receiving clinician, technician, or student immediately and coordinate placement of the animal in an examination room to minimize hospital contamination. Animals with suspected infectious diseases should be treated as outpatients if possible. If hospitalization is required, the animal should be transported to the appropriate housing area by the shortest route possible, preferably with a gurney to lessen hospital contamination. The gurney and any hospital materials in contact with potentially contaminated employees (including examination tables and doorknobs) should be immediately cleaned and disinfected as previously mentioned.

#### HOSPITALIZED PATIENTS

If possible, all animals with suspected infectious diseases, such as Salmonella spp., Campylobacter spp., parvovirus infection, kennel cough syndrome, acute feline upper respiratory disease syndrome, rabies, or plague, should be housed in an isolated area of the hospital. The number of staff members entering the isolation area should be kept to a minimum. On entry into the isolation area, outerwear should be left outside and surgical booties or other disposable shoe covers should be placed over the shoes. Alternatively, a foot bath filled with disinfectant should be placed by the exit and used when leaving the area. The room should be entered and a disposable gown (or smock designated for the patient) and latex gloves should be put on. A surgical mask should be worn when attending cats with plague, and extreme care should be taken to avoid being bitten. Separate equipment and disinfectant supplies should be used in the isolation

All biologic materials submitted to clinical pathology laboratories or diagnostic laboratories from animals with suspected or proven infectious diseases should be clearly marked as such. Fecal material should be placed in a plastic, screw-capped cup with a tongue depressor or while the clinician is wearing gloves. Place the cup in a clean area and place the lid on with a clean, gloved hand. Remove the used gloves and place the cup in a second bag clearly marked with the name of the infectious disease suspected. The outer surface of the bag should be disinfected before leaving the isolation

Disposable materials should be placed in plastic bags in the isolation area. The external surfaces of the bags should be sprayed with a disinfectant before being removed from the isolation area. After attending to the patient, contaminated equipment and surfaces should be cleaned and disinfected, and contaminated outer garments and shoe covers

should be removed. Hands should be washed after discarding the contaminated outerwear. Dishes and litter pans should be cleansed thoroughly with detergent before returning them to the central supply area of the hospital. Optimally, materials such as outerwear and equipment to be returned to the central supply area should be placed in plastic bags and sprayed with a disinfectant before transport. Procedures requiring general hospital facilities such as surgery and radiology should be postponed to the end of the day, if possible, and the contaminated areas disinfected before use with other animals. Animals should be discharged by the shortest path to the parking lot possible.

Some animals with infectious diseases can be maintained in the general hospital boarding or treatment areas with special management techniques. For example, cats positive for the feline leukemia virus (FeLV) or feline immunodeficiency virus (FIV) should not be placed in the isolation area, if possible, to avoid exposing them to other infectious agents. Because neither of these two viruses is transmitted by aerosolization, cats with these infectious diseases can be housed in close proximity to other cats. The cages should be labeled appropriately, and the infected cats should not be caged next to or above seronegative cats. In addition, no direct contact or sharing of litter boxes or food bowls should occur between infected and naïve cats.

#### **BASIC DISINFECTION PROTOCOLS**

To lessen the spread of potential infectious agents, hospitalized animals should never be moved from cage to cage. The key to effective disinfection is cleanliness. Cage papers and litter boxes soiled by feces, urine, blood, exudates, or respiratory secretions should be removed and placed in trash receptacles. Bulk fecal material should also be placed in trash receptacles.

Many infectious agents are resistant to disinfectants or require prolonged contact time to be inactivated (Greene, 2006). Contaminated surfaces, including the cage or run floors, walls, ceiling, door, and door latch, should be wetted thoroughly with a disinfectant that is then blotted with clean paper towels or mops. Surfaces should be in contact with the disinfectant for 10 to 15 minutes if possible, particularly if known infectious agents are present. Soiled paper towels should be placed in trash receptacles. If infectious disease is suspected, the trash bags should be sealed, the surface of the bag sprayed with a disinfectant, and the trash bags discarded.

Contaminated surfaces in examination rooms should be cleaned to remove hair, blood, feces, and exudates. Examination tables, countertops, floors, canister lids, and water taps should be saturated with disinfectant for 10 minutes. Surfaces should be blotted with paper towels until dry, and the soiled towels should be placed in a trash receptacle. Urine or feces on the floor should be contained with paper towels, blotted, and placed in trash receptacles. The soiled area of the floor should be mopped with disinfectant.

Disinfectants are relatively effective for viral and bacterial agents but require high concentrations and long contact

times to kill parasite eggs, cysts, and oocysts. Cleanliness is the key to lessening hospital-borne infection with these agents; detergent or steam cleaning inactivates most of these agents. Litter pans and dishes should be thoroughly cleaned with detergent and scalding water.

# BIOSECURITY PROCEDURES FOR CLIENTS

Housing animals indoors in a human environment to prevent exposure to other animals, fomites, or vectors is the optimal way to prevent infectious diseases. Some infectious agents can be carried into the home environment with the owners, by vectors, or by paratenic or transfer hosts. Although most infections occur in both immunocompromised and immunocompetent animals, clinical disease is often more severe in immunocompromised animals. Puppies, kittens, old animals, debilitated animals, animals with immunosuppressive diseases (e.g., hyperadrenocorticism, diabetes mellitus, cancer), animals with concurrent infections, and animals treated with glucocorticoids or cytotoxic agents are examples of immunocompromised patients. Avoiding exposure to infectious agents in this group is particularly important because of the potential for increased susceptibility to disease. These animals may also be less likely to have appropriate responses to immunization. Kennels, veterinary hospitals, dog and cat shows, and shelters have an increased likelihood for infectious agent contact because of the concentration of potentially infected animals and should be avoided when possible. Areas such as parks are common sources of infectious agents that survive for long periods in the environment; parvoviruses and enteric parasites are classic examples. Owners should avoid bringing new animals with unknown histories into a home environment with other pets until the new animal is evaluated by a veterinarian for infectious disease risk. If people are in contact with animals outside the home environment, they should wash their hands before contact with their own pet. The owner should consult the veterinarian concerning vaccination protocols and other preventive medical procedures (e.g., routine deworming, flea control, tick control) most indicated for each individual patient.

#### **VACCINATION PROTOCOLS**

#### **VACCINE TYPES**

Vaccines are available for some infectious agents of dogs and cats and can be administered to prevent infection or limit disease. Vaccination stimulates humoral, mucosal, or cell-mediated immune responses. Humoral immune responses are characterized by the production of immunoglobulin M (IgM), IgG, IgA, and IgE class antibodies, which are produced by B-lymphocytes and plasma cells after being presented an antigen by macrophages. Binding of antibodies to an infectious agent or its toxins helps prevent infection or disease by facilitating agglutination (viruses), improving

phagocytosis (opsonization), neutralizing toxins, blocking attachment to cell surfaces, initiating the complement cascade, and inducing antibody-dependent cell-mediated cytotoxicity. Antibody responses are most effective in controlling infectious agents during extracellular replication or toxin production. Cell-mediated immune responses are mediated principally by T-lymphocytes. Antigen-specific T-lymphocytes either destroy the infectious agent or mediate destruction of the agent by producing cytokines that stimulate other white blood cells, including macrophages, neutrophils, and natural killer cells. Cell-mediated immunity is required for the control of most cell-associated infections.

Currently available vaccines are either infectious (attenuated [modified-live] organisms or live virus—vectored recombinant vaccines) or noninfectious (killed virus, killed bacteria [bacterins], and subunit vaccines).

Attenuated vaccines replicate in the host to effectively stimulate an immune response and therefore generally have low antigen mass and do not require adjuvants. Different products are administered locally (e.g., modified-live Bordetella bronchiseptica intranasal vaccine) or parenterally (e.g., modified-live canine distemper vaccine). In live virusvectored recombinant vaccines, the specific DNA that codes for the immunogenic components of the infectious agent is inserted into the genome of a nonpathogenic organism (vector) that will replicate in the species being vaccinated. As the vector replicates in the host, it expresses the immunogenic components of the infectious agent, resulting in the induction of specific immune responses. Because the virusvectored vaccine is live and replicates in the host, adjuvants and high-antigen mass are not required. Because only DNA from the infectious agent is incorporated into the vaccine, no risk of reverting to the virulent parent strain exists, as occasionally occurs with attenuated vaccines. Only vectors that do not induce disease in the animal being vaccinated are used. Another advantage to vaccines of this type is the potential ability to overcome inactivation by maternal antibodies.

Killed virus, killed bacteria (bacterins), and subunit vaccines are noninfectious and therefore usually require higher antigen mass than infectious vaccines to stimulate immune responses because they do not replicate in the host. Some noninfectious vaccines may stimulate immune responses of lesser magnitude and shorter duration than infectious vaccines unless adjuvants are added. Adjuvants improve immune responses by stimulating uptake of antigens by macrophages that present the antigens to lymphocytes. Although adjuvants have historically been associated with vaccine adverse effects, newer generation adjuvants induce less inflammation. Subunit vaccines can be superior to killed vaccines that use the entire organism because only the immunogenic parts of the organism are used, which may decrease the potential for vaccine reactions. However, for some infections use of only one antigen does not adequate induce adequate protection. Native DNA vaccines and genedeleted vaccines are currently being evaluated for several infectious diseases.

#### VACCINE SELECTION

Selection of optimal vaccines for use in dogs and cats is complicated. Multiple products for most infectious agents are available, but efficacy studies that directly compare different products are generally lacking. The veterinarian may need to choose from infectious and noninfectious options for the same vaccine antigen. Some vaccine antigens are for intranasal administration and others are for parenteral administration. Not all vaccines for a given infectious disease are comparable in every situation. Long-term duration of immunity studies and studies evaluating a vaccine's ability to block infection by multiple field strains are not available for all individual products. When making decisions about which products to use or when evaluating a new vaccine, the practitioner should request information concerning efficacy, challenge studies, duration of immunity studies, adverse reactions, and cross-protection capability. Vaccine issues are commonly debated in veterinary journals and continuing education meetings; these are excellent sources of current information.

Not all dogs and cats need all available vaccines. Vaccines are not innocuous and should only be given if indicated. The type of vaccine and route of administration for the disease in question should also be considered. A benefit, risk, and cost assessment should be discussed with the owner of each individual animal before determining the optimal vaccination protocol. For example, FeLV only lives outside the host for minutes; it is highly unlikely that an owner would bring the virus into the household. Therefore cats housed indoors are not likely to come in contact with the virus.

Before administering vaccines, the animal should be evaluated for factors that may influence the ability to respond to the vaccine (Box 94-2) or that may affect whether vaccina-

BOX 94-2

#### Potential Causes of Vaccine Failure

- Protective immune responses were not stimulated by the antigens in the vaccine (humoral versus cell mediated).
- The animal was exposed to a field strain of the organism the vaccine fails to protect against.
- The vaccine-induced immune response waned by the time of exposure.
- The vaccine induced immune response was overwhelmed by the degree of exposure.
- The vaccine was handled or administered improperly.
- The animal was incubating the disease when vaccinated.
- The animal was unable to respond to the vaccine because of immunosuppression.
- The animal was unable to respond to the vaccine because of hypothermia or fever.
- The animal had maternal antibodies that lessened the response to vaccination.
- The modified-live product induced disease.

tion could be detrimental. Hypothermic animals have poor T-lymphocyte and macrophage function and are unlikely to respond appropriately to vaccination. Dogs with body temperature above 39.7° C respond poorly to canine distemper virus vaccines; this may be true for other vaccines as well. Immunosuppressed animals, including those with FeLV infection, FIV infection, canine parvovirus infection, Ehrlichia canis infection, and debilitating diseases, may not respond appropriately to vaccination; modified-live vaccines occasionally induce the disease in these animals.

If high levels of specific antibodies are present, vaccine efficacy is diminished. This is a particularly important consideration when vaccinating puppies or kittens from well-vaccinated dams. Disease may also develop in vaccinated puppies and kittens because infection had already occurred and was incubating when the animal was vaccinated. Vaccines can be rendered ineffective from mishandling. Vaccines should not be administered while the animal is under anesthesia because efficacy can be diminished; if a vaccine reaction occurs, it may be masked by the anesthesia.

Adverse reactions can potentially occur with any vaccine. However, they are relatively uncommon in dogs and cats. In a recent study of more than 1.2 million dogs, the overall rate of adverse reactions was 38.2/10,000 dogs that had received vaccines within the previous 3 days (Moore et al., 2005). In a recent study of 496,189 cats, the overall rate of adverse reactions was 51.6/10,000 cats that had received vaccines within the previous 30 days (Moore et al., 2007). Vaccination has been associated with soft tissue sarcomas in some cats and can be life threatening. These tumors can occur after administration of infectious or noninfectious vaccines. Intranasal products can result in transient sneezing and coughing. Feline vaccines for which the viruses were grown on Crandall Rees feline kidney cell cultures induce antibodies that cross-react with feline renal tissues (Lappin et al., 2005), and some hypersensitized cats have developed lymphocytic-plasmacytic interstitial nephritis (Lappin et al., 2006b). Whether this results in renal disease is currently unknown. Suspected adverse reactions to vaccination should be reported (Paul et al., 2006). Administration of any vaccine to animals with proven vaccine-associated sarcoma or immune-mediated diseases, such as immune-mediated polyarthritis, immune-mediated hemolytic anemia, immunemediated thrombocytopenia, glomerulonephritis, polyradiculoneuritis, is questionable because immune stimulation may exacerbate these conditions.

For some infectious agents, including canine distemper virus, canine parvovirus, feline panleukopenia virus (FPV), feline calicivirus (FCV), and FHV-1, serologic test results have been shown to correlate to resistance to disease on challenge in some studies. The advantages and disadvantages of the use of serologic testing were recently reviewed (Moore et al., 2006). If validated laboratories or kits are used, results can be used accurately to make vaccination decisions for some dogs and cats (Lappin et al., 2002). For example, previously vaccinated animals that were presumed to have had a vaccine reaction and are still at risk of exposure to infectious

agents could be assessed by serologic testing in lieu of arbitrary vaccination. In general, the positive predictive value of these tests is good (i.e., a positive test result usually predicts resistance on challenge).

#### **VACCINATION PROTOCOLS FOR CATS**

A physical examination, fecal parasite screen, and vaccine needs assessment should be performed at least yearly for all cats. The American Association of Feline Practitioners (AAFP) recently published the third version of the Feline Vaccine Advisory Panel Report (Richards et al., 2006; http://www.catvets.com). These guidelines are an excellent source of information for veterinarians to use when individualizing vaccination protocols. Vaccine antigens were divided into those that were considered core (FPV, FCV, FHV-1, and rabies), noncore (FeLV, FIV, Bordetella bronchiseptica, and Chlamydophila felis), and not generally recommended (Giardia and feline infectious peritonitis [FIP]). The following recommendations were adapted from the AAFP Panel Report.

#### **Core Vaccines**

Feline Panleukopenia Virus, Feline Calicivirus, Feline Immunodeficiency Virus-1. All healthy kittens and adult cats without a known vaccination history should be routinely vaccinated with an intranasal or parenteral vaccine that contains FPV, FCV, and FHV-1 (FVRCP). Multiple modified-live products and killed products are available, and the products available in the United States were recently reviewed (Richards et al., 2006). In general, modified-live FVRCP vaccines are recommended for kittens housed in environments at high risk for exposure to FPV. Modified-live FVRCP vaccines for intranasal administration can induce protection against FHV-1 as soon as 4 days after administration (Lappin and et al., 2006a), so this route of administration may be preferred for kittens housed in environments at high risk for exposure to FHV-1. Modified-live products should not be administered to clinically ill, debilitated, or pregnant animals. Owners should be informed that the administration of intranasal FVRCP vaccines can induce transient, mild sneezing or coughing.

For kittens believed to have no more than routine risk of exposure to FPV, FCV, or FHV-1, administration of FVRCP vaccines is recommended starting no sooner than 6 weeks of age, with boosters every 3 to 4 weeks until 16 weeks of age. Older kittens and adult cats with unknown vaccination history should receive two killed or two modified-live FVRCP doses 3 to 4 weeks apart.

For kittens believed to have high risk of exposure to FPV, such as those housed in animal shelters or pet stores, the AAFP panel currently recommends parenteral administration of modified-live FPV-containing vaccines as early as 4 weeks of age, particularly during an outbreak. However, intranasal administration of modified-live FVRCP vaccines instead of or in addition to parenteral administration of modified-live FVRCP vaccines may be superior for protection against FCV and FHV-1 in these environments.

The current AAFP Advisory Panel recommends a booster FVRCP vaccine 1 year later. However, a recent study showed that although no difference in FPV immunity occurred, the relative efficacy of FCV and FHV-1 vaccines were lower at 1 year after initial vaccination than at 4 weeks after initial vaccination (Poulet, 2007). The author concluded that the first FCV and FHV-1 booster vaccination after the completion of the initial series should be administered earlier than 1 year.

According to several challenge studies, administration of FVRCP vaccines does not appear to be needed more frequently than every third year after the 1-year booster vaccine; the duration of immunity may be much longer. As previously discussed, serologic test results for antibodies against FPV, FCV, and FHV-1 can be used to help determine vaccine needs (Lappin et al., 2002). (Validated serologic tests are available from New York State Veterinary Diagnostic Laboratory, Ithaca, and Heska Corporation, Loveland, Colo.)

Some variants of FCV induce systemic vasculitis in cats (virulent systemic calicivirus; VS-FCV), and clinical signs can be severe in some cats previously vaccinated with FVRCP vaccines (Hurley et al., 2004). A killed, VS-FCV-containing vaccine line is now available (Fort Dodge Animal Health, Overland Park, Kan.). Whether administration of this strain of FCV will be beneficial to cats is currently unknown. Factors to consider include the following. (1) The prevalence of VS-FCV infections is unknown and currently is believed to be rare. (2) The VS-FCV strains characterized to date have been genetically and antigenically distinct, so whether crossprotection among strains will occur is unknown. (3) The currently available vaccine line has only been shown to be effective against homologous challenge several weeks after completing the vaccine series, so the maximal duration of immunity is unknown. The AAFP recently published an informational brief on VJ-FCV (www.catvets.com). It is possible that use of two flu strains will help cross-protect against more flu strains than using one strain in vaccines.

Rabies. All cats should be vaccinated against rabies. Rabies vaccine should be administered subcutaneously in the distal right rear limb at the age recommended by the vaccine manufacturer (as early as 8 weeks depending on brand) in accordance with state and local statutes. Cats should be vaccinated 1 year later and then either annually or triennially according to state and local statutes and the vaccine product used. The currently available live virusvectored rabies vaccine (Merial, Duluth, Ga.) induces less inflammation than killed rabies vaccines, but whether this vaccine is less likely to be associated with soft tissue sarcomas is currently unknown.

## **Noncore Vaccines**

Bordetella bronchiseptica. The currently available Bordetella bronchiseptica vaccine for intranasal administration can be administered as early as 4 weeks of age, has an onset of immunity as early as 72 hours, and has a minimal duration of immunity of 1 year. Many cats have antibodies against B. bronchiseptica, the organism is commonly cultured from cats in crowded environments, and sporadic reports have been made of severe lower respiratory disease caused by bordetellosis in kittens and cats in crowded environments or other stressful situations. However, the significance of infection in otherwise healthy pet cats appears to be minimal. For example, in client-owned cats in northcentral Colorado, the organism was rarely cultured from cats with rhinitis or lower respiratory disease (approximately 3%). In addition, because the vaccine is administered by the intranasal route, mild sneezing and coughing can result. Bordetella vaccination should be considered primarily for use in cats at high risk for exposure and disease, such as those with a history of respiratory problems and living in shelters with culture-proven outbreaks. Because the disease is apparently not life threatening in adult cats, is uncommon in pet cats, and responds to a variety of antibiotics, routine use of this vaccine in client-owned cats seems unnecessary.

Chlamydophila felis. Killed and modified-live Chlamydophila felis-containing vaccines are available. Infection of cats by C. felis generally results in only mild conjunctivitis, is easily treated with antibiotics, has variable prevalence rates, and the organism is of minimal zoonotic risk to people. In addition, use of FVRCP vaccines that also contained C. felis was associated with more vaccine reactions in cats when compared with other products (Moore et al., 2007). Thus whether C. felis vaccination is ever necessary is controversial. The use of this vaccine should be reserved for cats with a high risk of exposure to other cats and in catteries with endemic disease. Duration of immunity for Chlamydophila vaccines may be short lived, so high-risk cats should be immunized before a potential exposure.

Feline Leukemia Virus. Several FeLV-containing vaccines are currently available. Some contain killed FeLV and an adjuvant, and others contain recombinant antigens of FeLV without adjuvant. In the United States the recombinant product is only available for delivery transdermally by a special device. Because of difficulties in assessing efficacy studies, which vaccine is optimal is unclear. The AAFP panel recommended vaccinating kittens for FeLV because they are more susceptible than adult cats, and their housing status may not have been determined at that time. Although administration of FeLV vaccines does not block proviral integration, FeLV-associated disease was lessened (Hofman-Lehmann et al., 2007). FeLV vaccines are most indicated in cats allowed to go outdoors or those who are exposed to cats of unknown FeLV status. Vaccinated cats should receive two vaccinations initially. Products with adjuvants should be administered subcutaneously in the distal left rear limb because of the risk for development of soft tissue sarcomas. Although the products without adjuvants are known to induce less inflammation, whether they are safer than the products containing adjuvants is currently unknown. Because little data are available concerning duration of immunity after 1 year, the AAFP Advisory Panel recommends annual boosters. The vaccine is not effective in persistently viremic cats and is therefore not indicated. However, administration of the vaccine to viremic or latently infected cats does not pose an increased risk of vaccine reaction. FeLV

testing should be performed before vaccination because the retrovirus serologic status of all cats should be known so appropriate husbandry can be maintained.

Feline Immunodeficiency Virus. A killed vaccine containing two FIV subtypes (clades A and D) is currently available for use in the United States (Fel-O-Vax FIV; Fort Dodge Animal Health). Administration of three doses, 3 to 4 weeks apart, starting no sooner than 8 weeks of age with annual boosters is currently recommended by the manufacturer. In prelicensing studies 689 cats received 2051 doses of vaccine, and adverse effects were detected in less than 1%. In a challenge study performed 375 days after inoculation with three doses (3 weeks apart), 84% of the vaccinated cats did not become infected with FIV, and 90% of the controls became infected, giving a preventable fraction of 82%. However, the efficacy and safety of the vaccine have not been assessed under field conditions in large numbers of cats exposed to multiple FIV subtypes (see Chapter 97). The primary problem with FIV vaccination at this time is that the vaccine induces antibodies detectable by the currently available antibody test. Thus after vaccination the practitioner will be unable to determine whether the cat is infected by FIV. Microchips are recommended so that owners of FIVvaccinated, seropositive cats can easily be found and euthanasia is not inadvertently performed because of the "FIV-positive status." Reverse-transcription polymerase chain reaction for detection of FIV provirus is available in some laboratories but, as discussed in Chapter 97, standardization and external quality control for laboratories providing this type of testing are not currently performed. The AAFP Advisory Panel recommends vaccinating only highrisk cats such as those that go outdoors and are known to fight and those housed with FIV-infected cats. Serologic testing should be performed before vaccination; the vaccine is not indicated in seropositive cats.

# **Vaccines not Generally Recommended**

Feline Infectious Peritonitis. A relatively safe coronavirus vaccine that may protect some cats from developing FIP is currently available for administration after 16 weeks of age. The vaccine may result in mild, transient sneezing because it is administered intranasally. Antibody-dependent enhancement of infectivity has not been detected in field studies. Results of the vaccine in field studies have been variable. If cats have previously been exposed to coronaviruses, the vaccine is unlikely to be effective (Fehr et al., 1997). Because the incidence of disease is low, cats are commonly exposed to coronaviruses before vaccination and the efficacy is questionable. The AAFP panel considered this vaccine as not generally recommended. The vaccine may be indicated for seronegative cats entering a known FIP-infected household or cattery.

**Giardia** spp. When administered twice, the currently available *Giardia* spp. vaccine lessened numbers of cysts shed and lessened clinical disease after challenge with one heterologous strain 1 year later. No published field studies currently prove the efficacy of the vaccine. In addition, multiple

Giardia spp. exist, including a feline-specific strain. Whether the vaccine is protective against strains other than the one used in challenge studies is unknown. In one study of experimentally infected cats, administration of three doses of the vaccine failed to change the course of cyst shedding with one strain of Giardia (Stein et al., 2003). Because giardiasis is usually not life threatening, typically responds to therapy, and vaccine efficacy has not been documented, the AAFP Advisory Panel considered this vaccine as not generally recommended.

#### **VACCINATION PROTOCOLS FOR DOGS**

A physical examination, fecal parasite screen, and vaccine needs assessment should be performed at least yearly for all dogs. The American Animal Hospital Association recently published the revised version of vaccination guidelines for dogs (Paul et al., 2006; http://www.aahanet.org/ PublicDocuments/VaccineGuidelines06Revised.pdf) that also included recommendations for use of canine vaccines in shelters. These guidelines are an excellent source of information for veterinarians to use when individualizing a vaccination protocol for dogs. Different forms of vaccine antigens were divided into those that were considered core, noncore, and not recommended. For two products (Crotalus atrox toxoid and Porphyromonas spp.), the Task Force chose to take no position because of a lack of experience and paucity of field validation of efficacy. The following discussion was adapted from those guidelines.

#### **Core Vaccines**

Canine Parvovirus, Canine Adenovirus, and Canine Distemper Virus. Because canine parvovirus (CPV-2), canine adenovirus 1 (CAV-1; infectious canine hepatitis), and canine distemper virus (CDV) can be lifethreatening diseases, all dogs should be vaccinated. For CPV-2, only modified-live products should be used because of increased risk of maternal antibody interference with killed products. Both modified-live CDV and recombinant CDV (rCDV)-containing vaccines are considered adequate by the AAHA Task Force. Because of adverse effects associated with CAV-1 vaccines and poor immune responses associated with killed CAV-2 or modified-live topical CAV-2 vaccines, only modified-live CAV-2 vaccines for parenteral administration should be used. These vaccines cross-protect against canine infectious hepatitis induced by CAV-1 and the kennel cough syndrome induced by CAV-2. All puppies should receive at least three CPV-2, CAV-2, and CDV-containing vaccines, every 3 to 4 weeks, between 6 and 16 weeks of age, with the last booster being administered at 14 to 16 weeks of age. Although one dose is likely protective, adult dogs with an unknown vaccination history can receive two doses 3 to 4 weeks apart. Puppies housed in shelters should be vaccinated on admission and then every 2 weeks while housed at the shelter or until 16 weeks of age. Vaccinated dogs should receive a booster vaccine 1 year later and then boosters at intervals of 3 years or longer. Several CDV-containing products, including the rCDV vaccine, were recently shown to

protect for at least 3 years (Abdelmagid et al., 2004; Larson et al., 2007).

Dogs should be evaluated at least yearly for risk of infection by CPV, CDV, and CAV during the physical examination and checked for enteric parasites. Positive serologic tests for CDV and CPV are predictive of resistance after challenge and can be used in lieu of arbitrary vaccine intervals if performed with validated assays. Dogs should complete the puppy series and be boosted at 1 year of age before using titers to help predict vaccine need. If the vaccination status of an adult dog is unknown, the dog should be vaccinated appropriately and then serologic assessment considered in subsequent years.

**Rabies.** All dogs should be vaccinated against rabies as early as 12 weeks of age. One-year and 3-year killed rabies products are available and should be administered according to the manufacturer's recommendations and state and local statutes. Both puppies and adult dogs with unknown vaccination history should be administered one dose and return for a booster vaccination 1 year later. Intervals and product after that booster should be based on state and local statutes.

#### **Noncore Vaccines**

**Bordetella bronchiseptica.** In general, *B. bronchiseptica* rarely causes life-threatening disease in otherwise healthy animals and is not the only cause of kennel cough syndrome. It is therefore considered a noncore vaccine. In addition, genetic information suggests that field strains of the bacterium vary considerably from vaccine strains, which may affect vaccine efficacy (Keil et al., 1999). Although parenteral products induce strong serum antibody responses, in one study intranasal administration was associated with superior protection on challenge (Davis et al., 2007). Booster vaccines should optimally be administered 7 days before potential exposure. No more than two boosters are needed per year.

Borrelia burgdorferi. The pros and cons of administering B. burgdorferi vaccines were discussed in depth in a recent American College of Veterinary Internal Medicine Consensus Statement (Littman et al., 2006; http://www. acvim.org). The AAHA Task Force suggested that B. burgdorferi vaccination only be considered in dogs with a known high risk of exposure (Paul et al., 2006). Depending on the product used, vaccination can start at 9 or 12 weeks of age and a second dose is recommended 2 to 4 weeks later, with annual boosters. Vaccination will not likely benefit a dog positive for antibody against the C6 peptide because most C6 antibody-positive dogs have already been infected. Whether vaccination protects against or is associated with Lyme nephropathy is unknown; the syndrome has been detected both in vaccinated and nonvaccinated dogs. Maintaining tick control is an important part of prevention of this disease.

**Distemper-Measles Virus.** This modified live product was used previously between 4 and 12 weeks of age to attempt to breakthrough maternal immunity to CDV. The need for this product is now in question because the rCDV vaccine immunizes puppies in the presence of maternal immunity.

Leptospira interrogans. Vaccines containing multiple Leptospira interrogans serovars (canicola, icterohaemorrhagiae, grippotyphosa, and pomona) are generally recommended for dogs with high risk in known endemic areas. However, some serovars in the environment are not in any vaccine, and minimal cross-protection exists between serovars. Thus clients should realize that even though their dog has been given a Leptospira vaccine, 100% protection cannot be guaranteed. Newer generation vaccines have fewer adverse effects than previous vaccines. If the vaccines are to be used, puppies should receive the first dose at 12 weeks of age with a booster 2 to 4 weeks later. Adults should receive two doses 2 to 4 weeks apart. Annual revaccination is recommended for vaccines containing the four serovars.

**Parainfluenza Virus.** Multiple products that contain CPV-2, CDV, and CAV-2 also contain modified-live parainfluenza, so they are commonly administered at the same schedule of those core vaccine antigens. Considered alone, parainfluenza is noncore because it is not life threatening, is not zoonotic, and is a self-limited cause of kennel cough syndrome. A modified-live strain for intranasal administration combined with a live avirulent strain of *B. bronchiseptica* is also available. If used, the intranasal vaccine can be administered as early as 3 weeks of age; transient sneezing and coughing can occur. Booster vaccines are administered following the same schedule as the antigens in which parainfluenza is combined.

#### Not Recommended

As previously discussed, killed CPV-2 vaccines, MLV or killed CAV-1 vaccines, killed CAV-2 vaccines, and modified-live CAV-2 vaccines for topical administration are considered not recommended by the AAHA Task Force. The following vaccines are also considered not recommended.

**Coronavirus.** Coronavirus infection in dogs results in mild gastrointestinal disease unless concurrent infection with parvovirus occurs. The virus rarely causes disease in dogs after 6 weeks of age. In one study of healthy dogs and dogs with diarrhea, coronavirus was only detected in one healthy dog. Based on these findings, vaccination against coronavirus is not indicated in dogs.

Giardia spp. When administered twice, the currently available Giardia spp. vaccine lessened numbers of cysts shed and lessened clinical disease after challenge with one heterologous strain 1 year later. Several field studies of the vaccine have been carried out in dogs; none has documented lessening of giardiasis in asymptomatic dogs (Anderson et al., 2004). Dog-specific Giardia strains have become apparent; vaccine efficacy against these strains is unknown. Because giardiasis is usually not life threatening, typically responds to therapy, and vaccine efficacy has not been documented, the AAHA Task Force considers this vaccine to not be generally recommended. In one study of 17 dogs with resistant giardiasis, cyst shedding and diarrhea resolved in all dogs after administration of two doses of Giardia vaccine, so it may be effective as an immunotherapy in some dogs (Olson et al., 2001).

#### Insufficient Information

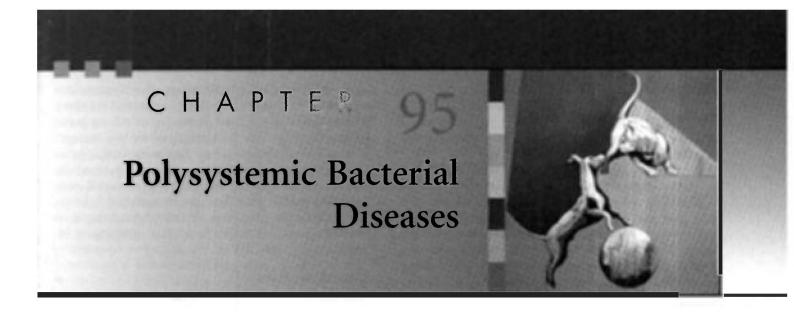

**Periodontal Disease Vaccine.** The *Porphyromonas* spp. vaccine is designed to aid in the prevention and control of periodontal disease in dogs. Because efficacy has not been determined, the AAHA Task Force declined to take a position on this vaccine (Paul et al., 2006).

**Rattlesnake Vaccine.** The *Crotalus atrox* toxoid vaccine was designed to protect dogs against the venom of the Western Diamondback Rattlesnake. Some cross-protection may exist against the Eastern Diamondback Rattlesnake but not the Mojave Rattlesnake. Local reactions to this toxoid are common. Because efficacy has not been determined, the AAHA Task Force declined to take a position on this vaccine (Paul et al., 2006).

# CHAPTER OUTLINE

CANINE BARTONELLOSIS
FELINE BARTONELLOSIS
FELINE PLAGUE
LEPTOSPIROSIS
MYCOPLASMA AND UREAPLASMA

# CANINE BARTONELLOSIS

# **Etiology and Epidemiology**

Bartonella vinsonii subspecies berkhoffii was initially isolated from a dog with endocarditis in North Carolina (Breitschwerdt et al., 1995). Since that time, dogs in multiple areas of the world have been shown to seroreact with B. vinsonii (berkhoffii) antigens. B. vinsonii (berkhoffii) is thought to be tickborne. Serum of some infected dogs also seroreacts with B. henselae and B. clarridgeiae antigens; these Bartonella species are transmitted by fleas. Bartonella species that have been isolated from dogs or from which DNA has been amplified from blood or tissues include B. vinsonii (berkhoffii), B. henselae, B. clarridgeiae, B. washoensis, B. quintana, and B. elizabethae. Each of these organisms potentially can induce illness in dogs. Dogs infected with a Bartonella species are commonly coinfected with other agents, such as Anaplasma spp. or Ehrlichia spp., which may play a role in the pathogenesis of disease.

# **Clinical Features**

Clinical findings or syndromes most frequently attributed to *Bartonella* spp. infections of dogs include endocarditis, fever, arrhythmias, hepatitis, granulomatous lymphadenitis, cutaneous vasculitis, rhinitis, polyarthritis, meningoencephalitis, thrombocytopenia, eosinophilia, monocytosis, immunemediated hemolytic anemia, epistaxis, and uveitis. *B. vinsonii* (berkhoffii) and *B. henselae* seem to be the most likely species

to be associated with clinical disease (Breitschwerdt et al., 2004; Goodman and Breitschwerdt, 2005; Henn et al., 2005). In one study of valvular endocarditis, all dogs with *Bartonella* spp.—associated disease were also seropositive for *Anaplasma phagocytophilum* (MacDonald et al., 2004). Whether the coinfection potentiated the *Bartonella*-associated disease is unknown.

# Diagnosis

Serum antibodies can be detected in both healthy and clinically ill dogs, so the presence of antibodies does not always correlate to illness. Some *Bartonella* species, in particular *B. vinsonii (berkhoffii)*, can be difficult to culture; amplification of DNA by polymerase chain reaction (PCR) assay with or without culture is often needed to confirm infection (Duncan et al., 2007). If positive test results are detected in a clinically ill dog and no other explanation for the illness is obvious, treatment is indicated.

#### **Treatment**

Because many cases of bartonellosis in dogs have been apparently resistant to administration of doxycycline, some clinicians believe that azithromycin is the treatment of choice. Fluoroquinolones, alone or in combination with azithromycin, were apparently effective for the treatment of some dogs with suspected clinical bartonellosis. Rifampin may be required for resistant cases. No matter which drug is used, a minimum of 4 to 6 weeks of treatment is usually needed. In one study successfully treated dogs became seronegative (Breitschwerdt et al., 2004).

# **Zoonotic Aspects and Prevention**

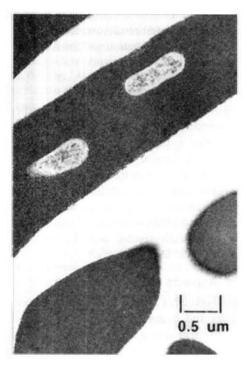

B. vinsonii (berkhoffii) and B. henselae have been detected in both dogs and human beings, and cat scratch disease has been documented in a human being after exposure to a dog (Chen et al., 2007). Care should be taken to avoid bites or scratches while handling or treating infected dogs. Flea and tick control is likely to lessen transmission of Bartonella species between dogs and perhaps from dogs to people.

# **FELINE BARTONELLOSIS**

# **Etiology and Epidemiology**

Cats have been proven to be infected by B. henselae, B. clarridgeiae, B. koehlerae, B. quintana, and B. bovis by culture or DNA amplification (Brunt et al., 2006). Antibodies against B. elizabethae have been detected in some cats, but these results should be interpreted cautiously because of the serologic cross-reactivity among Bartonella spp. Cats are the main reservoir hosts for B. henselae and B. clarridgeiae and are likely the reservoir for B. koehlerae. B. henselae is the most common cause of cat scratch disease as well as bacillary angiomatosis and peliosis hepatis, common disorders in human beings with acquired immunodeficiency syndrome. Bartonella species have both intraendothelial and intraerythrocytic phases of infection (Fig. 95-1). The intracellular location may relate to the difficulties in permanently eliminating bacteremia (Kordick and Breitschwerdt, 1995; Seubert et al., 2002).

On the basis of results of seroprevalence studies, culture, or PCR assay, cats are commonly exposed to or infected by *Bartonella* species. The organism is transmitted between cats by *Ctenocephalides felis*, so prevalence is greatest in cats from regions where fleas are common. A recent study in the United States collected fleas from cats and attempted to amplify *Bartonella* species DNA from flea digests as well as the blood of the cat (Lappin et al., 2006). The prevalence rates for *B. henselae* in cats and their fleas were 34.8% and 22.8%, respectively. The prevalence rates for *B. clarridgeiae* in cats and

**FIG 95-1** Electron micrograph of a feline erythrocyte showing intracellular *Bartonella henselae*. (Courtesy Dr. Dorsey Kordick.)

their fleas were 20.7% and 19.6%, respectively. Results have been similar in other studies performed around the world. *B. henselae* survives in flea feces for days after being passed by infected *C. felis*. Infected flea feces are likely to contaminate cat claws during grooming, then *Bartonella* species are inoculated into the person when scratched. Open wounds also may be contaminated with infected flea feces. However, *Bartonella* species DNA can also be amplified from the mouths of healthy cats and those with gingivostomatitis, so bites and scratches should be avoided (Quimby et al., 2007).

#### **Clinical Features**

Most cats with serologic evidence of exposure to Bartonella spp., Bartonella spp. cultured from blood, or microbial DNA amplified from blood by PCR assay are clinically normal. However, Bartonella spp. infection of cats has also been associated directly or indirectly with a variety of clinical manifestations such as fever, lethargy, lymphadenopathy, uveitis, gingivitis, and neurologic diseases. How often cats become ill from Bartonella spp. infections is unknown, and more information is needed. For example, the association of B. henselae infection to uveitis in a cat was first made in an individual case with uveitis that ultimately responded to doxycycline therapy (Lappin and Black, 1999; Lappin et al. 2000) subsequently found Bartonella antibody production and DNA in the aqueous humor of cats previously presumed to have idiopathic uveitis. A series of clinical cases of feline ocular disease that were responsive to antibiotic therapy was recently reported (Ketring et al., 2004). Thus Bartonella species appears to cause ocular disease in some cats. However, which cats have been exposed and which cats are diseased can be difficult to determine. In one study of feral cats in North Carolina the seroprevalence rate was 93% (Nutter et al., 2005). In another study the presence of Bartonella species antibodies failed to correlate to the presence of most clinical syndromes in ill cats (Breitschwerdt et al., 2005b). In recent studies in the author's laboratory, the prevalence rates for Bartonella species antibodies in feline sera were not significantly different for cats with or without seizures (Pearce et al., 2006) or cats with or without stomatitis (Dowers et al., 2005). Why some cats develop Bartonella-associated illness and others do not is still not clear. For example, Powell et al. (2002) failed to induce Toxoplasma gondii or Bartonella species uveitis when Bartonella was intravenously inoculated into cats with chronic toxoplasmosis.

#### Diagnosis

Blood culture, PCR assay on blood, and serologic testing can be used to assess individual cats for *Bartonella* spp. infection. Cats that are culture negative or PCR negative and antibody negative and cats that are culture negative or PCR negative and antibody positive are probably not a source of flea, cat, or human infection. However, bacteremia can be intermittent and false-negative culture or PCR results can occur, limiting the predictive value of a single battery of tests. False-positive results can occur with PCR, and positive results do

not necessarily indicate that the organism is alive. Although serologic testing can be used to determine whether an individual cat has been exposed, both seropositive and seronegative cats can be bacteremic, limiting the diagnostic utility of serologic testing. Thus testing healthy cats for Bartonella spp. infection is not currently recommended (Brunt et al., 2006). Testing should be reserved for cats with suspected clinical bartonellosis. If the results of Bartonella tests are negative in a clinically ill cat, the organism is not likely the cause of the clinical syndrome unless the infection was peracute and serologic testing was used as the diagnostic test. If the results of Bartonella tests are positive, the agent remains on the list of differential diagnoses, but other causes of the clinical syndrome must also be excluded. The American Association of Feline Practitioners (AAFP) Bartonella Panel Report suggests that the diagnosis of clinical bartonellosis include the following combination of findings (Brunt et al., 2006):

- · Presence of a syndrome reported to be associated with Bartonella spp. infection
- · Exclusion of other causes of the clinical syndrome
- Detection of a positive Bartonella spp. test (culture, PCR assay, or serology)
- Response to administration of a drug with presumed anti-Bartonella activity

However, fulfillment of these criteria does not always prove a definitive diagnosis. The antibiotics used for the treatment of bartonellosis in cats generally have a broad spectrum, are effective for other infecting organisms that can cause syndromes resembling bartonellosis, and can also have antiinflammatory properties.

#### **Treatment**

In experimental studies administration of doxycycline, tetracycline, erythromycin, amoxicillin-clavulanate, and enrofloxacin can limit bacteremia but does not cure infection in all cats. To date, use of antibiotics in healthy cats has not been shown to lessen the risk of cat scratch disease (Brunt et al., 2006). In addition, treating healthy cats with antibiotics that do not eliminate infection may predispose to resistant stains of the organism. Thus in the United States treatment is generally recommended for clinically ill cats. If clinical bartonellosis is suspected, the AAFP Panel Report recommends doxycycline at 10 mg/kg PO daily for 7 days as the initial therapeutic trial (Brunt et al., 2006). Doxycycline should be formulated into a flavored suspension or water should be administered after pilling to avoid esophageal strictures. If a beneficial response is achieved, continue treatment for 2 weeks past clinical resolution of the disease or for a minimum of 28 days. If a poor response is achieved by day 7 or doxycycline is not tolerated and bartonellosis is still a valid differential diagnosis, azithromycin or a fluoroquinolone is a good second choice. Other differential diagnoses should be considered for Bartonella spp.-positive cats that have not responded after administration of two different drugs with presumed anti-Bartonella activity. Because cats can be reinfected with Bartonella spp., clinical value to following results of Bartonella spp. tests seems to be minimal if the cat is clinically normal.

# **Zoonotic Aspects and Prevention**

Bartonella spp. infections are an occupational risk for veterinary health care providers (Breitschwerdt et al., 2007). To lessen the likelihood of acquiring a Bartonella species infection from a cat, the following adaptations of recommendations to HIV-infected people and other cat owners by the Centers for Disease Control and Prevention and the American Association of Feline Practitioners have been developed:

- · Flea control should be initiated and maintained year round
- If a family member is immunocompromised and a new cat is to be acquired, adopt a healthy cat older than 1 year and free of fleas.
- · Immunocompromised individuals should avoid contact with cats of unknown health status.
- · Declawing of cats is generally not required, but claws should be trimmed regularly.
- Bites and scratches should be avoided (including rough play with cats).
- Cat-associated wounds should be washed promptly and thoroughly with soap and water and medical advice
- · Although Bartonella species have not been shown to be transmitted by saliva, cats should not be allowed to lick open wounds.
- · Keep cats indoors to minimize hunting and exposure to fleas and other possible vectors.

The Centers for Disease Control and Prevention do not recommend testing or treating healthy cats for Bartonella spp. infections.

# **FELINE PLAGUE**

# **Etiology and Epidemiology**

Yersinia pestis is the facultatively anaerobic gram-negative coccobacillus that causes plague. The organism is maintained in a sylvan life cycle between rodent fleas and infected rodents, including rock squirrels, ground squirrels, and prairie dogs. Cats are susceptible to infection and can die after natural or experimental infection; dogs are highly resistant to infection. Antibodies against Y. pestis are also detected in serum of nondomestic felids (Biek et al., 2006). Clinical disease is recognized most frequently from spring through early fall, when rodents and rodent fleas are most active. Most of the cases in human beings and cats have been documented in Colorado, New Mexico, Arizona, California, and Texas (Undisclosed authors, 2006). Of the cases of human plague diagnosed from 1977 to 1998, 23 (7.7%) resulted from contact with infected cats (Gage et al., 2000).

BOX 95-1

Clinical Findings in Cats with Yersinia pestis Infection (Plague)

#### **Signalment**

All ages, breeds, and gender

#### **History and Physical Examination**

Outdoor cats

Male cats

Hunting of rodents or exposure to rodent fleas

Depression

Cervical swellings, draining tracts, lymphadenopathy Dyspnea or cough

#### Clinicopathologic and Radiographic Evaluation

Neutrophilia with or without a left shift Lymphopenia

Neutrophilic lymphadenitis or pneumonitis

Homogenous population of bipolar rods cytologically (lymph node aspirate or airway washings)

Serum antibody titers, either negative (peracute) or positive

Interstitial and alveolar lung disease

#### Diagnosis

Culture of blood, exudates, tonsillar region, respiratory secretions

Fluorescent antibody identification of organism in exudates

Fourfold increase in antibody titer and appropriate clinical signs

Cats are infected after being bitten by infected rodent fleas, after ingestion of bacteremic rodents, or after inhalation of the organism. After ingestion, the organism replicates in the tonsils and pharyngeal lymph nodes, disseminates in the blood, and results in a neutrophilic inflammatory response and abscess formation in infected tissues. The incubation period is 2 to 6 days after a flea bite and 1 to 3 days after ingestion or inhalation of the organism. Outcomes in experimentally infected cats include death (six of 16 cats; 38%), transient febrile illness with lymphadenopathy (seven of 16 cats; 44%), or inapparent infection (three of 16 cats; 18%) (Gasper et al., 1993).

#### **Clinical Features**

Bubonic, septicemic, and pneumonic plague develop in infected human beings and cats (Box 95-1); clinical disease is extremely rare in dogs (Orloski et al., 1995). Bubonic plague is the most common form of the disease in cats, but individual cats can show clinical signs of all three syndromes. Most infected cats are housed outdoors and have a history of hunting. Anorexia, depression, cervical swelling, dyspnea, and cough are common presenting complaints; fever is detected in most infected cats. Unilateral or bilateral enlarged tonsils, mandibular lymph nodes, and anterior cervical

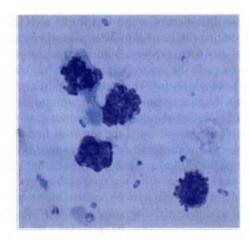

FIG 95-2 Lymph node aspirate from a cat with bubonic plague stained with Wright's stain. Bipolar rods are scattered throughout the field.

lymph nodes are detected in approximately 50% of infected cats. Cats with pneumonic plague commonly have respiratory signs and may cough.

# **Diagnosis**

Hematologic and serum biochemical abnormalities reflect bacteremia and are not specific for *Y. pestis* infection. Neutrophilic leukocytosis, left shift and lymphopenia, hypoalbuminemia, hyperglobulinemia, hyperglycemia, azotemia, hypokalemia, hypochloremia, hyperbilirubinemia, and increased activities of alkaline phosphatase and alanine transaminase are common. Pneumonic plague causes increased alveolar and diffuse interstitial densities on thoracic radiographs. Cytologic examination of lymph node aspirates reveals lymphoid hyperplasia, neutrophilic infiltrates, and bipolar rods (Fig. 95-2).

Cytologic demonstration of bipolar rods on examination of lymph node aspirates, exudates from draining abscesses, or airway washings combined with a history of potential exposure, the presence of rodent fleas, and appropriate clinical signs lead to a presumptive diagnosis of feline plague. Because some cats survive infection and antibodies can be detected in serum for at least 300 days, detection of antibodies alone may indicate only exposure, not clinical infection. However, demonstration of a fourfold increase in antibody titer is consistent with recent infection. A definitive diagnosis is made by culture or fluorescent antibody demonstration of *Y. pestis* in smears of the tonsillar region, lymph node aspirates, exudates from draining abscesses, airway washings, or blood.

#### **Treatment**

Supportive care should be administered as indicated for any bacteremic animal (see Chapter 93). Cervical lymph node abscesses should be drained and flushed with the clinician wearing gloves, a mask, and a gown. Parenteral antibiotics should be administered until anorexia and fever resolve.

Optimal antibiotics for treatment of plague in infected cats in the United States are unknown. Streptomycin administered intramuscularly at 5 mg/kg q12h was used historically but is not widely available. Cats treated with gentamicin intramuscularly or intravenously at 2 to 4 mg/kg q12-24h, or enrofloxacin intramuscularly or intravenously at 5.0 mg/ kg q24h, has resolved clinical signs. Chloramphenicol administered orally or intravenously at 15 mg/kg q12h can be used in cats with central nervous system signs. Antibiotics should be administered orally for 21 days after the cat has survived the bacteremic phase; doxycycline at 5 mg/kg q12-24h or tetracycline at 20 mg/kg q8h is an appropriate choice. Care should be taken to avoid tetracycline-associated esophageal strictures by giving water after drug administration or liquefying the product. In one study 90.9% of cats treated with antibiotics survived, whereas only 23.8% of untreated cats survived (Eidson et al., 1991). The prognosis is poor for cats with pneumonic or septicemic plague.

# **Zoonotic Aspects and Prevention**

Cats should be housed indoors and not allowed to hunt. Flea control should be used and the rodent population should be controlled if possible. Tetracycline or doxycycline at the doses listed for therapy should be administered for 7 days to animals with potential exposure. Human infection occurs after contact with infected fleas; contact with the tissues or exudates from infected animals, including cats; and from bites and scratches from infected cats. Even though fomite transmission is unlikely, because the organism is sensitive to drying it can survive for weeks to months in infected carcasses and for up to 1 year in infected fleas. Cats from endemic areas with clinical signs of bacteremia, respiratory tract disease, or cervical draining areas or masses in the spring, summer, and early fall months should immediately be treated for fleas and handled with the clinician wearing gloves, a mask, and a gown until the diagnosis is made or discarded. While hospitalized, infected cats should be handled by as few personnel as possible while in isolation. Exposed people should see their physicians to discuss prophylactic antibiotic therapy; antimicrobial-resistant strains of Y. pestis are uncommon (Welch et al., 2007). Cats are not infectious to human beings after 3 days of antibiotic therapy. Areas where infected cats are handled should be thoroughly cleaned with routine disinfectants (see Chapter 94).

#### LEPTOSPIROSIS

# **Etiology and Epidemiology**

Leptospires are 0.1 to 0.2 μm wide by 6 to 12 μm long, motile, filamentous spirochetes that infect animals and human beings. Leptospirosis can be caused by many different serovars of Leptospira interrogans and L. kirschneri (Table 95-1). Seropositive dogs have been detected in many countries, and the most prevalent serovars vary by country and regions within countries. In the United States antibodies against L. autumnalis, L. bratislava, L. canicola, L. grippoty-

TABLE 95-1

Reservoirs for Leptospira Serovars Known to Infect Dogs

SEROVAR	PRIMARY RESERVOIR
L. bataviae L. bratislava L. canicola L. grippotyphosa L. harjo L. icterohaemorrhagiae L. pomona L. tarassovi	Dog, rat, mouse Pig, horse, dog Dog Vole, raccoon, skunk, opossum Cow Rat Pig, skunk, opossum Cow, pig

phosa, L. hardjo, L. icterohaemorrhagiae, and L. pomona have been detected most commonly. Cats are infected by L. bratislava, L. canicola, L. grippotyphosa, and L. pomona but appear to be resistant to clinical disease.

Prevalence and risk factors for cases of canine leptospirosis have been evaluated in several studies in the last few years (Ward et al., 2002; Boutilier et al., 2003; Ward et al., 2004ab; Goldstein et al., 2006; Ghneim et al., 2007; Stokes et al., 2007). In the United States the number of seropositive dogs increased between 2002 and 2004 (Moore et al., 2006). Infection by leptospires occurs in both rural and suburban environments in semitropical areas of the world with alkaline soil conditions. Exposure to water outdoors, wetlands, and public open spaces were identified as risk factors in one case-control study (Ghneim et al., 2006). Clinical cases are most commonly diagnosed in the summer and early fall, and numbers of cases often increase in years with heavy rainfall. Infection by host-adapted species results in subclinical infection; the host acts as a reservoir, shedding the organism intermittently. Infection by non-host-adapted species results in clinical illness. Leptospires are passed in urine and enter the body through abraded skin or intact mucous membranes. Transmission also occurs through bite wounds; by venereal contact; transplacentally; and by ingestion of contaminated tissues, soil, water, bedding, food, and other fomites. In a recent experimental study L. pomona but not L. bratislava was successfully transmitted by conjunctival inoculation and resulted in fever and lethargy starting within 7 days (Greenlee et al., 2005). Hosts with preexisting antibody titers usually eliminate the organism quickly and remain subclinically infected. Leptospires replicate in multiple tissues of nonimmune hosts or hosts infected by a non-host-adapted species; in the dog the liver and kidneys develop the highest levels of infection. Inflammation induced by organism replication and production of toxins leads to renal, hepatic, or pulmonary disease. Dogs that are treated or develop appropriate immune responses usually survive. Some animals clear the infection 2 to 3 weeks after exposure without treatment but develop chronic active hepatitis or chronic renal disease. Cats are generally subclinically affected but may shed the organism into the environment for variable periods after exposure.

# **Clinical Findings**

Dogs of any age or breed or either gender can develop leptospirosis if not previously immune. Male, middle-aged, herding dogs; hounds; working dogs; and mixed breeds are at greater risk than companion dogs younger than 1 year (Ward et al., 2002). Most dogs have subclinical infection. Dogs with peracute clinical disease are usually presented for evaluation of anorexia, depression, generalized muscle hyperesthesia, tachypnea, and vomiting (Box 95-2). Fever,

BOX 95-2

Clinical Findings in Dogs with Leptospirosis

#### Signalment

All ages, breeds, and gender Greatest risk in young adult, male, working dogs

#### History

Exposure to appropriate reservoir host or contaminated environment

Anorexia, depression, lethargy

#### **Physical Examination**

Fever

Anterior uveitis

Hemorrhagic tendencies, including melena, epistaxis, petechiae, and ecchymoses

Vomiting, diarrhea

Muscle or meningeal pain

Renomegaly with or without renal pain

Hepatomegaly

Polyuria/polydipsia

lcterus

Coughing or respiratory distress

#### Clinicopathologic and Radiographic Evaluation

Thrombocytopenia

Leukopenia (acute)

Leukocytosis (subacute)

Azotemia

Suboptimal urine concentrating ability

Pyuria and hematuria without obvious bacteriuria

Hyperbilirubinemia and bilirubinuria

Increased activities of alanine transaminase, aspartate transaminase, alkaline phosphatase, and creatine kinase

Interstitial to alveolar lung disease

Hepatomegaly or renomegaly

#### Diagnosis

Culture of urine, blood, or tissues

Demonstration of the organism in urine by darkfield or phase-contrast microscopy

Demonstration of organismal DNA in urine, blood, or tissues by PCR

Combination of increasing antibody titer with clinical signs and response to therapy

pale mucous membranes, and tachycardia are usually present. Petechiae, ecchymoses, melena, and epistaxis occur frequently from thrombocytopenia and disseminated intravascular coagulation. Peracute infections may rapidly progress to death before marked renal or hepatic disease is recognized.

Fever, depression, and clinical signs or physical examination findings consistent with hemorrhagic syndromes, hepatic disease, renal disease, or a combination of hepatic and renal disease are common in subacutely infected dogs. Conjunctivitis, panuveitis, rhinitis, tonsillitis, cough, and dyspnea occur occasionally. Oliguric or anuric renal failure can develop during the subacute phase. Clinical findings can vary based on the infecting serovar (Goldstein et al., 2006).

Some dogs that survive peracute or subacute infection develop chronic interstitial nephritis or chronic active hepatitis. Polyuria, polydipsia, weight loss, ascites, and signs of hepatic encephalopathy secondary to hepatic insufficiency are the most common manifestations of chronic leptospirosis.

# **Diagnosis**

Multiple nonspecific clinicopathologic and radiographic abnormalities occur in dogs with leptospirosis and vary depending on the host, the serovar, and whether the disease was peracute, subacute, or chronic. Leukopenia (peracute leptospiremic phase), leukocytosis with or without a left shift, thrombocytopenia, regenerative anemia (from blood loss), or nonregenerative anemia (from chronic renal or hepatic disease) are common hematologic abnormalities. Hyponatremia; hypokalemia; hyperphosphatemia; hypoalbuminemia; hypocalcemia; azotemia; hyperbilirubinemia; decreased total carbon dioxide concentrations; and increased activities of alanine transaminase, alkaline phosphatase, and aspartate transaminase are common serum biochemical abnormalities that develop from renal disease, hepatic disease, gastrointestinal losses, or acidosis. Hyperglobulinemia is detected in some dogs with chronic leptospirosis. Dogs with myositis may have increased creatine kinase activity. Urinalysis abnormalities include bilirubinuria, suboptimal urine specific gravity in the face of azotemia, granular casts, and increased numbers of granulocytes and erythrocytes. The organism is not seen in the urine sediment by light microscopy. Renomegaly, hepatomegaly, and interstitial or alveolar pulmonary infiltrates are common radiographic abnormalities. Mineralization of the renal pelves and cortices can occur with chronic leptospirosis.

Detection of anti-Leptospira antibodies is commonly performed by a microscopic agglutination test. Because of the wide range of leptospires infecting dogs, as many serovars as possible should be used for screening. L. bratislava, L. canicola, L. grippotyphosa, L. hardjo, L. icterohaemorrhagiae, and L. pomona are commonly used. Positive titers can result from active infection, previous infection, or vaccination. Antibody titers can be negative in animals with peracute disease; seronegative dogs with classic clinical disease should be retested in 2 to 4 weeks. The serovar with the highest titer is usually considered the infecting serovar, but this should be

interpreted cautiously. When the same sera were sent to different laboratories, the results were not always in agreement for the serovar giving the highest titer (Miller et al., 2007).

Documentation of seroconversion (negative result becoming positive over time), a single microscopic agglutination test titer greater than 1:3200, or a fourfold increase in antibody titers combined with appropriate clinicopathologic abnormalities and clinical findings, are suggestive of clinical leptospirosis. A definitive diagnosis is made by demonstrating the organism in urine, blood, or tissues. The organism can be seen in urine using darkfield or phasecontrast microscopy, but because of intermittent shedding of small numbers of organisms these procedures can be falsely negative. The organism can be cultured from urine collected by cystocentesis, blood, or renal or hepatic tissue. Materials for culture should be collected before administration of antibiotics, placed in transport media immediately after collection, and transported to the laboratory as quickly as possible. Leptospiremia can be of short duration, and urine shedding of the organism can be intermittent, giving false-negative results. PCR can be used to demonstrate the organism in urine, blood, or tissues (Harkin et al., 2003a, 2003b). In one study of 500 dogs, 41 (8.2%) were PCR positive for a Leptospira spp. in urine, and some of these dogs were clinically normal (Harkin et al., 2003a). None of the PCR-positive dogs was culture positive, and titers were not always elevated.

#### Treatment

Fluid therapy is required for most dogs; intense diuresis for renal involvement may be required (see Chapter 44). Hemodialysis may increase the probability of survival in dogs with oliguric or anuric renal failure. Dogs should be treated during the initial treatment period with ampicillin administered intravenously at 22 mg/kg q8h or penicillin G administered intramuscularly or intravenously at 25,000 to 40,000 U/kg q12h. Some quinolones have an effect against leptospires and can be used in combination with penicillins during the acute phase of infection. Ampicillin and enrofloxacin were used concurrently in one study; 83% of infected dogs survived (Adin et al., 2000). Penicillins such as amoxicillin or amoxicillin clavulanate should be administered for 2 weeks. Doxycycline administered orally at 2.5 to 5.0 mg/kg q12h for 2 weeks after penicillin therapy should be used to eliminate the renal carrier phase.

# **Zoonotic Aspects and Prevention**

All mammalian serovars should be considered potentially zoonotic to human beings. Some human beings have antibodies against canine serovars, suggesting the dog can be a reservoir for human infection (Brod et al., 2005). Infected urine, contaminated water, and reservoir hosts should be avoided. Infected dogs should be handled with the clinician wearing gloves. Contaminated surfaces should be cleaned with detergents and disinfected (see Chapter 94).

To lessen risk of exposure, owners should attempt to restrict dogs from drinking potentially contaminated water.

Vaccines available for some serovars reduce the severity of disease. Vaccination against serovars *L. canicola* and *L. ictero-haemorrhagiae* can induce serologic cross-reactivity against serovars not contained in the vaccine, but cross-protection against other serovars is not always induced (Barr et al., 2005). Products containing serovars *L. canicola*, *L. ictero-haemorrhagiae*, *L. grippotyphosa*, and *L. pomona* are now available and provide the greatest spectrum of protection (see Chapter 94). Vaccination can lessen shedding of leptospires in the urine; not all vaccines perform the same (Andre-Fontaine et al., 2003; Schreiber et al., 2005). Dogs in endemic areas should receive three vaccinations 2 to 3 weeks apart. The duration of immunity is longer than 1 year in dogs receiving three vaccinations.

# MYCOPLASMA AND UREAPLASMA

# **Etiology and Epidemiology**

Mycoplasma spp. and Ureaplasma spp. are small, free-living microorganisms that lack a rigid, protective cell wall and depend on the environment for nourishment. Some Mycoplasma spp. and Ureaplasma spp. are considered normal flora of mucous membranes. For example, Mycoplasma spp. have been isolated from the vagina of 75% of healthy dogs (Doig et al., 1981), the pharynx of 100% of healthy dogs, and the pharynx of 35% of healthy cats (Randolph et al., 1993). Haemobartonella felis and H. canis were recently shown to be Mycoplasmas. Cats are infected by three species, M. haemofelis, "Candidatus M. haemominutum," and "Candidatus M. turicensis." Dogs are infected by two species, M. haemocanis and Candidatus M. haematoparvum. These organisms are associated with red blood cells and may result in the development of anemia. These organisms are discussed in Chapter 85.

M. felis conjunctivitis in cats, M. felis upper respiratory tract infection in cats, M. gateae polyarthritis in cats, and M. cynos pneumonia in dogs have been induced experimentally. The pathogenic potential for most Mycoplasma spp. or Ureaplasma spp. is difficult to determine because the organisms can be cultured or amplified from both healthy and sick animals. In many cases Mycoplasma spp. or Ureaplasma spp. may be colonizing diseased tissues as opportunists as a result of inflammation induced by other causes. Other bacteria are usually isolated concurrently with Mycoplasma spp. or Ureaplasma spp., making it difficult to determine which agent is inducing disease. Ureaplasma spp. have been cultured from the vagina (40%) and prepuce (10%) of healthy dogs (Doig et al., 1981).

Mycoplasma spp. were isolated in pure culture from 20 of 2900 dogs with clinical signs of urinary tract inflammation (Jang et al., 1984), M. canis was isolated from four of 100 dogs (three in pure culture) with clinical signs of lower urinary tract disease (Ulgen et al., 2006), and M. canis was isolated from nine dogs with clinical signs of urogenital disease (L'Abee-Lund et al., 2003). Some M. canis—infected dogs were azotemic, suggesting pyelonephritis (Ulgen et al.,

2006), and some have been resistant to therapy (L'Abeelund et al., 2003). Multiple studies suggest that some *Mycoplasma* spp. can be primary pathogens of the respiratory tract of dogs. *Mycoplasma* spp. were the only organism cultured from seven of 93 dogs (Jameson et al., 1995), five of 38 dogs (Randolph et al., 1993), and 14 dogs (Chandler et al., 2002) with lower respiratory tract disease. In one study that compared *Mycoplasma* isolates from dogs with and without respiratory disease, *M. cynos* in the lower respiratory tract was statistically associated with respiratory disease (Chalker et al., 2004b). In another study, 80% of dogs that developed antibodies to *M. cynos* had respiratory signs of disease (Rycroft et al., 2007).

In a recent study of cats with and without conjunctivitis, the presence of *Mycoplasma* spp. DNA was associated with the presence of conjunctivitis (Low et al., 2007). Both *M. felis* and *M. gateae* have been associated with feline ulcerative keratitis (Gray et al., 2005). *M. gateae* and *M. felis* have been detected in cats with polyarthritis. *Mycoplasma* spp. have also been associated with the presence of rhinosinusitis (Johnson et al., 2005; Bannasch et al., 2005), lower respiratory disease (Randolph et al., 1993; Chandler et al., 2002; Foster et al., 2004a, 2004b), and pyothorax (Gulbahar et al., 2002; Barrs et al., 2005).

# **Clinical Findings**

Mycoplasma spp. infection should be considered a potential differential diagnosis for cats presented for evaluation of conjunctivitis, keratitis, sneezing and mucopurulent nasal discharge, coughing, dyspnea, fever, lameness with or without swollen painful joints, subcutaneous abscessation, or abortion. Mycoplasma spp. or Ureaplasma spp. infections were not associated with lower urinary tract disease of cats in one study (Abou et al., 2006). Mycoplasma spp. or Ureaplasma spp. infection should be considered a potential differential diagnosis for dogs presented for evaluation of coughing, dyspnea, fever, pollakiuria, hematuria, azotemia, lameness with or without swollen painful joints, mucopurulent vaginal discharge, or infertility. Mycoplasma spp. and Ureaplasma spp. are generally not recognized cytologically and usually do not grow on aerobic media; infection should be suspected in animals with neutrophilic inflammation without visible bacteria or negative aerobic culture. The index of suspicion for Mycoplasma spp. or Ureaplasma spp. infection is higher if the animal has neutrophilic inflammation and has been poorly responsive to cell wall-inhibiting antibiotics such as penicillins or cephalosporins.

#### Diagnosis

The clinical laboratory and radiographic abnormalities associated with *Mycoplasma* spp. or *Ureaplasma* spp. infections are similar to those induced by other bacterial infections. Neutrophilia and monocytosis are common in dogs with pneumonia; pyuria and proteinuria occur in dogs with urinary tract disease.

Preputial discharges, vaginal discharges, chronic draining wounds, airway washings, and synovial fluid from animals

with *Mycoplasma* spp. or *Ureaplasma* spp. infections have nondegenerate neutrophils as the most common cell type. Dogs with lower respiratory tract disease and pure *Mycoplasma* cultures have alveolar lung patterns that cannot be differentiated from those in dogs with mixed bacterial and *Mycoplasma* cultures. In some dogs and cats with small airway disease evident radiographically, *Mycoplasma* spp. are isolated from the airways in pure culture (Chandler et al., 2002). Joint radiographs of animals with *Mycoplasma*-associated polyarthritis reveal nonerosive changes.

Specimens for Mycoplasma spp. or Ureaplasma spp. culture should be plated immediately or transported to the laboratory in Hayflicks broth medium, Amies medium without charcoal, or modified Stuart bacterial transport medium. Specimens should be shipped on ice packs if the transport time is expected to be less than 24 hours and on dry ice if the transport time is expected to be longer than 24 hours. Most Mycoplasma spp. require special media, but in one report M. canis grew on regular blood agar plates (L'Abee-Lund et al., 2003). Because the organisms are part of the normal flora, culture of the mucous membranes of healthy animals is never indicated. Because Mycoplasma spp. or *Ureaplasma* spp. can be cultured from healthy animals, interpretation of positive culture results in sick animals is difficult. Most laboratories do not report results of antibiotic susceptibility testing. The disease association is strong if Mycoplasma spp. or Ureaplasma spp. are isolated in pure culture from tissues from which isolation is unusual (lower airway, uterus, joints). Response to treatment with drugs with known activity against Mycoplasma spp. or Ureaplasma spp. may help support the diagnosis of disease induced by these agents. PCR assays are now available for detection of mycoplasmal DNA (Johnson et al., 2004; Chalker et al., 2004a; Low et al., 2007) in several diagnostic laboratories, but they have the same diagnostic limitations as culture and positive results do not prove the organism is alive.

#### **Treatment**

Tylosin, erythromycin, clindamycin, lincomycin, tetracyclines, chloramphenicol, aminoglycosides, and fluoroquinolones are effective for treatment of Mycoplasma spp. or Ureaplasma spp. infections (see Chapter 93). Doxycycline administered orally at 5-10 mg/kg q12-24h is generally effective in animals with a competent immune system or without life-threatening disease and is proposed to have the added benefit of being antiinflammatory. In animals with mixed infections with gram-negative organisms, life-threatening disease, or suspected tetracycline-resistant strains, fluoroquinolones or azithromycin are good alternate antibiotic choices. In one cat with mycoplasmal polyarthritis, enrofloxacin therapy, but not doxycycline therapy, eliminated infection. Treatment for 4 to 6 weeks is usually required for lower airway, subcutaneous, or joint infections. Erythromycin administered orally at 20 mg/kg q8-12h or lincomycin administered orally at 22 mg/kg q12h should be used in pregnant animals.

# **Zoonotic Aspects and Prevention**

Although risk of zoonotic transfer is likely minimal, bite wound transmission of Mycoplasma spp. from an infected cat to the hand of a human being has been reported (McCabe et al., 1987). Most Mycoplasma spp. or Ureaplasma spp. infections in dogs and cats are opportunistic and associated with other causes of inflammation; thus they are not likely to be directly contagious from animal to animal. However, M. felis may be transmitted from cat to cat by conjunctival discharges. Mycoplasma spp. appear to have been associated with respiratory tract disease in dogs and cats as primary pathogens and may be spread from animal to animal, as with M. pneumoniae in human beings. Animals with conjunctivitis or respiratory tract disease should be isolated from other animals until clinical signs of disease have resolved (see Chapter 94). Mycoplasma spp. and Ureaplasma spp. are susceptible to routine disinfectants and rapidly die outside the host.

# CHAPTER OUTLINE

CANINE GRANULOCYTOTROPIC ANAPLASMOSIS FELINE GRANULOCYTOTROPIC ANAPLASMOSIS CANINE THROMBOCYTOTROPIC ANAPLASMOSIS CANINE MONOCYTOTROPIC EHRLICHIOSIS FELINE MONOCYTOTROPIC EHRLICHIOSIS CANINE GRANULOCYTOTROPIC EHRLICHIOSIS ROCKY MOUNTAIN SPOTTED FEVER OTHER RICKETTSIAL INFECTIONS

The organisms of the order Rickettsiales, in the families Rickettsiaceae and Anaplasmataceae, were reclassified in 2001 after phylogenetic analyses of the 16S rRNA and groESL gene sequences (Dumler et al., 2001). Some Ehrlichia spp. were transferred to the Neorickettsia genus (including E. risticii) and some Ehrlichia spp., including E. phagocytophila (also called E. equi and human granulocytic Ehrlichia) and E. platys were placed into the genus Anaplasma. The genera Ehrlichia and Neorickettsia were transferred to the family Anaplasmataceae; the genera of Rickettsia and Orientia remained in the Rickettsiaceae. The organisms in Ehrlichia, Anaplasma, and Neorickettsia are classified genetically and by cell tropism (monocytotropic, granulocytotropic, or thrombocytotropic). The organisms of most importance to dogs and cats discussed in this chapter include A. phagocytophilum, A. platys, Ehrlichia canis, E. chaffeensis, E. ewingii, Neorickettsia risticii, Rickettsia rickettsii, and R. felis (Table 96-1).

# CANINE GRANULOCYTOTROPIC ANAPLASMOSIS

# **Etiology and Epidemiology**

Anaplasma phagocytophilum (previously known as E. equi, E. phagocytophila, canine granulocytic Ehrlichia, and human granulocytic ehrlichiosis agent) is known to infect a variety of animals, including small mammals, mountain lions,

coyotes, sheep, cattle, deer, dogs, horses, and human beings (Dumler et al., 2001). Small mammals and deer are natural reservoirs. The distribution of A. phagocytophilum is defined by the range of Ixodes ticks and so is most common in California, Wisconsin, Minnesota, and the northeastern states as well as other areas of the world with this tick genus, including Europe, Asia, and Africa. Birds may play a role in spreading infected ticks and may also serve as a reservoir. In endemic areas, seroprevalence can be quite high; in one study of healthy dogs in California, 47.3% of the dogs tested in one county were seropositive (Foley et al., 2001). Borrelia burgdorferi is also transmitted by Ixodes ticks, so coinfections can occur (Jaderlund et al., 2007). The vector must be attached for approximately 24 to 48 hours to transmit the agent. Clinical signs usually develop approximately 1 to 2 weeks after infection. Neutrophils (and rarely other leukocytes) phagocytize the organism, and once intracellular A. phagocytophilum prevents phagolysosome fusion. This mechanism allows multiplication within the phagosome, which gives the appearance of morula in neutrophils under light microscopy. The exact pathogenesis of disease is still undetermined, and why some dogs but not others develop clinical signs of disease is unclear.

# **Clinical Features**

A. phagocytophilum infection appears to be primarily an acute disease in dogs. It has been associated most commonly with nonspecific signs of fever, lethargy, and inappetence. Stiffness and lameness consistent with musculoskeletal pain are also common, and A. phagocytophilum has been associated with polyarthritis. Vomiting, diarrhea, difficult breathing, cough, lymphadenopathy, hepatosplenomegaly, and central nervous system signs (seizures and ataxia) have also been reported. Dogs can be chronic subclinical carriers, so exacerbation of disease could occur in some dogs. However, chronic disease syndromes such as those associated with E. canis infection have not been documented. In a recent study of dogs with neurologic diseases in Sweden, serologic evidence of exposure to A. phagocytophilum and B. burgdorferi was common, but neither organism was linked to the presence of neurologic disease (Jaderlund et al., 2007). In one

study of valvular endocarditis, all dogs with *Bartonella* spp.– associated disease were also seropositive for *A. phagocyto-philum* (MacDonald et al., 2004). Whether the coinfection potentiated the *Bartonella*-associated disease is unknown.

#### Diagnosis

Morula of A. phagocytophilum are commonly detected in neutrophils of most clinically affected dogs, so infection can be confirmed during performance of a complete blood cell count. Although thrombocytopenia and lymphopenia are common, neutrophil counts are usually normal. Hemolytic anemia and thrombocytopenia were thought to be from A. phagocytophilum infection in one dog in the United Kingdom (Boxfield et al., 2005). Reported biochemical panel and urinalysis abnormalities are mild and nonspecific. The morulae cannot be distinguished from those of E. ewingii, but the geographic range of the infections varies between the organisms; the travel history can help rank the differentials. Serologic test results (immunofluorescence assay [IFA] and enzyme-linked immunosorbent assay [ELISA]) can be used if morulae are not identified. A point of care assay that detects antibodies against A. phagocytophilum is available (SNAP 4Dx, IDEXX, Westbrook, Maine). Antibody assay results can be falsely negative in acute cases, so a convalescent test 2 to 3 weeks later may be required to confirm exposure. This assay also detects antibodies against A. platys. Because A. phagocytophilum infections are limited geographically, this antibody test result is not needed in the majority of the United States. Polymerase chain reaction assays performed on blood collected in ethylenediamine tetraacetic acid can be used to confirm infection and differentiate A. phagocytophilum infection from other infections, but microbial DNA can also be amplified from healthy dogs (Henn et al., 2007). Most dogs infected by A. phagocytophilum have subclinical infections, most infected dogs only have an acute phase, exposure rates in endemic areas are high, and the disease syndromes associated with infection have multiple other causes. Thus antibody test results and polymerase chain reaction (PCR) assay results alone cannot be used to prove clinical disease associated with A. phagocytophilum infection. For example, although A. phagocytophilum is known to cause thrombocytopenia and polyarthritis in some dogs, a recent study failed to show an association between A. phagocytophilum PCR assay or serologic test results in dogs with polyarthritis or thrombocytopenia (Foley et al., 2007).

# **Treatment**

Several antibiotics are effective against A. phagocytophilum in vitro (Maurin et al., 2003). Doxycycline administered at 5-10 mg/kg PO q12-24h for at least 10 days is recommended by most clinicians. Whether a 28-day course of

<sup>†</sup> The vector has not been identified and attempts to transmit by R. sanguineus have failed.

<sup>‡</sup>Horses may be infected by ingestion of *N. risticii*-infected metacercariae of trematodes found in intermediate host such as aquatic insects or snails.

<sup>§</sup> Rickettsia are not classified by cell tropism.

doxycycline therapy as recommended for *E. canis* is needed is unknown (Neer et al., 2002). If tetracyclines are used, 22 mg/kg PO q8h for 2 to 3 weeks is recommended. Most dogs respond to therapy within hours to days of initiating therapy.

# **Zoonotic Aspects and Prevention**

A. phagocytophilum infects people as well as dogs and so is zoonotic. Human infections are most likely acquired by direct tick transmission, but handling infected blood and carcasses can also lead to infection. Care should also be taken when handling ticks. No vaccine for A. phagocytophilum infection is currently available. Infection can be avoided by tick control or prophylactic use of tetracyclines when visiting endemic areas. In one study, application of imidacloprid-permethrin prevented transmission of A. phagocytophilum from naturally infected Ixodes scapularis ticks to dogs (Blackburn et al., 2004). Dogs appear to be susceptible to reinfection, so tick control should be maintained at all times in endemic areas. Dogs used for blood donors that reside in endemic areas should be screened for A. phagocytophilum infections by serology or PCR.

# FELINE GRANULOCYTOTROPIC ANAPLASMOSIS

# **Etiology and Epidemiology**

Cats have shown to be susceptible to A. phagocytophilum infection after experimental inoculation (Lewis et al., 1975; Foley et al., 2003). In naturally exposed cats, DNA of A. phagocytophilum has been amplified from several countries, including Sweden, Denmark, Ireland, and the United States (Bjoersdorff et al., 1999; Shaw et al., 2001; Lappin et al., 2004). Morulae consistent with A. phagocytophilum have been detected cytologically in neutrophils of naturally infected cats in other countries, including Brazil, Kenya, and Italy (Almonsy et al., 1998; Buoro, 1989; Tarello et al., 2005). Cats living in endemic areas are commonly seropositive (Magnarelli et al., 2005; Billeter et al., 2007). As in dogs, A. phagocytophilum is transmitted by Ixodes ticks, so infections of cats are likely to be most common in these areas. Although rodents are commonly infected with A. phagocytophilum, whether ingestion or direct contact with rodents plays a role in A. phagocytophilum infection of cats is currently unknown. Although the pathogenesis of disease associated with A. phagocytophilum in cats is unknown, some cats experimentally inoculated with A, phagocytophilum developed antinuclear antibodies and increased interferon-y mRNA, suggesting that an immune pathogenesis of disease may contribute to the clinical findings (Foley et al., 2003).

# **Clinical Features**

Fever, anorexia, and lethargy were the most common clinical abnormalities. Tachypnea has also been detected. Ticks may or may not currently be infesting infected cats. Overall, clinical signs associated with *A. phagocytophilum* infection in

cats were mild and resolved quickly after initiating tetracycline therapy.

# Diagnosis

Approximately 50% of cats with proven clinical infections induced by A. phagocytophilum have a mild thrombocytopenia (66,000 to 118,000/μL). Neutrophilia with a left shift, lymphocytosis, lymphopenia, and hyperglobulinemia have been detected in some cats. Morulae are less commonly detected than in dogs. The abnormalities resolved quickly after doxycycline treatment was initiated (Bjoersdorff et al., 1999; Lappin et al., 2004). Biochemical and urinalysis abnormalities are unusual. Some commercial laboratories offer serologic testing. Infected cats are negative for antibodies against E. canis, so A. phagocytophilum IFA slides should be used. Approximately 30% of cats with proven clinical infections induced by A. phagocytophilum are seronegative when first assessed serologically, but all proven cases to date have ultimately seroconverted. Some mountain lions with A. phagocytophilum DNA amplified from blood have been serum antibody negative (Foley et al., 1999), so a single negative antibody result in an acutely infected cat does not exclude infection. Therefore cats with suspected anaplasmosis may need convalescent serum samples to prove infection. Alternately, antibody testing could be combined with PCR testing of whole blood in acute cases (Lappin et al., 2004).

#### Therapy

Supportive care should be administered as needed. Several antibiotics have been administered to naturally infected cats, but all cats in two studies became clinically normal within 24 to 48 hours after initiation of tetracycline or doxycycline administration and recurrence was not reported (Bjoersdorff et al., 1999; Lappin et al., 2004). Although clinically normal, two cats were still PCR positive 17 days and 90 days after treatment (of 21 to 30 days' duration), respectively, which suggests that treatment with tetracyclines for 21 to 30 days may be inadequate for eliminating the organism from the body (Lappin et al., 2004).

#### **Zoonotic Aspects and Prevention**

See the section on canine granulocytic anaplasmosis for a discussion of zoonotic aspects. To prevent *A. phagocytophilum* infection in cats, ascaricidal products approved for use on cats should be used. *A. phagocytophilum* can likely be transmitted by blood; therefore cats used as blood donors in endemic areas should be screened for infection by serum antibody tests or PCR assay, and positive cats should be excluded as donors.

# CANINE THROMBOCYTOTROPIC ANAPLASMOSIS

#### **Etiology and Epidemiology**

Anaplasma platys was formerly classified as Ehrlichia platys (Dumler et al., 2001). The organism forms morulae in

circulating platelets and has been called canine infectious cyclic thrombocytopenia. Infected dogs have been detected primarily in the south and southeastern United States, Western Europe, South America, Australia, Africa, and the Middle East. Inclusions morphologically similar to A. platys have been detected in one cat in Brazil, but attempts to transmit the organism from a dog to a cat failed (Harvey, 2006). A tick vector is suspected because A. platys DNA has been amplified from ticks. However, attempts to transmit infection by Rhipicephalus sanguineous have failed. After intravenous inoculation the incubation period is 8 to 15 days. Although cyclic thrombocytopenia and parasitemia can occur at 10- to 14-days intervals, organism numbers and severity of thrombocytopenia may lessen over time. Later in infection thrombocytopenia can be severe, but the organism may not be recognized cytologically or by PCR with blood (Eddlestone et al., 2007). In these experimentally infected dogs microbial DNA could be amplified from bone marrow and splenic aspirates. Anemia and thrombocytopenia in dogs experimentally infected with either A. platys and/or E. canis were more persistent in the coinfected dogs (Gaunt et al., 2007).

# **Clinical Features**

Dogs with A. platys infections in the United States are usually subclinically infected or have mild fever. More severely affected dogs have exhibited fever, uveitis, and clinical evidence of bleeding, including ecchymosis, petechia, epistaxis, melena, gingival bleeding, retinal hemorrhage, and hematoma formation. Coinfection with other tick borne agents such as E. canis is common and may potentiate clinical disease (Kordick et al, 1999; Gaunt et al, 2007).

# Diagnosis

Anemia, thrombocytopenia, and neutrophilic leukocytosis can occur. Morulae may or may not be present within platelets. In endemic areas A. platys infection, alone or in combination with other tick-borne agents, should be suspected in dogs with anemia or thrombocytopenia. Serum antibodies can be detected by IFA. Cross-reactivity with E. canis is thought to be minimal but A. platys antibodies may be detected in serologic assays for A. phagocytophilum. Antibody assay results can be falsely negative in acute cases, so a convalescent test 2 to 3 weeks later may be required to confirm exposure. PCR assays performed on blood collected in ethylenediamine tetraacetic acid (EDTA) can be used to confirm infection and differentiate A. platys infections from other infections and microbial DNA can also be amplified from healthy dogs (Kordick et al., 1999) and can be negative in clinically ill dogs (Eddlestone et al., 2007). Most dogs infected by A. platys have subclinical infections, most infected dogs only have an acute phase, exposure rates in endemic areas are high, and the disease syndromes associated with infection have multiple other causes. Thus antibody test results and PCR assay results alone cannot be used to prove clinical disease associated with A. platys infection.

#### **Treatment**

The doxycycline and tetracycline treatment protocols discussed for A. phagocytophilum infections of dogs should also be effective for A. platys infections. If coinfection with E. canis exists, treatment duration should be at least 4 weeks (Neer et al., 2002).

# **Zoonotic Aspects and Prevention**

The strategies discussed for control of A. phagocytophilum infection of dogs should also be effective for A. platys. No known human health risk exists with A. platys.

# CANINE MONOCYTOTROPIC **EHRLICHIOSIS**

# **Etiology and Epidemiology**

Organisms that are associated with monocytotropic ehrlichiosis in naturally infected dogs include Ehrlichia canis, E. chaffeensis, and Neorickettsia risticii var atypicalis. An individual dog can be infected by more than one ehrlichial agent, and coinfection with other tick-borne pathogens is common (Kordick et al., 1999).

E. canis is the most common of these agents and causes the most severe clinical disease; it is maintained in the environment from passage from ticks to dogs. Rhipicephalus sanguineus and Dermacentor variabilis are the known vectors. The organism is not passed transovarially in the tick, so unexposed ticks must feed on a rickettsemic dog in the acute phase to become infected and perpetuate the disease. Male R. sanguineus can take multiple feedings and can both acquire and transmit E. canis in the absence of female ticks (Bremer et al., 2005). Dogs seropositive for E. canis have been identified in many regions of the world and most of the United States, but the majority of cases occur in areas with high concentrations of R. sanguineus, such as the Southwest and Gulf Coast.

E. chaffeensis is a cause of human mononuclear ehrlichiosis. White-tailed deer, voles, coyotes, and opossums are reservoirs, and Amblyomma americanum, D. variabilis, and some Ixodes ticks are vectors. Infections by E. chaffeensis are detected primarily in the southeastern United States. Clinical manifestations in dogs are currently being detailed (Breitschwerdt et al., 1998; Zhang et al., 2003) and appear to be rare. N. risticii var atypicalis has been detected only in the United States to date and causes similar clinical signs as E. canis (Kokoma et al., 1991). Bats and swallows may be the natural reservoirs of this organism. Trematodes of snails and water insects are thought to be the vectors (Pusterla et al., 2003).

Ehrlichia canis infection causes acute, subclinical, and chronic phases of disease. Infected mononuclear cells marginate in small vessels or migrate into endothelial tissues, inducing vasculitis during the acute phase. The acute phase begins 1 to 3 weeks after infection and lasts 2 to 4 weeks; most immunocompetent dogs survive. The subclinical phase lasts months to years in naturally infected dogs. Although

some dogs clear the organism during the subclinical phase, the organism persists intracellularly in some, leading to the chronic phase of infection. Many of the clinical and clinicopathologic abnormalities that develop during the chronic phase are from immune reactions against the intracellular organism. The variable duration of the subclinical phase of disease explains why *E. canis* infection does not have a distinct seasonal incidence as does Rocky Mountain spotted fever (RMSF). However, acute-phase disease is recognized most frequently in the spring and summer when the tick vectors are most active.

#### **Clinical Features**

Clinical disease from ehrlichial infection can occur in any dog, but its severity varies depending on the organism, host factors, and presence of coinfections. Virulence is thought to vary with different field strains of *E. canis*. Dogs with depressed cell-mediated immunity develop severe disease. However, *E. canis* itself did not cause immunosuppression in young, experimentally infected dogs within the first several months of infection (Hess et al., 2006).

Clinical findings in dogs with E. canis infections vary with the timing of infection (Table 96-2). The clinical manifestations of acute-phase disease are quite similar to those of RMSF as a result of the development of vasculitis. Ticks are most commonly found on dogs during the acute phase of infection. Fever can occur in both clinical phases of infection but is more common in dogs with acute ehrlichiosis. Petechiae or other evidence of bleeding noted during the acute phase is generally caused by a combination of mild thrombocytopenia (consumption or immune-mediated destruction) and vasculitis; thrombocytopenia (consumption, immune-mediated destruction, sequestration, decreased production), vasculitis, and platelet function abnormalities (Brandao et al., 2006) occur in the chronic phase. The thrombocytopenia in the acute phase is generally not severe enough to result in spontaneous bleeding, so bleeding may be primarily from vasculitis and decreased platelet function.

Pale mucous membranes usually only occur in the chronic phase during the development of pancytopenia. Hepatomegaly, splenomegaly, and lymphadenopathy are from chronic immune stimulation (i.e., lymphoreticular hyperplasia) and are detected most frequently in dogs in the chronic phase. Interstitial or alveolar edema secondary to vasculitis or inflammation, pulmonary parenchymal hemorrhage secondary to vasculitis or thrombocytopenia, or secondary infections from neutropenia are mechanisms resulting in dyspnea or cough in some dogs with ehrlichiosis. Polyuria, polydipsia, and proteinuria are reported in some dogs that develop renal insufficiency.

Stiffness, exercise intolerance, and swollen, painful joints occur in some dogs with suppurative polyarthritis. Most dogs with polyarthritis from which the organism has been demonstrated have been infected with *E. ewingii* or *A. phagocytophilum*. Ophthalmic manifestations of disease are common; tortuous retinal vessels, perivascular retinal infiltrates, retinal hemorrhage, anterior uveitis, and exudative

**TABLE 96-2** 

Clinical Abnormalities Associated with Ehrlichia canis Infection in Dogs

STAGE OF	ARMORAALIPIKÉ
INFECTION	ABNORMALITIES
	r
Acute	Fever
	Serous or purulent oculonasal discharge
	Anorexia

	corneal edema
	Central nervous system: meningeal pain, paresis, cranial nerve deficits, seizures
	Hepatomegaly
	Arrhythmias and pulse deficits
	Polyuria and polydipsia
	Stiffness and swollen, painful joints

retinal detachment occur (Komnenou et al., 2007). Central nervous system signs can include depression, pain, ataxia, paresis, nystagmus, and seizures.

#### Diagnosis

Clinicopathologic and radiographic abnormalities consistent with *E. canis* infection are summarized in Table 96-3. Neutropenia is common during acute-phase vasculitis and after bone marrow suppression in the chronic phase. Chronic immune stimulation causes monocytosis and lymphocytosis; lymphocytes often have cytoplasmic azurophilic granules (i.e., large granular lymphocytes). Regenerative anemia is from blood loss (acute and chronic phases); normocytic, normochromic nonregenerative anemia is from bone marrow suppression or anemia of chronic disease (chronic phase). Thrombocytopenia can occur with either acute or chronic ehrlichiosis but is generally more severe with chronic phase disease. Thrombocytopathies from hyperglobulinemia potentiate bleeding in some dogs with chronic ehrlichiosis. Chronic ehrlichiosis is classically associated with pancytopenia,

but any combination of neutropenia, thrombocytopenia, and anemia can occur. Changes in bone marrow cell lines associated with ehrlichiosis vary from hypercellular (acute phase) to hypocellular (chronic phase). Bone marrow plasmacytosis is common in dogs with subclinical and chronic ehrlichiosis, and the disease can be confused with multiple myeloma, particularly in dogs with monoclonal gammopathies. Dogs with ehrlichiosis are usually not hypercalcemic and do not have lytic bone lesions.

Hypoalbuminemia in the acute phase is probably caused by third spacing of albumin in tissues because of vasculitis, whereas in chronic-phase disease it is caused by glomerular loss from immune complex deposition or chronic immunostimulation (i.e., monoclonal or polyclonal gammopathy). Prerenal azotemia can occur with acute or chronic disease; renal azotemia develops in some dogs with severe glomerulonephritis from chronic ehrlichiosis. The combination of hyperglobulinemia and hypoalbuminemia is consistent with subclinical or chronic ehrlichiosis. Polyclonal gammopathies are most common, but monoclonal (e.g., immunoglobulin G) gammopathies can also occur.

Aspirates of enlarged lymph nodes and spleen reveal reactive lymphoreticular and plasma cell hyperplasia. Nondegenerate neutrophils are the primary cells in synovial fluid from dogs with polyarthritis caused by any Ehrlichia spp.; E. ewingii and A. phagocytophilum morulae can be identified in synovial neutrophils from some dogs. Bone marrow aspirates in dogs with chronic ehrlichiosis typically reveal myeloid, erythroid, and megakaryocytic hypoplasia in association with lymphoid and plasma cell hyperplasia. Morulae from E. canis are rarely detected in the cytoplasm of mononuclear cells. Ehrlichiosis generally causes mononuclear pleocytosis and increased protein concentrations in cerebrospinal fluid. Antiplatelet antibodies, antinuclear antibodies, antierythrocyte antibodies (by direct Coombs test), and rheumatoid factors are detected in some dogs with ehrlichiosis, leading to an inappropriate diagnosis of primary immune-mediated disease (Smith et al, 2004).

No pathognomonic radiographic signs appear in dogs with ehrlichiosis. The polyarthritis is noncrosive, and dogs with respiratory signs most commonly have increased pulmonary interstitial markings, but alveolar patterns can occur.

Identification of morulae in cells documents *Ehrlichia* infection, but it is uncommon with monocytotropic strains. Examination of buffy coat smears or blood smears made from blood collected from an ear margin vessel may increase the chances of finding morulae. Some *Ehrlichia* spp. can be cultured, but the procedure is low yield and expensive and so is not clinically useful.

Most commercial laboratories (using IFAs) and one point-of-care diagnostic test (SNAP 4Dx) use reagents that detect antibodies against *E. canis* in serum. These tests are generally used as the first screening procedures in dogs suspected to have ehrlichiosis. The American College of Veterinary Internal Medicine (ACVIM) Infectious Disease Study Group suggests that *E. canis* IFA antibody titers between 1:10 and 1:80 be rechecked in 2 to 3 weeks because of the potential for false-positive results at these titer levels (Neer et al., 2002). At low titers, agreement between IFA and ELISA can be poor (O'Connor et al., 2006).

If serum antibodies against *E. canis* are detected in a dog with clinical findings consistent with ehrlichiosis, a presumptive diagnosis of canine ehrlichiosis infection should be made and appropriate treatment begun. However, detection of antibodies alone is not diagnostic of ehrlichiosis because of the existence of cross-reactive antibodies among *E. canis*, *N. helminthoeca*, and *Cowdria ruminantium* and because some dogs are subclinically infected. In addition, negative

test results do not totally exclude ehrlichiosis from the list of differential diagnoses because clinical disease can be detected before seroconversion and not all *Ehrlichia* spp. induce antibodies that are consistently detected in *E. canis* assays.

PCR assays are now available commercially and can be used to detect organism-specific DNA in peripheral blood. It can be performed on joint fluid, aqueous humor, cerebrospinal fluid, and tissues. Blood PCR results can be positive before seroconversion in some experimentally inoculated dogs and positive results document infection, whereas positive serologic tests only document exposure. However, as for serology, no standardization among laboratories currently exists, and insufficient quality control can lead to falsepositive or false-negative results. Until more information is available, the ACVIM Infectious Disease Study Group suggests using PCR with serology, not in lieu of it. Because antibiotic treatment rapidly induces negative blood PCR results, the clinician should draw the blood sample for testing and place it in an EDTA tube before treatment. In one recent study tissues (lymph nodes, spleen, liver, bone marrow, and blood) from naturally infected dogs were assayed by PCR. Blood and lymph nodes were the most likely to be positive but were falsely negative in approximately 30% of the samples (Gal et al., 2007).

#### **Treatment**

Supportive care should be provided as indicated. Several different tetracycline, doxycycline, chloramphenicol, and imidocarb diproprionate protocols have been used. The ACVIM Infectious Disease Study Group currently recommends doxycycline (10 mg/kg PO q24h for at least 28 days). In one study of experimentally infected dogs, ticks still could acquire E. canis from feeding on dogs previously treated with doxycycline for 14 days (Schaefer et al., 2007). Clinical signs and thrombocytopenia should rapidly resolve. If clinical abnormalities are not resolving within 7 days, other differential diagnoses should be considered. Results of studies that used imidocarb diproprionate (5 to 7 mg/kg IM or SQ repeated in 14 days) to treat canine ehrlichiosis have been variable. In one recent study thrombocytopenia persisted and infection was not cleared in experimentally inoculated dogs (Eddlestone et al., 2006). Some patients develop pain at the injection site, salivation, oculonasal discharge, diarrhea, tremors, and dyspnea after administration of this drug. Quinolones are not effective for the treatment of E. canis infections in dogs. Although coinfections common occur, the presence of agents such as A. phagocytophilum, A. platys, and Leishmania infantum did not adversely affect the response to therapy (Mylonakis et al., 2004).

Positive antibody titers have been detected for up to 31 months after therapy in some naturally infected dogs. Dogs with low (less than 1:1024) antibody titers generally revert to negative by 1 year after therapy. Dogs with antibody titers greater than 1:1024 often maintain positive antibody titers after therapy. Whether these dogs are persistent carriers of the organism is undetermined. On the basis of these findings antibody titers are considered to be ineffective for monitor-

ing response to therapy. The ACVIM Infectious Disease Study Group recommends monitoring resolution of thrombocytopenia and hyperglobulinemia as markers of therapeutic elimination of the organism.

Whether ehrlichial infections are cleared by treatment is currently unknown. If PCR is to be used to monitor treatment, the ACVIM Infectious Disease Study Group recommends the following steps be taken. The PCR test should be repeated 2 weeks after stopping treatment. If still positive, treatment should be reinstituted for 4 weeks and retesting performed. If PCR results are still positive after two treatment cycles, an alternate anti-Ehrlichia drug should be used. If PCR results are negative the test should be repeated in 8 weeks, and if still negative therapeutic elimination is assumed to be likely. In one study PCR assay performed on splenic aspirates was superior to blood PCR to document elimination of infection (Harrus et al., 2004).

Whether to treat seropositive healthy dogs is controversial. Arguments for and against testing or treating healthy dogs were reviewed by the ACVIM Infectious Disease Study Group (Neer et al., 2002). The primary reason to treat a seropositive healthy dog is to try to eliminate infection before development of chronic-phase disease. However, treatment of healthy dogs is controversial for at least six reasons: (1) whether treatment halts progression to the chronic phase is unknown; (2) not all seropositive dogs are infected; (3) not all seropositive dogs progress to the chronic phase; (4) whether treatment eliminates infection is unknown; (5) even if infection is eliminated, reinfection can occur; and (6) treatment of healthy carriers may result in antimicrobial resistance.

Because further data are needed to make definitive recommendations, owners should be given the pros and cons and asked to make treatment decisions.

The prognosis is good for dogs with acute ehrlichiosis, and it is variable to guarded for those with chronic ehrlichiosis. Fever, petechia, vomiting, diarrhea, epistaxis, and thrombocytopenia often resolve within days after initiation of therapy in acute cases. Bone marrow suppression from chronic-phase ehrlichiosis may not respond for weeks to months, if at all. Anabolic steroids and other bone marrow stimulants can be administered but are unlikely to be effective because precursor cells are often lacking. Immunemediated events resulting in the destruction of red blood cells or platelets are likely to occur with ehrlichiosis, leading to the recommendation to administer antiinflammatory or immunosuppressive doses of glucocorticoids to acutely affected animals. Prednisone (2.2 mg/kg PO divided q12h during the first 3 to 4 days after diagnosis) may be beneficial in some cases.

#### Zoonotic Aspects and Prevention

Dogs and human beings are both infected by *E. canis*, *E. ewingii*, and *E. chaffeensis* (Buller et al., 1999). Although people cannot acquire ehrlichiosis from handling an infected dog, dogs may be reservoirs for these agents and may play a role in the human disease by bringing vectors into the human

environment. Ticks should be removed and handled with care.

Tick control should be maintained at all times; administration of fipronil was shown to lessen transmission in one study (Davoust et al., 2003). Because E. canis is not passed transovarially in the tick, it can be eliminated in the environment by tick control or by treating all dogs through a generation of ticks. Rhipicephalus can only transmit E. canis for approximately 155 days; if tick control is not feasible tetracycline can be administered (6.6 mg/kg PO daily for 200 days). During this time infected dogs will not infect new ticks and previously infected ticks will lose the ability to transmit the organism. Doxycycline given at 100 mg/dog/day was used successfully as a chemopreventative (Davoust et al., 2005). Dogs used as blood donors should be screened serologically yearly and seropositive dogs should not be used.

# FELINE MONOCYTOTROPIC **EHRLICHIOSIS**

# **Etiology and Epidemiology**

Ehrlichia-like bodies or morulae have been detected in peripheral lymphocytes or monocytes of naturally exposed cats in a number of countries, including the United States, Kenya, France, Brazil, and Thailand (Bouloy et al., 1994; Buoro et al., 1994; Beaufils et al., 1995; Beaufils et al, 1999; Almosny et al, 1998; Jittapalapong, 1993). Two studies of naturally infected cats have amplified DNA consistent with E. canis (Breitschwerdt et al., 2002; Beaufils et al., 2002). Other studies of cats in endemic areas (Florida and Arizona) have failed to amplify Ehrlichia spp. DNA from the blood of cats (Luria et al., 2004; Eberhardt et al., 2006). To our knowledge, only two experimental inoculation studies of cats with monocytotropic Ehrlichia spp. have been performed (Dawson et al., 1988; Lappin and Breitschwerdt, unpublished observations, 2007). Morulae of N. risticii were detected in mononuclear cells from two of six cats inoculated intravenously but not subcutaneously; diarrhea developed in one cat and depression, anorexia, and lymphadenomegaly developed in the other. When cats were inoculated subcutaneously with an E. canis strain (North Carolina State University canine isolate) maintained in cell culture, microbial DNA or antibodies that reacted to E. canis morulae were not detected in an 8-week follow-up period (Lappin and Breitschwerdt, unpublished observations, 2007). These results indicate the E. canis-like DNA amplified from naturally infected cats may be from a different Ehrlichia spp. more infective to cats, not all E. canis stains will infect cats, not all cats are susceptible to infection by E. canis, or subcutaneous inoculation is not an effective method for infecting cats with E. canis.

Sera from cats have been assessed for Ehrlichia spp. antibodies by using IFA or Western immunoblot. However, standardization of methods among laboratories has not been performed, the most appropriate cutoff values have not been determined, and variable serologic cross-reactivity has occurred among Ehrlichia spp., Neorickettsia spp., and Anaplasma spp. Therefore results of serologic studies should be interpreted cautiously. Serum antibodies that react with E. canis morulae have been detected by IFA in cats from multiple states in the United States, France, Italy, and Kenya (Bouloy et al., 1994; Matthewman et al., 1996; Pcavy et al., 1989; Beaufils et al., 1999; Stubbs et al., 2000). Although antibodies have been commonly detected in naturally exposed cats, DNA of Ehrlichia spp. is rarely amplified from blood. When taken together these results suggest that cats are less susceptible to monocytotropic ehrlichial infections than are dogs.

How cats are exposed to monocytotropic ehrlichial agents is currently unknown. Documentation of arthropod exposure in proven cases has been variable. Pathogenesis of disease associated with monocytotropic ehrlichiosis in cats is unknown but is likely to be similar to that for E. canis infection of dogs.

#### **Clinical Features**

All ages of cats have been infected; most cats were domestic short haired, and both males and females have been affected. Anorexia, fever, inappetence, lethargy, weight loss, hyperesthesia or joint pain, pale mucous membranes, splenomegaly, dyspnea, and lymphadenomegaly were the most common historic and physical examination abnormalities. Dyspnea, petechiae, retinal detachments, vitreous hemorrhages, and pale mucous membranes were other reported physical examination abnormalities. Concurrent diseases are rarely reported but have included hemoplasmas (previously Haemobartonella felis), Cryptococcus neoformans, feline leukemia virus and feline immunodeficiency virus infections, and lymphoma.

#### Diagnosis

Anemia is common and usually nonregenerative. Leukopenia; leukocytosis characterized by neutrophilia, lymphocytosis, and monocytosis; and intermittent thrombocytopenia have been reported in some cats. Bone marrow evaluation of cats with cytopenias has revealed primarily hypoplasia of the effected cell line. However, one cat had bone marrow cytologic characteristics consistent with myeloid leukemia (Breitschwerdt et al., 2002). Hyperglobulinemia was reported in multiple cats; protein electrophoresis usually reveals a polyclonal gammopathy. An epidemiologic link has been made between the presence of Ehrlichia spp. antibodies in serum and monoclonal gammopathy (Stubbs et al., 2000). On the basis of the cases reported to date, ehrlichiosis should be considered on the differential list for cats with unexplained leukocytosis, cytopenias, and hyperglobulinemia. Biochemical abnormalities were infrequently reported in cats with suspected monocytotropic ehrlichiosis and were nonspecific. The three cats with E. canis-like DNA in the blood also had antinuclear antibodies, similar to results reported for infected dogs (Breitschwerdt et al., 2002).

Some cats with suspected clinical ehrlichiosis seroreacted to E. canis or N. risticii morulae. Antibodies that seroreact to more than one Ehrlichia spp. are sometimes detected. Some cats with E. canis-like DNA in blood were seronegative

(Breitschwerdt et al., 2002). In contrast, most *A. phagocyto-philum*—infected cats have strongly positive antibody test results. Positive serologic test results occur in both healthy and clinically ill cats, so a diagnosis of clinical ehrlichiosis should not be based on serologic test results alone. A tentative diagnosis of clinical feline ehrlichiosis can be based on the combination of positive serologic test results, clinical signs of disease consistent with *Ehrlichia* infection, exclusion of other causes of the disease syndrome, and response to anti-rickettsial drugs. *Ehrlichia* spp. have been cultured from some cats on monocyte cell cultures. PCR and gene sequencing can also be used to confirm infection and should be considered the tests of choice at this time. However, no standardization for dogs exists among laboratories providing *Ehrlichia* spp. PCR assays.

#### **Treatment**

Clinical improvement after therapy with tetracycline, doxycycline, or imidocarb dipropionate was reported for most cats. However, for some cats a positive response to therapy was a criterion for the diagnosis of ehrlichiosis. The current recommendation of the ACVIM Infectious Disease Study Group is to give doxycycline (10 mg/kg PO q24h for 28 days). For cats with treatment failure or those intolerant of doxycycline, imidocarb diproprionate can be given safely (5 mg/kg IM or SQ twice, 14 days apart). Salivation and pain at the injection site are the common adverse effects, and imidocarb efficacy is in question for the treatment of canine monocytotropic ehrlichiosis (Eddlestone et al., 2007).

# Zoonotic Aspects and Prevention

Although cats and human beings can both be infected by *E. canis*, direct transmission is not known to occur. Care should be taken when removing ticks, and arthropod control should be maintained at all time for cats, particularly if allowed outdoors.

# CANINE GRANULOCYTOTROPIC EHRLICHIOSIS

# Etiology and Epidemiology

Ehrlichia ewingii forms morulae in neutrophils and eosinophils and has been detected in dogs and human beings that reside in the southern and southeastern United States. Although one canine case was reported in New York, A. phagocytophilum is more likely in this region (see sections on canine and feline granulocytotropic anaplasmosis). E. ewingii has been detected in a number of ticks, but A. americanum is the only proven vector to date (Murphy et al., 1998). Deer are infected and serve as a reservoir (Yabsley et al., 2002). The incubation period after tick exposure is approximately 13 days. Pathogenesis of disease is unknown but is likely be to similar to other Ehrlichia spp. In general, clinical signs of E. ewingii infection are less severe that those of E. canis. Concurrent disease or infections may play a significant role in the pathogenesis of E. ewingii infection.

#### **Clinical Features**

Nonspecific signs of *E. ewingii* infection include fever, lethargy, anorexia, depression, and signs consistent with polyarthritis, such as stiffness. Other clinical signs include vomiting, diarrhea, and peripheral edema and neurologic signs such as ataxia, paresis, and vestibular disease. Clinical signs can be mild, self-limited, or inapparent (Goodman et al., 2003). Similar to *R. rickettsii*, acute disease seems to be most common, so *E. ewingii* infection should be highest on the list of differential diagnoses from the spring through autumn when *A. americanum* is most active.

# Diagnosis

Suppurative polyarthritis is most common. Other clinicopathologic findings typically associated with acute E. canis infection (Table 96-3), such as mild to moderate thrombocytopenia and anemia, also occur. Morulae can be detected in neutrophils and eosinophils in peripheral blood and in neutrophils from synovial fluid. However, presence of morulae is transient and so easily missed cytologically. The organism has not been cultured to date, so a specific serologic test is not available. However, because the organism is closely related to E. canis, antibodies against E. ewingii can often be detected in E. canis IFA assays. However, E. ewingii antibodies do not bind to the E. canis peptide used in a point-of-care diagnostic assay in the United States (SNAP 4Dx), so this assay cannot be used to screen dogs for E. canis infection (Daniluk et al., 2007). PCR assays are now used to differentiate between members of the Ehrlichia, Anaplasma, and Neorickettsia genera and should be performed on blood collected in EDTA before administration of antibiotics.

#### **Treatment**

Supportive care should be provided as indicated. The tetracycline, doxycycline, and chloramphenicol protocols recommended for *E. canis* infections are generally effective. The ACVIM Infectious Disease Study Group currently recommends doxycycline (10 mg/kg PO q24h for at least 28 days) for *Ehrlichia* spp. infections of dogs (Neer et al., 2002).

# **Zoonotic Aspects and Prevention**

Dogs and human beings are both infected by *Ehrlichia canis*, *E. ewingii*, and *E. chaffeensis* (Buller et al., 1999). Although people cannot acquire ehrlichiosis from handling an infected dog, dogs may be reservoirs for these agents and may play a role in the human disease by bringing vectors into the human environment. Ticks should be removed and handled with care. Dogs used as blood donors should be screened serologically with *E. canis* IFA tests yearly, and seropositive dogs should not be used.

# **ROCKY MOUNTAIN SPOTTED FEVER**

# **Etiology and Epidemiology**

RMSF is caused by *R. rickettsii*. Other members of the genus also infect dogs in the United States; however, they are not

associated with clinical disease but can induce antibodies that cross-react with R. rickettsii (see Diagnosis below). For example, 17 of 22 canine sera submitted for R. akari (rickettsialpox in human beings) IFA testing cross-reacted serologically with R. rickettsii (Comer et al., 2001). In another study of dogs coinfected with several tick-borne pathogens, infection with an uncharacterized rickettsial agent commonly induced cross-reacting antibodies to R. rickettsii (Kordick et al., 1999). Canine RMSF is recognized predominantly in the southeastern states from April through September when the tick vectors are most active. From 1993 to 1996, 52% of human cases of RMSF were reported from the south Atlantic region (Treadwell et al., 2000). Dermacentor andersoni (American wood tick), Dermacentor variabilis (American dog tick), and A. americanum (Lone Star tick) are the principal vectors, host, and reservoir of R. rickettsii. A reemergence of RMSF in the southwestern states has recently occurred, and R. sanguineous ticks are the vector (Demma et al., 2005, 2006; Nicholson et al., 2006). The organism has also been detected in R. sanguineous in California (Wikswo et al., 2007). Strains of R. rickettsii that infect dogs and human beings are closely related genetically (Kidd et al., 2006). Seroprevalence rates are high in endemic areas. In one study of dogs in the southeastern United States 14.1% and 29.7% of healthy and clinically ill dogs, respectively, had detectable R. rickettsii serum antibody titers (Solano-Gallego et al., 2004).

The organism is maintained in nature in a cycle between ticks and small mammals such as voles, ground squirrels, and chipmunks, and it is transmitted transovarially in ticks, so nymphs and larvae can be infected without feeding. R. rickettsii replicates in endothelial tissues (causing vasculitis) and so can lead to diverse and sometimes severe clinical manifestations of disease as soon as 2 to 3 days after exposure. Antiplatelet antibodies can be detected in many infected dogs, suggesting an immune-mediated component to the thrombocytopenia that is frequently present (Grindem et al., 1999). Although seropositive cats have been detected, whether clinical illness occurs is unclear (Case et al., 2006).

# **Clinical Features**

Any dog not previously exposed to R. rickettsii can develop RMSF. The tick frequently feeds on and leaves the dog before the development of clinical signs. In one study only five of 30 owners knew their dogs had been infested by ticks (Gasser et al., 2001). After infection the majority of dogs are subclinical; some develop acute disease with a clinical course of approximately 14 days. No age or sex predilection exists.

Fever and depression are the most common clinical signs. Interstitial pulmonary disease, dyspnea, and cough occur in some dogs, and gastrointestinal signs occur in some acutely infected dogs. Because the disease is generally acute, lymphadenopathy and splenomegaly are not as common as in dogs with ehrlichiosis. Petechiae, epistaxis, subconjunctival hemorrhage, hyphema, anterior uveitis, iris hemorrhage, retinal petechiae, and retinal edema occur frequently. Cutaneous manifestations can include hyperemia, petechiae, edema, and dermal necrosis. Hemorrhage results from vasculitis, thrombocytopenia from consumption of platelets at sites of vasculitis, thrombocytopenia from immune destruction and, in some dogs, disseminated intravascular coagulation. Central nervous system signs include vestibular lesions (nystagmus, ataxia, head tilt), seizures, paresis, tremors, changes in mentation, and hyperesthesia (Mikszewski et al., 2005). Fatal RMSF is generally secondary to cardiac arrhythmias and shock, pulmonary disease, acute renal failure, or severe central nervous system disease.

# Diagnosis

Clinicopathologic and radiographic abnormalities are common but do not definitively document RMSE Neutrophilic leukocytosis, with or without a left shift and toxic cells, is found in most clinically affected dogs. Platelet counts are variable, but in one study 14 of 30 dogs had less than 75,000 platelets/µL without evidence of disseminated intravascular coagulation (Gasser, 2001). In other dogs hemostatic abnormalities consistent with disseminated intravascular coagulation occur. Anemia occurs in some dogs, primarily from blood loss. Increased activities of alanine aminotransferase, aspartate aminotransferase, and alkaline phosphatase, as well as hypoalbuminemia from blood loss or third spacing of albumin in tissues secondary to vasculitis, occur frequently. Because R. rickettsii does not result in chronic intracellular infection as does ehrlichiosis, hyperglobulinemia is rare. Renal insufficiency in some dogs causes azotemia and metabolic acidosis. Serum sodium, chloride, and potassium concentrations decrease in many dogs with gastrointestinal tract signs or renal insufficiency. Compared with dogs with chronic ehrlichiosis, chronic proteinuria from glomerulonephritis is rare. Positive direct Coombs test results occur in some dogs.

Nonseptic, suppurative polyarthritis occurs in some dogs. CNS inflammation usually causes increased protein concentrations and neutrophilic pleocytosis in cerebrospinal fluid; some dogs may have mononuclear cell pleocytosis or mixed inflammation. No pathognomonic radiographic abnormalities are associated with RMSF, but both experimentally and naturally infected dogs commonly develop unstructured pulmonary interstitial patterns.

A presumptive diagnosis of canine RMSF can be based on the combination of appropriate clinical, historic, and clinicopathologic evidence of disease; serologic test results; exclusion of other causes of the clinical abnormalities; and response to anti-rickettsial drugs. Documentation of seroconversion or an increasing titer 2 to 3 weeks after initial serologic testing suggests recent infection. Diagnostic criteria used in one study included a fourfold rise in antibody titer or a single titer of greater than 1:1024 if the initial titer was submitted 1 week or more after initial onset of clinical abnormalities (Gasser et al., 2001). Positive serum antibody test results alone do not prove RMSF because subclinical infection is common. In addition, positive serum antibody tests do not document infection by R. rickettsii because infection with nonpathogenic spotted fever group agents can induce cross-reacting antibodies. Demonstration of *R. rickettsii* by inoculating affected tissues or blood into susceptible laboratory animals or by documenting the organism in endothelial cells by using direct fluorescent antibody staining leads to a definitive diagnosis of RMSF but is not clinically practical. PCR can be used to document the presence of rickettsial agents in blood, other fluids, or tissues and document infection. However, some apparently healthy dogs have had *Rickettsia* spp. DNA amplified from blood, so positive PCR assay results may not always correlate to RMSF (Kordick et al., 1999).

#### **Treatment**

Supportive care for gastrointestinal tract fluid and electrolyte losses, renal disease, disseminated intravascular coagulation, and anemia should be provided as indicated. Overzealous fluid therapy may worsen respiratory or central nervous system manifestations of disease if vasculitis is severe.

Tetracycline derivatives, chloramphenicol, and enrofloxacin are the antirickettsial drugs used most frequently. Trovafloxacin and, to a lesser extent, azithromycin were beneficial for treatment of RMSF in experimentally inoculated dogs (Breitschwerdt et al., 1999). Tetracycline (22 mg/kg PO q8h for 14 to 21 days) has been commonly used historically. Doxycycline (5 to 10 mg/kg PO q12h for 14 to 21 days) is an alternative to tetracyclines; gastrointestinal absorption and central nervous system penetration are superior to tetracycline because of increased lipid solubility. Chloramphenicol (22 to 25 mg/kg PO q8h for 14 days) can be used in puppies younger than 5 months to avoid dental staining associated with tetracyclines. Enrofloxacin (3 mg/kg PO q12h for 7 days) is as effective as tetracycline or chloramphenicol. In one study of 30 dogs with RMSF, all dogs survived and no apparent differences in response rate occurred among tetracycline, doxycycline, chloramphenicol, or enrofloxacin (Gasser et al., 2001). Fever, depression, and thrombocytopenia often begin to resolve within 24 to 48 hours after starting therapy. Administration of prednisolone at antiinflammatory or immunosuppressive doses in combination with doxycycline did not potentiate RMSF in experimentally infected dogs. The prognosis for canine RMSF is fair; death occurs in less than 5% of affected dogs.

# **Zoonotic Aspects and Prevention**

Because RMSF has not been reported twice in the same dog, permanent immunity is likely. Infection can be prevented by providing strict tick control. Human beings probably do not acquire *R. rickettsii* from contact with dogs, but dogs may increase human exposure to RMSF by bringing ticks into the human environment. People can also be infected when removing ticks with activated *R. rickettsii* from the dog by hand. Two dogs and the owner all died of RMSF in one study (Elchos and Goddard, 2003). As in dogs, RMSF in people is most commonly recognized from April to September when the tick vectors are most active. Untreated RMSF is fatal in approximately 20% of infected people.

# OTHER RICKETTSIAL INFECTIONS

Rickettsia felis was originally detected in a commercial cat flea (Ctenocephalides felis) colony and has been shown to belong in the spotted fever group. Fever, headache, myalgia, and macular rash in human beings have been attributed to R. felis infection around the world. In addition, one person in Mexico developed neurologic symptoms after R. felis infection, suggesting that the organism may be the cause of severe debilitating disease in some people. The organism has been detected in C. felis, C. canis, and Pulex irritans; these fleas have a worldwide distribution. C. felis is a biologic vector for R. felis; the organism can be transmitted transovarially and transtadially within the flea. Rickettsia felis DNA has been amplified from C. felis collected from cats in the United Kingdom, France, Israel, New Zealand, Australia, Thailand, and the United States (Hawley et al., 2006).

In a recent study in our laboratory we assayed 92 pairs of cat blood and flea extracts from Alabama, Maryland, and Texas by using PCR assays that amplify a region of the citrate synthase gene (gltA) and the outer membrane protein B gene (ompB). Of the 92 pairs, 62 (67.4%) of flea extracts and none of the cat blood samples were positive for R. felis DNA (Hawley et al., 2006). In another study we showed R. felis and R. rickettsii antibody prevalence rates in cats with fever to be 5.6% and 6.6%, respectively, but neither organism was amplified from blood (Bayliss et al., 2007). These results prove that cats are sometimes exposed, but further data are needed to determine significance of diseases associations. Because clinical illness in cats has not been documented, optimal treatment is unknown. However, on the basis of results in dogs, doxycycline or a fluoroquinolone would be logical choices. Prevention in cats and people should include flea control.

Neorickettsia helminthoeca (salmon poisoning) causes enteric signs of disease in dogs from the Pacific Northwest. Coxiella burnetii infection is associated with parturient or aborting cats and is primarily a zoonotic disease (see Chapter 100). H. felis has been reclassified as a Mycoplasma.

# CHAPTER OUTLINE

CANINE DISTEMPER VIRUS
FELINE CORONAVIRUS
FELINE IMMUNODEFICIENCY VIRUS
FELINE LEUKEMIA VIRUS

There are multiple viral infections of dogs and cats. Several, including canine distemper virus, some feline coronaviruses, feline leukemia virus, and feline immunodeficiency virus, can cause systemic signs of disease. See other chapters for discussions of viral diseases specific to one organ system.

# **CANINE DISTEMPER VIRUS**

# **Etiology and Epidemiology**

Canine distemper virus (CDV) induces disease predominantly in terrestrial carnivores, but many other species, including seals, ferrets, skunks, badgers, porpoises, and exotic Felidae, have been infected by either CDV or related morbilliviruses. The virus replicates in lymphoid, nervous, and epithelial tissues and is shed in respiratory exudates, feces, saliva, urine, and conjunctival exudates for up to 60 to 90 days after natural infection. After inhalation, the virus is engulfed by macrophages and within 24 hours is carried by lymphatics to tonsillar, pharyngeal, and bronchial lymph nodes, where replication occurs. Central nervous system (CNS) and epithelial tissues are infected approximately 8 to 9 days after initial infection.

The degree of clinical illness and the tissues involved vary depending on the strain of the virus and the immune status of the host (Greene et al., 2006). Nonimmune dogs of any age are susceptible, but the disease is most common in puppies between 3 and 6 months of age. An estimated 25% to 75% of susceptible dogs are subclinically infected after exposure. Massive replication of the virus in the epithelial cells of the respiratory tract, gastrointestinal system, and

genitourinary system occurs in dogs with poor immune responses by postinfection days 9 to 14; these dogs usually die from polysystemic disease. In dogs with moderate immune responses by postinfection days 9 to 14, the virus replicates in epithelial tissues and may result in clinical signs of disease. Dogs with good cell-mediated responses and virus-neutralizing antibody titers by postinfection day 14 clear the virus from most tissues and may not be clinically affected. Most infected dogs develop CNS infection, but clinical signs of CNS disease occur only in dogs with low or no antibody response. Acute demyelination results from restrictive infection of oligodendrogliocytes and subsequent necrosis; chronic demyelination is caused by immune-mediated mechanisms, including antimyelin antibodies and CDV immune complex formation and removal.

#### **Clinical Features**

Many clinically affected dogs are unvaccinated, failed to receive colostrum from an immune bitch, were inappropriately vaccinated, or are immunosuppressed and also have a history of exposure to infected animals. Owners generally present affected dogs for evaluation of depression, malaise, oculonasal discharge, cough, vomiting, diarrhea, or CNS signs. Dogs with poor immune responses generally have the most severe signs and progress rapidly to life-threatening disease. Some partially immune dogs have only mild respiratory disease, presumptively diagnosed as kennel cough syndrome. Tonsillar enlargement, fever, and mucopurulent ocular discharge are common physical examination findings. Increased bronchial sounds, crackles, and wheezes are usually auscultated in dogs with bronchopneumonia.

Hyperesthesia, seizures, cerebellar or vestibular disease, paresis, and chorea myoclonus are common CNS signs that generally develop within 21 days of recovery from systemic disease (Table 97-1). CNS disease is generally progressive and carries a poor prognosis. Some dogs with signs of CNS disease never had systemic signs of disease recognized. Old dog encephalitis is a chronic, progressive panencephalitis in older dogs (older than 6 years) thought to be attributable to CDV infection in which microglial proliferation and neuronal degeneration in the cerebral cortex result in depression,

TABLE 97-1

# Clinical Manifestations of CDV Infection

In utero infection Stillbirth

Abortion

Fading puppy syndrome in the neonatal period

CNS signs at birth

Gastrointestinal tract disease Vomiting

Small-bowel diarrhea

Mucoid to mucopurulent nasal discharge Respiratory tract disease

Sneezing

Coughing with increased bronchovesicular sounds or crackles on auscultation

Dyspnea

Ocular disease Retinochoroiditis, medallion lesions (see Fig. 97-1), optic neuritis

> Keratoconjunctivitis sicca Mucopurulent ocular discharge

Neurologic Disease

Cerebellar disease

Miscellaneous

Spinal cord disease Paresis and ataxia

Head tilt, nystagmus, other cranial nerve and conscious proprioception deficits Central vestibular disease

Ataxia, head bobbing, hypermetria

Generalized or partial seizures ("chewing gum fits") Cerebral disease

Depression

Unilateral or bilateral blindness

Chorea myoclonus Rhythmic jerking of single muscles or muscle groups

> Fever Anorexia

Tonsillar enlargement

Dehydration Pustular dermatosis

Hyperkeratosis of the nose and footpads Enamel hypoplasia in surviving puppies

CDV, Canine distemper virus; CNS, central nervous system.

circling, head pressing, and visual deficits (see Chapter 69 for more information on CNS distemper).

Ocular abnormalities associated with CDV infection include anterior uveitis, optic neuritis with resultant blindness and dilated pupils, and retinochoroiditis. The combination of retinochoroiditis and encephalitis is detected in approximately 40% of affected dogs. Keratoconjunctivitis sicca and hyperreflective retinal scars called medallion lesions occur in some dogs with chronic infection (Fig. 97-1).

Other less-common syndromes have been attributed to CDV infection. Dogs infected before the development of permanent dentition usually have enamel hypoplasia. Hyperkeratosis of the nose and footpads and pustular dermatitis are the most common dermatologic abnormalities. Puppies infected transplacentally can be stillborn, aborted, or born with CNS disease.

#### Diagnosis

The combination of clinical findings and routine clinicopathologic and radiographic evaluation usually leads to a presumptive diagnosis of CDV infection. Lymphopenia and mild thrombocytopenia are consistent hematologic abnormalities. Interstitial and alveolar pulmonary infiltrates are common radiographic findings in dogs with respiratory disease. Although some dogs with CNS infection have normal cerebrospinal fluid (CSF) analyses, most have mononuclear cell pleocytosis and increased protein concentrations. The ratio of serum/CSF immunoglobulin G (IgG) and albumin is commonly high in dogs with encephalitis, but this only documents inflammation of the CNS, not CDV infection.

Measurement of serum or CSF antibody titers can aid in the diagnosis of CDV infection. Documentation of a fourfold increase in the serum IgG titer over a 2- to 3-week period or detection of IgM antibodies in serum is consistent with recent infection or recent vaccination but does not prove clinical disease. CSF antibody titers to CDV are increased in some dogs with encephalitis. False-positive results can occur in CSF samples contaminated with blood. If CSF antibody titers are greater than those in serum, the antibody in the CSF had to be produced locally and is consistent with CNS CDV infection. If increased CSF protein concentrations, mononuclear pleocytosis, and antibodies against CDV are detected in a CSF sample not contaminated with peripheral blood, a presumptive diagnosis of CDV encephalitis can be made.

Definitive diagnosis of CDV infection requires demonstration of viral inclusions by cytologic examination, direct fluorescent antibody staining of cytologic or histopathologic

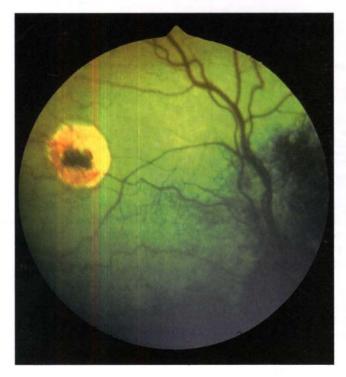

FIG 97-1
Medallion lesions resulting from canine distemper virus infection. (Courtesy Dr. Cynthia Powell, Colorado State University, Fort Collins.)

specimens, histopathologic evaluation, virus isolation, or reverse transcriptase polymerase chain reaction (RT-PCR) documentation of CDV RNA in peripheral blood, CSF, or conjunctival scrapings. Viral inclusions are rarely found in erythrocytes, leukocytes, and leukocyte precursors of infected dogs. Inclusions are generally present for only 2 to 9 days after infection and therefore often are not present when clinical signs occur. Inclusions may be easier to find in smears made from buffy coats or bone marrow aspirates than in those made from peripheral blood. Viral particles can be detected by immunofluorescence in cells from the tonsils, respiratory tree, urinary tract, conjunctival scrapings, and CSF for 5 to 21 days after infection. Recent administration of modified-live CDV-containing vaccines can lead to positive results in direct fluorescent antibody assays and RT-PCR assays. False-positive results have been detected occasionally in direct fluorescent antibody assays performed on conjunctival cells from specific pathogen-free puppies, so results of these tests should be interpreted cautiously (Lappin et al., unpublished data, 2007).

# **Treatment**

Therapy for CDV infection is nonspecific and supportive. Secondary bacterial infections of the gastrointestinal tract and respiratory system are common and, if indicated, should be treated with appropriate antibiotics (see Chapter 93). Anticonvulsants are administered as needed to control seizures (see Chapter 67), but chorea myoclonus has no known

effective treatment. Glucocorticoid administration may be beneficial in some dogs with CNS disease from chronic CDV infection, but it is contraindicated in acutely infected dogs. The prognosis for dogs with CNS distemper is poor.

# **Prevention and Zoonotic Aspects**

The CDV survives in exudates only for approximately 1 hour at body temperature and 3 hours at room temperature and is susceptible to most routine hospital disinfectants. Dogs with gastrointestinal or respiratory signs of disease should be housed in isolation to avoid aerosolization to susceptible populations. Care should be taken to avoid transmission by contaminated fomites (see Chapter 94). All puppies should receive at least three CPV-2, CAV-2, and CDV-containing vaccines, every 3 to 4 weeks, between 6 and 16 weeks of age, with the last booster administered at 14 to 16 weeks of age (see Chapter 94). Modified-live CDV vaccines and the recombinant CDV (rCDV) vaccine are considered adequate by the AAHA Task Force (Paul et al., 2006). Maternal antibodies can block CDV vaccines; therefore in high-risk puppies a modified-live measles virus vaccine has been used between 4 and 12 weeks of age to induce heterologous antibodies that will protect puppies against CDV as maternal antibodies wane. The need for this product is now in question because the rCDV vaccine immunizes puppies in the face of maternal immunity (see Chapter 94). Vaccination against CDV is not as effective if the body temperature is 39.9° C or higher or if other systemic diseases are detected. Vaccines should be boosted at 1 year of age. Recent data suggest that after the 1-year booster, repeat boosters are not needed again for a minimum of 3 years (see Chapter 94).

Disease from CDV infection has occurred in some vaccinated dogs and rarely is attributed to modified-live virus vaccination. Clinical disease in vaccinated dogs develops if the host was immunocompromised, infected with the virus before vaccination, had vaccine-suppressive levels of maternal antibodies, or was incompletely vaccinated. Alternately, the vaccine may have been inactivated by improper handling or may not have protected against all field strains of CDV. Distemper virus encephalitis develops after modified-live vaccination of some dogs coinfected with canine parvovirus; administration of modified-live CDV vaccines should be delayed in dogs with clinical signs of disease consistent with parvovirus infection. Mild, transient thrombocytopenia can be induced by modified CDV vaccination but has not been associated with spontaneous bleeding unless the patient has an underlying subclinical coagulopathy. No proven public health risks are associated with CDV.

# **FELINE CORONAVIRUS**

# **Etiology and Epidemiology**

Coronaviruses causing disease in cats include feline infectious peritonitis (FIP) virus and feline enteric coronavirus (FECV). Enteric infection generally results in mild gastrointestinal signs; systemic infection can induce a clinical syn-

drome with diverse manifestations commonly referred to as FIP. Multiple field strains of FECV and FIP virus have varying degrees of virulence. Mutations or recombinant strains of endemic FECV capable of inducing FIP are believed to develop in the gastrointestinal tract of some infected cats (Vennema et al., 1998).

Enteric coronaviruses are commonly shed in feces and rarely in saliva (Addie et al., 2001) and are highly contagious. Although the prevalence of transplacental transmission is unknown, one epidemiologic study suggested that it is unlikely (Addie et al., 1993). By RT-PCR testing, coronaviruses can be detected in feces as early as 3 days after infection. In studies of FECV-infected, closed cat colonies, almost every cat becomes infected. In one study of 155 pet cats with naturally occurring FECV infection, viral RNA was shed continuously (n = 18) or intermittently (n = 44) in the feces of some cats (Addie et al., 2001). Others were initially shedding viral RNA and then ceased shedding (n = 56), and some were resistant to infection (n = 4). The cats that stopped viral shedding were susceptible to reinfection. Viral RNA was detected in the ileum, colon, and rectum of cats with persistent shedding.

Coronaviruses with the ability to infect monocytes can cause viremia and disseminate throughout the body, potentially resulting in FIP. Between 1986 and 1995, one of every 200 feline accessions at veterinary teaching hospitals in North America was given a clinical diagnosis of FIP (Rohrbach et al., 2001). Most cases of FIP develop in multiple-cat households or catteries. The effusive form of disease develops in cats with poor cell-mediated immune responses; the noneffusive form develops in cats with partial cell-mediated immunity. The effusive form of disease is an immune complex vasculitis characterized by leakage of protein-rich fluid into the pleural space, the peritoneal cavity, the pericardial space, and the subcapsular space of the kidneys. In the noneffusive form pyogranulomatous or granulomatous lesions develop in multiple tissues, particularly the eyes, brain, kidneys, omentum, and liver. Some affected cats have characteristics of both forms of FIP.

Clinical disease associated with FIP virus may be influenced by a number of factors, including the virulence of the strain, the dose of the virus, the route of infection, the immune status of the host, genetically determined host factors, the presence of other concurrent infections, and whether the cat had been previously exposed to a coronavirus. Some breeds appear to be predisposed to the development of FIP (Pesteanu-Somogyi et al., 2006). Feline leukemia virus infection and respiratory tract infection increase the risk for FIP, suggesting that the immune status of the host is important in determining the development of clinical disease. Cats concurrently infected with FIV shed 10 to 100 times more FECV in stool than FIV-naive cats. Experimentally infected, seropositive kittens develop accelerated FIP compared with seronegative kittens when exposed to FIP virus. This antibody-dependent enhancement of virus infectivity occurs because macrophages are more effectively infected by virus complexed with antibody than by virus alone. This phenomenon appears to be rare in naturally infected cats.

#### **Clinical Features**

Enteric replication of coronaviruses commonly results in fever, vomiting, and mucoid diarrhea. With FECV infection clinical signs are self-limiting and generally respond to supportive care within days. Fulminant FIP can occur in cats of any age but is generally recognized in cats younger than 5 years; most cases are younger than 1 year. Intact males are overrepresented in some studies. In cattery outbreaks, usually only one or two kittens in a litter are clinically affected. This may relate to poor transmissibility of strains capable of inducing FIP. Anorexia, weight loss, and general malaise are common presenting complaints (Box 97-1). Icterus, ocular inflammation, abdominal distension, dyspnea, or CNS abnormalities are occasionally noted by the owner.

Fever and weight loss are common with both the effusive and noneffusive forms of the disease. Pale mucous membranes or petechiae are noted in some cats. FIP is one of the most common causes of icterus in cats younger than 2 years; liver size can be normal or enlarged, and the margins are usually irregular. Abdominal distension is common, a fluid wave can often be balloted, and occasionally masses (pyogranulomas or lymphadenopathy) can be palpated in the omentum, mesentery, or intestines. A solitary ileocecocolic or colonic mass, resulting in obstruction leading to vomiting and diarrhea, occurs in some cats. Kidneys can be small (chronic disease) or large (acute disease or subcapsular effusion); renal margins are usually irregular. Pleural effusion can result in dyspnea and a restrictive breathing pattern (shallow and rapid) as well as muffled heart and lung sounds. Male cats sometimes have scrotal enlargement from fluid accumulation.

Anterior uveitis and chorioretinitis occur most frequently with the noneffusive form of the disease and can be its only manifestation. Pyogranulomatous disease can develop anywhere in the CNS, leading to a variety of neurologic signs that include seizures, posterior paresis, and nystagmus.

Feline coronaviruses have been suggested as a cause of failure to conceive, abortion, stillbirth, and congenital defects as well as the fading kitten syndrome (kitten mortality complex). However, one epidemiologic study failed to link feline coronavirus with reproductive failure or neonatal kitten death (Addie et al., 1993).

# Diagnosis

Multiple hematologic, serum biochemical, urinalysis, diagnostic imaging, and CSF abnormalities develop in cats with FIP. Several authors have assessed the predictive values of individual and combinations of tests (Hartmann et al., 2003; Sparkes et al., 1994). Other than histopathology, the positive predictive values of tests used to aid in the diagnosis of FIP are less than 100%. A presumptive diagnosis of FIP is usually based on the combination of clinical and clinicopathologic findings.

BOX 97-1

Clinical Findings Suggestive of FIP in Cats

# Signalment and History

Cats <5 years or >10 years of age

Purebred cat

Purchase from a cattery or multiple-cat household

Previous history of a mild, self-limiting gastrointestinal or respiratory disease

Serologic evidence of infection by FeLV

Nonspecific signs of anorexia, weight loss, or depression

Seizures, nystagmus, or ataxia

Acute, fulminant course in cats with effusive disease Chronic, intermittent course in cats with noneffusive disease

#### **Physical Examination**

Fever

Weight loss

Pale mucous membranes with or without petechiae

Dyspnea with a restrictive breathing pattern

Muffled heart or lung sounds

Abdominal distension with a fluid wave with or without scrotal swelling

Abdominal mass from focal intestinal granuloma or lymphadenopathy

lcterus with or without hepatomegaly

Chorioretinitis or iridocyclitis

Multifocal neurologic abnormalities

Irregularly marginated kidneys with or without renomegaly Splenomegaly

# **Clinicopathologic Abnormalities**

Nonregenerative anemia

Neutrophilic leukocytosis with or without a left shift Lymphopenia

Hyperglobulinemia characterized as a polyclonal gammopathy; rare monoclonal gammopathies

Nonseptic, pyogranulomatous exudate in pleural space, peritoneal cavity, or pericardial space

Increased protein concentrations and neutrophilic pleocytosis in CSF

Positive coronavirus antibody titer in the majority (especially noneffusive)

Pyogranulomatous or granulomatous inflammation in perivascular location on histologic examination of tissues

Positive results of immunofluorescence or RT-PCR performed on pleural or peritoneal exudate

FIP, Feline infectious peritonitis; FeLV, feline leukemia virus; CSF, cerebrospinal fluid; RT-PCR, reverse transcriptase polymerase chain reaction

Normocytic, normochromic, nonregenerative anemia; neutrophilic leukocytosis; and lymphopenia are common. Disseminated intravascular coagulation resulting in thrombocytopenia occurs in some cats. Hyperproteinemia with or without hypoalbuminemia can occur. Polyclonal gammopathies from increases in  $\alpha_2$ -globulin and  $\gamma$ -globulin concentrations are most commonly detected; monoclonal

gammopathies are rare. Most of these findings are consistent with chronic inflammation and do not prove FIP.

Hyperbilirubinemia with variable increases in alanine aminotransferase and alkaline phosphatase activities occurs in some cats with hepatic disease. Prerenal azotemia, renal azotemia, and proteinuria are the most common renal abnormalities. Radiographs can reveal pleural, pericardial, or peritoneal effusions; hepatomegaly; or renomegaly. Mesenteric lymphadenopathy may result in mass lesions in some cats. Ultrasonography can be used to confirm the presence of abdominal fluid in cats with minimal fluid volumes and to evaluate the pancreas, liver, lymph nodes, and kidneys, Magnetic resonance imaging showed periventricular contrast enhancement, ventricular dilation, and hydrocephalus in one group of cats with neurologic FIP (Foley et al., 1998). Protein concentrations and nucleated cell counts (neutrophils predominate in most cases) are commonly increased in CSF from cats with CNS involvement. Although high coronavirus antibody titers are common in the CSF of cats with neurologic FIP, the antibodies appear to be derived from blood and, as the authors of one study concluded, were of equivocal value (Boettcher et al., 2007).

Effusions from cats with FIP are sterile, colorless to straw colored, may contain fibrin strands, and may clot when exposed to air. The protein concentration on fluid analysis commonly ranges from 3.5 g/dL to 12 g/dL and is generally higher than that associated with other diseases. Mixed inflammatory cell populations of lymphocytes, macrophages, and neutrophils occur most commonly; neutrophils predominate in most cases, but in some cats macrophages are the primary cell type seen. In some cats the coronavirus antibody titers are greater in the effusion than in serum. Measurement of protein concentrations in effusions and calculation of the albumin/globulin ratio can aid in the diagnosis of effusive FIP. In one study an albumin/globulin ratio of 0.5 had a positive predictive value of 89%, and an albumin/ globulin ratio of 1.0 had a negative predictive value of 91% (Hartmann et al., 2003). Coronavirus antigens are commonly detected by direct immunofluorescence in the effusions of cats with FIP but not in the effusions of cats with other diseases. In addition, viral RNA can be detected by RT-PCR in effusions and is unlikely to be in effusions from other causes.

Detection of serum antibodies is of limited benefit in the diagnosis of FIP. Infection of cats by any coronavirus can cause cross-reacting antibodies; therefore a positive antibody titer does not diagnose FIP, protect against disease, or predict when a cat may develop clinical FIP. Because coronavirus antibody tests are not standardized, results from different laboratories commonly do not correlate. Cats with FIP are occasionally serologically negative because of rapidly progressive disease, with a delayed rise in titer, disappearance of antibody in terminal stages of the disease, or immune complex formation. Maternal antibodies decline to undetectable concentrations by 4 to 6 weeks of age; kittens infected in the postnatal period become seropositive

at 8 to 14 weeks of age. Thus serologic testing of kittens can be used to prevent the spread of coronaviruses (see below).

Because virus isolation is not practical clinically, RT-PCR is used most frequently to detect coronaviruses in feces. However, positive test results do not differentiate FIP virus from FECV. RNA of both FIP virus and FECV can be amplified from the blood of cats, so positive test results do not always correlate with the development of FIP. Amplification of the mRNA of the M gene by RT-PCR has had mixed results in two studies performed to date (Simons et al., 2005; Can-S Ahna K et al., 2007). In the latter study, 13 of 26 apparently normal cats were positive for FECV mRNA in blood, suggesting that the positive predictive value of this assay for the diagnosis of FIP was low.

Definitive diagnosis of FIP is based on detection of characteristic histopathologic findings, virus isolation, demonstration of the virus in effusions or tissue by use of immunocytochemical or immunohistochemical staining, or demonstration of viral RNA in effusions or tissues by RT-PCR.

#### **Treatment**

Because an antemortem diagnosis of FIP is difficult to make, assessment of studies reporting successful treatment is virtually impossible. A small percentage of cats have spontaneous remission, adding to the confusion concerning therapeutic response. Supportive care, including correction of electrolyte and fluid balance abnormalities, should be provided to cats with FIP as needed.

Optimal treatment of cats with FIP would ideally combine virus elimination with suppression of B-lymphocyte function and stimulation of T-lymphocyte function. In vitro inhibition of FIP virus replication has been demonstrated with a number of drugs, including ribavirin, human interferon-α, feline fibroblastic interferon-β, adenine arabinoside, and amphotericin B. However, to date no uniformly successful antiviral treatment has been developed, and the drugs typically have potentially serious adverse effects.

Because disease from FIP is secondary to immune-mediated reactions against the virus, modulation of the inflammatory reaction is the principal form of palliative therapy. Low-dose prednisolone (1 to 2 mg/kg PO q24h) may lessen clinical manifestations of noneffusive FIP. However, the use of immune-suppressive drugs is controversial because cats with FIP have impaired immune responses (Knotek, 2000). The use of prednisolone and feline interferon has recently been promoted for the treatment of both effusive and noneffusive FIP (Isida et al., 2004). In that study four cats with effusive disease believed to be from FIP virus had prolonged remission. However, the results should be viewed cautiously because the cases were atypical (older cats), the diagnosis of FIP was not confirmed, no control group was used and, if a treatment response occurred, whether it was from the prednisolone or interferon-ywas impossible to determine because both drugs were administered to all cats. Procurement of feline interferon is currently difficult in the United States; whether a positive effect could be achieved by use of human interferons is unknown.

Antibiotics do not have primary antiviral effects but may be indicated for the treatment of secondary bacterial infection. Other supportive care treatments, such as anabolic steroids (stanozolol, 1 mg PO q12h), aspirin (10 mg/kg PO q48-72h), and ascorbic acid (125 mg PO q12h) have also been recommended for the treatment of FIP. Most cats with systemic clinical signs of FIP die or require euthanasia within days to months of diagnosis. The effusive form of disease carries a grave prognosis. Depending on the organ system involved and the severity of polysystemic clinical signs, cats with noneffusive disease have variable survival times. Cats with only ocular FIP may respond to antiinflammatory treatment or enucleation of the affected eye(s) and have a better prognosis than cats with systemic FIP.

# **Prevention and Zoonotic Aspects**

Prevention of coronavirus infections is best accomplished by avoiding exposure to the virus. Although viral particles of FIP can survive in dried secretions for up to 7 weeks, routine disinfectants inactivate the virus. Epidemiologic studies suggest the following:

- · Some healthy, coronavirus-seropositive cats shed the
- Seronegative cats do not usually shed the virus.
- · Kittens are usually not infected by coronaviruses transplacentally.
- · Maternally derived coronavirus antibodies wane by 4 to 6 weeks of age.
- · Kittens are most likely to become infected by contact with cats other than their queens after maternal antibodies wane.
- Coronavirus antibodies from natural infection develop by 8 to 14 weeks of age.

These findings have lead to recommendations that kittens born in a breeding situation with coronavirus-seropositive cats should be housed only with the queen and littermates until sold, should be tested for coronavirus antibodies at 14 to 16 weeks of age, and should be sold only if seronegative. Maintaining a coronavirus-seronegative household and not allowing cats to have contact with other cats would be optimal. Cats can eliminate coronavirus infections; a previously infected cat should be shown to be negative for viral RNA in feces for 5 months and should be seronegative to be considered coronavirus naïve (Addie et al., 2001).

An intranasally administered, mutant strain of coronavirus that induces mucosal immune response but minimal systemic immune response is available (Primucell FIP, Pfizer Animal Health, Exton, Pa.). This strain does not induce FIP; the majority of cats with adverse effects have exhibited only mild signs associated with placement of liquid in the nares, and the vaccine does not appear to potentiate antibodydependent enhancement of virus infectivity when administered to previously seropositive cats (see Chapter 94). The vaccine appears to be effective in at least some cats, but whether the vaccine protects against all field strains, mutations, or recombinants is unknown. The vaccine is not likely to be effective in cats that have previously been infected by a coronavirus. The only indication for the vaccine is for seronegative cats with risk of exposure to coronaviruses, and the American Association of Feline Practitioners considers the vaccine generally not recommended (see Chapter 94). Zoonotic transfer of FIP virus or FECV to human beings has not been documented.

# FELINE IMMUNODEFICIENCY VIRUS

# **Etiology and Epidemiology**

Feline immunodeficiency virus (FIV) is an exogenous, single-strand RNA virus in the family Retroviridae, subfamily Lentivirinae. The virus is morphologically similar to the human immunodeficiency virus (HIV) but it is antigenically distinct. Like FeLV, FIV produces reverse transcriptase to catalyze the insertion of viral RNA into the host genome. Multiple subtypes of the virus exist, and some isolates have differing biologic behavior. For example, immune deficiency is induced much more quickly by some isolates, and clinical diseases, such as uveitis, are induced by some but not all isolates.

Aggressive biting behavior is thought to be the primary route of transmission of FIV; older, male, outdoor cats with clinical signs of disease are most commonly infected. The prevalence of FIV antibodies in North America was 2.5% in a recent study (Levy et al., 2006). FIV is present in semen and can be transmitted by artificial insemination. Transplacental and perinatal transmission occurs from infected queens to kittens. Arthropod transmission appears to be unlikely. Transmission by routes other than biting is less common because high levels of viremia are of short duration. FIV infection of cats has worldwide distribution, and prevalence rates vary greatly by region and the lifestyle of the cats tested. FIV replicates in several cell types, including Tlymphocytes (CD4+ and CD8+), B-lymphocytes, macrophages, and astrocytes. The primary phase of infection occurs as the virus disseminates throughout the body, initially leading to low-grade fever, neutropenia, and generalized reactive lymphadenopathy. A subclinical, latent period of variable length then develops; the length of this period is related in part to the strain of virus and the age of the cat when infected. The median age of healthy, naturally infected cats and clinically ill naturally infected cats is approximately 3 years and 10 years, respectively, suggesting a latent period of years for most strains of FIV. Chronic experimental and naturally occurring infection results in a slow decline in circulating CD4+ lymphocyte numbers, response to mitogens, and decreased production of cytokines associated with cell-mediated immunity, such as interleukin (IL)-2 and IL-10; neutrophil function and natural killer cell function are also affected. Humoral immune responses are often intact, and a polyclonal gammopathy develops from nonspecific

B-lymphocyte activation. Within months to years, an immune deficiency stage similar to acquired immunodeficiency syndrome (AIDS) in human beings develops. Coinfection with FeLV potentiates the primary and immune deficiency phases of FIV. However, coinfection with *Mycoplasma haemofelis*, *Toxoplasma gondii*, feline herpesvirus, and feline calicivirus, as well as immunization, failed to potentiate FIV-associated immunodeficiency.

#### **Clinical Features**

Clinical signs of infection with FIV can arise from direct viral effects or secondary infections that ensue after the development of immunodeficiency (Table 97-2). Most of the clinical syndromes diagnosed in FIV-seropositive cats also occur in FIV-naïve cats, which makes proving disease causation difficult during the subclinical stage of infection. A positive FIV antibody test does not prove immunodeficiency or disease from FIV and does not necessarily indicate a poor prognosis. The only way to determine accurately whether an FIV-seropositive cat with a concurrent infectious disease has a poor prognosis is to treat the concurrent infection.

Primary (acute) FIV infection is characterized by fever and generalized lymphadenopathy. Owners commonly present FIV-infected cats in the immunodeficiency stage for evaluation of nonspecific signs such as anorexia, weight loss, and depression or for evaluation of abnormalities associated with specific organ systems. When a clinical syndrome is diagnosed in a cat seropositive for FIV, the workup should include diagnostic tests for other potential causes (see Table 97-2).

Clinical syndromes reportedly from primary viral effects include chronic small-bowel diarrhea, nonregenerative anemia, thrombocytopenia, neutropenia, lymphadenopathy, pars planitis (inflammation in the anterior vitreous humor), anterior uveitis, glomerulonephritis, renal insufficiency, and hyperglobulinemia. Behavioral abnormalities, with dementia, hiding, rage, inappropriate elimination, and roaming, are the most common neurologic manifestations of FIV infection. Seizures, nystagmus, ataxia, and peripheral nerve abnormalities may occasionally be attributable to primary viral effects. Lymphoid malignancies, myeloproliferative diseases, and several carcinomas and sarcomas have been detected in FIV-infected, FeLV-naïve cats, suggesting a potential association between FIV and malignancy; FIV-infected cats are at higher risk for the development of lymphoma. Although FIV is not oncogenic, it predisposes to neoplasia because of its immunosuppressive effects.

#### Diagnosis

Neutropenia, thrombocytopenia, and nonregenerative anemia are the most common hematologic abnormalities associated with FIV infection. Monocytosis and lymphocytosis occur in some cats and may be caused by the virus or chronic infection with opportunistic pathogens. Cytologic examination of bone marrow aspirates may reveal maturation arrest (i.e., myelodysplasia), lymphoma, or leukemia. A progressive decline in CD4+ lymphocytes, a plateau or pro-

**TABLE 97-2** 

# Clinical Syndromes Associated with FIV Infection and Possible Opportunistic Agents

CLINICAL SYNDROME	PRIMARY VIRAL EFFECT	OPPORTUNISTIC AGENTS		
Dermatologic/otitis externa	None	Bacterial; atypical Mycobacterium; Otodectes cynotis; Demodex cati; Notoedres cati; dermatophytosis; Cryptococcus neoformans; cowpox		
Gastrointestinal	Yes; small-bowel diarrhea	Cryptosporidium spp.; Cystoisospora spp.; Giardia spp.; Salmonella spp.; Campylobacter jejuni; others		
Glomerulonephritis	Yes	Bacterial; FeLV, FIP, SLE		
Hematologic	Yes; nonregenerative anemia; neutropenia; thrombocytopenia	M. haemofelis; FeLV; Bartonella henselae?		
Neoplasia	Yes; myeloproliferative disorders and lymphoma	FeLV		
Neurologic	Yes; behavioral abnormalities	T. gondii; C. neoformans; FIP; FetV, B. henselae?		
Ocular	Yes; pars planitis, anterior uveitis	T. gondii; FIP; C. neoformans, FHV-1, B. henselae		
Pneumonia/pneumonitis	None	Bacterial; T. gondii; C. neoformans		
Pyothorax	None	Bacterial		
Renal failure	Yes	Bacterial; FIP; FeLV		
Stomatitis	None	Calicivirus; overgrowth of bacteria flora; candidiasis, B henselae?		
Upper respiratory tract	None	FHV-1; calicivirus; overgrowth of bacterial flora;  Cryptococcus neoformans		
Urinary tract infection	None	Bacterial		

FIV, Feline immunodeficiency virus; FeLV, feline leukemia virus; FIP, feline infectious peritonitis; SLE, systemic lupus erythematosus; FHV-1, feline herpesvirus type 1.

gressive increase in CD8+ lymphocytes, and an inversion of the CD4+/CD8+ ratio occurs in experimentally infected cats over time. A multitude of serum biochemical abnormalities is possible depending on what FIV-associated syndrome is occurring. Renal azotemia and polyclonal gammopathy are the changes most likely to be attributable to direct viral effects. No pathognomonic imaging abnormalities are associated with FIV infection.

Antibodies against FIV are detected in serum in clinical practice most frequently by enzyme-linked immunosorbent assay (ELISA). Comparisons between different tests have shown the results of most assays are comparable (Hartmann et al., 2007). Clinical signs can occur before seroconversion in some cats and some infected cats never seroconvert; thus false-negative reactions can occur. Results of virus isolation or PCR on blood are positive in some antibody-negative cats. False-positive reactions are common with ELISA; therefore positive ELISA results in healthy or low-risk cats should be confirmed by Western blot immunoassay or RT-PCR. Kittens can have detectable, colostrum-derived antibodies for several months. Kittens younger than 6 months that are FIV seropositive should be tested every 60 days until the result is negative. If antibodies persist at 6 months of age, the kitten is likely infected. Virus isolation or PCR on blood can also be performed to confirm infection. The biggest problem with FIV RT-PCR assays to date is lack of standardization among laboratories and the potential for both false-positive and false-negative results (Crawford et al., 2005). A vaccine against FIV has been licensed in the United States (see

Chapter 94). This vaccine induces antibodies that cannot be distinguished from those induced by naturally occurring disease with currently available tests (see below).

Detection of antibodies against FIV in the serum of cats that have not been vaccinated against FIV documents exposure and correlates well with persistent infection but does not correlate with disease induced by the virus. Because many clinical syndromes associated with FIV can be caused by opportunistic infections, further diagnostic procedures may determine treatable etiologies (see Table 97-2). For example, some FIV-seropositive cats with uveitis are coinfected by *T. gondii* and often respond to the administration of anti-*Toxoplasma* drugs (see Chapter 99).

#### **Treatment**

Because FIV-seropositive cats are not necessarily immunosuppressed or diseased from FIV, the cat should be evaluated and treated for other potential causes of the clinical syndrome. Some FIV-seropositive cats are immunodeficient; if infectious diseases are identified, bacteriocidal drugs administered at the upper end of the dosage should be chosen. Long-term antibiotic therapy or multiple treatment periods may be required. The only way to determine if an FIVseropositive cat with a concurrent infection has a poor prognosis is to treat the concurrent infection.

A variety of antiviral drugs and immune stimulation therapies have been administered to cats with FIV or FeLV infection (Table 97-3). Administration of interferons has shown promise in some studies. Oral administration of

# Drug Treatment Regimens for Viremic, Clinically Ill Cats with FIV or FeLV Infections

THERAPEUTIC AGENT*	ADMINISTRATION
Acemannan	2 mg/kg intraperitoneal once weekly for 6 weeks
AZT	5 mg/kg PO or SQ q12h; monitor for the development of anemia
Bovine lactoferrin	175 mg PO in milk or VAL syrup, q12-24h for treatment of stomatitis
Erythropoietin	100 U/kg SQ three times weekly and then titrate to effect
Interferon-a*	10 IU/kg PO q24h as long as effective
Interferon-feline	1 million U, SQ, q24h for 5 days in three series starting on days 0, 14, and 60
Staphylococcus A	10 µg/kg intraperitoneal twice weekly for 10 weeks and then monthly
Propionibacterium acnes	0.5 mL IV once or twice weekly to effect

Limited information from controlled studies is available for any of these protocols.

Modified from Hartmann K et al: Treatment of feline leukemia virus infection with 3'-azido-2,3-dideoxythymidine and human alpha-interferon, J Vet Intern Med 16:345, 2002.

AZT, Azidothymidine; FIV, feline immunodeficiency virus; FeLV, feline leukemia virus.

10 IU/kg of human interferon-α led to improved clinical signs and prolonged survival compared with a placebotreated control group in one study (Pedretti et al., 2006). In another study feline recombinant interferon was administered at 106 U/kg/day SQ for 5 days in three series (starting on days 0, 14, and 60) and was shown to improve clinical signs early in the study and prolong survival in treated cats (de Mari et al., 2004). Administration of antiviral agents such as the reverse transcriptase inhibitor azidothymidine (AZT) has had mixed success in the treatment of FIV. Use of AZT at a dosage of 5 mg/kg PO or SQ q12h improved overall quality of life and stomatitis in FIV-infected cats and is believed to aid in the treatment of neurologic signs (Hartmann et al., 1995a, 1995b). Cats treated with AZT should be monitored for the development of anemia. Administration of bovine lactoferrin by mouth was beneficial in the treatment of intractable stomatitis in FIV-seropositive cats (Sato et al., 1996). Removal of all premolar and molar teeth has also been effective for treatment of intractable stomatitis in some FIV-seropositive cats (see Chapter 31). Immunomodulators have not been shown to have reproducible clinical effect, but owners sometimes report positive responses. Human recombinant crythropoietin administration increased red blood cell and white blood cell counts, did not increase viral load, and had no measurable adverse clinical effects in FIV-infected cats compared with placebo (Arai et al., 2000). In contrast, although administration of human recombinant granulocyte-monocyte colony-stimulating factor (GM-CSF) to FIV-infected cats increased white blood cell counts in some treated cats, it also induced fever, anti-GM-CSF antibodies, and increased viral load. GM-CSF therefore appears to be contraindicated for the treatment of FIV in cats.

# **Prevention and Zoonotic Aspects**

Housing cats indoors to avoid fighting and testing new cats before introduction to an FIV-seronegative, multiple-cat household will prevent most cases of FIV. Transmission by fomites is unusual because the virus is not easily transmitted by casual contact, is susceptible to most routine disinfectants, and dies when out of the host after minutes to hours, especially when dried. Cleaning litter boxes and dishes shared by cats with scalding water and detergent inactivates the virus. Cats with potential exposure from fighting should be retested 60 days after the potential exposure. Cats that are FIV infected should be housed indoors at all times to avoid exposing FIV-naïve cats in the environment to the virus and to lessen the affected animal's chance of acquiring opportunistic infections. Kittens queened by FIV-infected cats should not be allowed to nurse to avoid transmission by ingestion of milk. Kittens queened by FIV-infected cats should be shown to be serologically negative at 6 months of age to document failure of lactogenic or transplacental transmission before being sold. A killed vaccine containing immunogens from two FIV isolates was recently licensed for use in the United States (Fel-O-Vax FIV, Fort Dodge Animal Health, Overland Park, Kan). However, the efficacy and safety of the vaccine has not been assessed under field conditions in large numbers of cats, so the American Association of Feline Practitioners considers the vaccine noncore (see Chapter 94). In addition, the vaccine induces antibodies that cannot be distinguished from those induced by natural exposure by currently available tests.

HIV and FIV are morphologically similar but antigenically distinct. Antibodies against FIV have not been documented in the serum of human beings, even after accidental exposure to virus-containing material (Butera et al., 2000). Cats with FIV infection resulting in immunodeficiency may be more likely to spread other zoonotic agents into the human environment; clinically ill, FIV-seropositive cats should therefore undergo a thorough diagnostic evaluation (see Chapter 100).

<sup>\*</sup> Several human interferon-α products are available in the United States.

# FELINE LEUKEMIA VIRUS

# **Etiology and Epidemiology**

Feline leukemia virus (FeLV) is a single-strand RNA virus in the family Retroviridae, subfamily Oncovirinae. The virus produces reverse transcriptase, which catalyzes the reaction, resulting in the formation of a DNA copy (provirus) of FeLV viral RNA in the cytoplasm of infected cells; the provirus is inserted into the host cell genome. On subsequent host cell divisions the provirus serves as a template for new virus particles formed in the cytoplasm and is released across the cell membrane by budding. FeLV is composed of several core and envelope proteins. Envelope protein p15e induces immunosuppression. Core protein p27 is present in the cytoplasm of infected cells, peripheral blood, saliva, and tears of infected cats; detection of p27 is the basis of most FeLV tests. The envelope glycoprotein 70 (gp70) contains the subgroup antigens A, B, or C, which are associated with the infectivity, virulence, and disease caused by individual strains of the virus. Neutralizing antibodies are produced by some cats after exposure to gp70. Antibodies against feline oncornavirus-associated cell membrane antigen (FOCMA) are formed by some cats but are generally not used clinically.

The principal route of infection by FeLV is prolonged contact with infected cat saliva and nasal secretions; grooming or sharing common water or food sources effectively results in infection. Because the organism does not survive in the environment, feces, or urine, fomite and aerosol transmission is unlikely. Transplacental, lactational, and venereal transmission is less important than casual contact. FeLV infection has worldwide distribution; the seroprevalence of infection varies geographically and by the population of cats tested. Infection is most common in outdoor male cats between ages 1 and 6 years. In a recent study (Levy et al., 2006) the prevalence of FeLV antigenemia in cats in North

America was 2.3%. FeLV can be detected in feces of infected fleas for 2 weeks (Vobis et al., 2006). However, the prevalence rates for FeLV vary little across regions of the United States with high and low prevalence rates of fleas, so this is an unlikely route of infection.

The virus replicates first in the oropharynx, followed by dissemination through the body to the bone marrow (Table 97-4). If persistent bone marrow infection occurs, infected white blood cells and platelets leave the bone marrow with ultimate infection of epithelial structures, including salivary and lacrimal glands. Whether infection occurs after natural exposure to FeLV is determined by the virus subtype or strain, the virus dose, the age of the cat when exposed, and the cat's immune responses. Using realtime PCR and antigen ELISA results, four classes of FeLV infection were defined (Torres et al. 2005; Levy et al. 2008). Some FeLV-exposed cats can eliminate the infection (abortive) whereas others progress to clinical illness and persistent viremia (progressive). Other FeLV-exposed cats will develop regressive infection characterized by antigen-negative results and lower transiently positive realtime PCR results. Latent FeLV infections are transiently antigen positive but have persistently positive realtime PCR results. Latent and regressive infections can be potentially activated by the administration of glucocorticoids or other immunosuppressive drugs.

The pathogenesis of various syndromes induced by FeLV is complex but includes induction of lymphoma from activation of oncogenes by the virus or insertion of a provirus into the genome of lymphoid precursors; subgroup C induction of aplastic anemia from increased secretion of tumor necrosis factor-α; immunodeficiency attributable to T-lymphocyte depletion (both CD4+ and CD8+ lymphocytes) or dysfunction; neutropenia; neutrophil function disorders; malignant transformation; and viral induction of bone marrow growth-promoting substances leading to myeloproliferative diseases.

**TABLE 97-4** 

Peripheral Blood Test Results in Different Stages of Progressive FeLV Infection

STAGE	ORGANISM LOCALIZATION	TIMING	IFA	ELISA	PCR
ŀ	Replication in local lymphoid tissues (tonsillar and pharyngeal with oronasal exposure)	2-4 days	-	-	-
11	Dissemination in circulating lymphocytes and monocytes	1-14 days	_	+	+
III	Replication in the spleen, distant lymph nodes, and gut- associated lymphoid tissue	3-12 days	-	+	+
IV	Replication in bone marrow cells and intestinal epithelial crypts	7-21 days	-*	+	+
٧	Peripheral viremia, dissemination by infected bone marrow— derived neutrophils and platelets	14-28 days	+	+	+
VI	Disseminated epithelial cell infection with virus secretion in saliva and tears	Day 28+	+†	+	+

Adapted from Rojko JL et al: Pathogenesis of infection by the feline leukemia virus, J Am Vet Med Assoc 199:1305, 1991, and Wolf, 2000. \*IFA may be positive on bone marrow.

<sup>†</sup> Saliva and tears may be positive.

FeLV, Feline leukemia virus; IFA, immunofluorescent antibody; ELISA, enzyme-linked immunosorbent assay; PCR, polymerase chain reaction; —, negative; +, positive.

# **Clinical Features**

Owners generally present FeLV-infected cats for evaluation of nonspecific signs such as anorexia, weight loss, and depression or abnormalities associated with specific organ systems. Of the FeLV-infected cats evaluated at necropsy, 23% had evidence of neoplasia (96% lymphoma/leukemia); the remainder died from nonneoplastic diseases (Reinacher, 1989). Specific clinical syndromes can result from specific effects of the virus or from opportunistic infections caused by immunosuppression. A positive FeLV test result does not prove disease induced by FeLV. When a clinical syndrome is diagnosed in a FeLV-seropositive cat, the workup should include diagnostic tests for other potential causes. The opportunistic agents discussed for FIV also are common in FeLV-infected cats (see Table 97-2).

Bacterial or calicivirus-induced stomatitis occurs in some FeLV-infected cats as a result of immunosuppression. FeLV infection can result in vomiting or diarrhea from a form of enteritis clinically and histopathologically resembling panleukopenia, from alimentary lymphoma, or from secondary infections attributable to immunosuppression. Icterus in FeLV-infected cats can be prehepatic from immunemediated destruction of red blood cells induced by FeLV or secondary infection by *Mycoplasma haemofelis* or "Candidatus Mycoplasma haemominutum"; hepatic from hepatic lymphoma, hepatic lipidosis, or focal liver necrosis; or posthepatic from alimentary lymphoma. Some FeLV-infected cats with icterus may be concurrently infected by FIP virus or T. gondii.

Clinical signs of rhinitis or pneumonia occur in some FeLV-infected cats as a result of secondary infections. Dyspnea or dysphagia from mediastinal lymphoma occurs in some cats. These cats are generally younger than 3 years and may have decreased cranial chest compliance on palpation as well as muffled heart and lung sounds if pleural effusion is present.

Mediastinal, multicentric, and alimentary lymphomas are the most common neoplasms associated with FeLV; lymphoid hyperplasia also occurs. Alimentary lymphoma most commonly involves the small intestine, mesenteric lymph nodes, kidneys, and liver of older cats; most cats with alimentary lymphoma are FeLV negative. Renal lymphoma can involve one or both kidneys, which are usually enlarged and irregularly marginated on physical examination. Fibrosarcomas occasionally develop in young cats coinfected with FeLV and feline sarcoma virus. Lymphocytic, myelogenous, erythroid, and megakaryocytic leukemia all are reported with FeLV infection; erythroleukemia and myelomonocytic leukemia are the most common. The history and physical examination findings are nonspecific.

Renal failure occurs in some FeLV-infected cats from renal lymphoma or glomerulonephritis. Affected cats are presented for evaluation of polyuria, polydipsia, weight loss, and inappetence during the last stages of disease. Urinary incontinence from sphincter incompetence or detrusor hyperactivity occurs in some cats; small-bladder nocturnal incontinence is reported most frequently. Some FeLV-infected cats are presented for miosis, blepharospasm, or cloudy eyes from ocular lymphoma. Aqueous flare, mass lesions, keratic precipitates, lens luxations, and glaucoma are often found on ocular examination. FeLV does not likely induce uveitis without lymphoma. Neurologic abnormalities associated with FeLV infection include anisocoria, ataxia, weakness, tetraparesis, paraparesis, behavioral changes, and urinary incontinence. Nervous system disease is likely to develop as a result of polyneuropathy or lymphoma. Intraocular and nervous system disease in FeLV-infected cats can occur from infection with other agents, including FIP virus, *Cryptococcus neoformans*, or *T. gondii*.

Abortion, stillbirth, or infertility occurs in some FeLV-infected queens. Kittens infected in utero that survive to birth generally develop accelerated FeLV syndromes or die as part of the kitten mortality complex.

Some FeLV-seropositive cats present for lameness or weakness from neutrophilic polyarthritis attributed to immune complex deposition. Multiple cartilaginous exostoses occur in some cats and may be FeLV related.

# **Diagnosis**

A variety of nonspecific hematologic, biochemical, urinalysis, and radiographic abnormalities occur in FeLV-infected cats. Nonregenerative anemia alone or in combination with decreases in lymphocyte, neutrophil, and platelet counts is common. The presence of increased numbers of circulating nucleated red blood cells or macrocytosis in association with severe nonregenerative anemia occurs frequently; examination of bone marrow often documents a maturation arrest in the erythroid line (erythrodysplasia). Immune-mediated destruction of erythrocytes can be induced by FeLV and occurs in cats coinfected with hemoplasmas; regenerative anemia, microagglutination or macroagglutination of erythrocytes, and a positive result on the direct Coombs test are common in these cats. Neutropenia and thrombocytopenia occur from bone marrow suppression or immune-mediated destruction. FeLV-infected cats with the panleukopenia-like syndrome have gastrointestinal tract signs and neutropenia and are difficult to differentiate from cats with panleukopenia virus infection or salmonellosis. Cats with FeLV-induced panleukopenia-like syndrome usually have anemia and thrombocytopenia, abnormalities rarely associated with panleukopenia virus infection. Azotemia, hyperbilirubinemia, bilirubinuria, and increased activity of liver enzymes are common biochemical abnormalities. Proteinuria occurs in some FeLV-infected cats with glomerulonephritis. Cats with lymphoma have mass lesions radiographically depending on the organ system affected. Mediastinal lymphoma can result in pleural effusion; alimentary lymphoma can cause obstructive intestinal patterns.

Lymphoma can be diagnosed by cytologic or histopathologic evaluation of affected tissues (see Chapters 75 and 80). Because lymphoma can be diagnosed cytologically and treated with chemotherapy, cats with mediastinal masses, lymphadenopathy, renomegaly, hepatomegaly, splenomeg-

aly, or intestinal masses should be evaluated cytologically before surgical intervention. Malignant lymphocytes are also occasionally identified in peripheral blood smears, effusions, and CSF.

Most cats with suspected FeLV infection are screened for FeLV antigens in neutrophils and platelets by immunofluorescent antibody (IFA) testing or in whole blood, plasma, serum, saliva, or tears by ELISA. Serum is the most accurate fluid to assess in ELISA tests. IFA results are not positive until the bone marrow has been infected (see Table 97-4). The results of IFA testing are accurate more than 95% of the time. False-negative reactions may occur when leukopenia or thrombocytopenia prevents evaluation of an adequate number of cells. False-positive reactions can occur if the blood smears submitted for evaluation are too thick. A positive IFA result indicates that the cat is viremic and contagious; approximately 90% of cats with positive IFA results are viremic for life. The rare combination of IFA-positive and ELISA-negative results suggests technique-related artifact. Negative ELISA results correlate well with negative IFA results and an inability to isolate FeLV. Comparisons of different antigen tests have shown the results of most assays to be comparable (Hartmann et al., 2007).

The virus can be detected in serum by ELISA before infection of bone marrow and can therefore be positive in some cats during early progressive stages of infection or during early latent infection even though IFA results are negative. Other possibilities for discordant results (ELISA positive, IFA negative) are false-positive ELISA results or false-negative IFA results. Cats with positive ELISA results and negative IFA results are probably not contagious at that time but should be isolated until retested 4 to 6 weeks later because progression to persistent viremia and epithelial cell infection may be occurring.

ELISA-positive cats that revert to negative have developed latent infections or regressive infection. Virus isolation, IFA performed on bone marrow cells, immunohistochemical staining of tissues for FeLV antigen, and PCR can be used to confirm latent or regressive infection in some cats. Cats with latent or regressive infection are not likely contagious to other cats, but infected queens may pass the virus to kittens during gestation or parturition or by milk. Cats with regressive or latent infection can be immunodeficient and may become viremic (IFA and ELISA positive) after receiving corticosteroids or after extreme stress.

A delay of 1 to 2 weeks generally occurs after the onset of viremia before ELISA tear and saliva test results become positive; therefore these test results can be negative even when results with serum are positive. Antibody titers to FeLV envelope antigens (neutralizing antibody) and against virustransformed tumor cells (FOCMA antibody) are available in some research laboratories, but the diagnostic and prognostic significance of results from these tests is unknown. Realtime PCR assays are more sensitive than conventional PCR for FeLV infections, but validated and standardized assays are not currently available in the United States (Torres et al. 2005).

# Treatment

Several antiviral agents have been proposed for the treatment of FeLV; the reverse transcriptase inhibitor AZT has been studied the most (see Table 97-3). Unfortunately, administration of AZT to persistently viremic cats does not appear to clear viremia in most, and it had minimal benefits for clinically ill cats in a recent study (Hartmann et al., 2002). Interferons have an effect against FeLV in vivo and in vitro (Collado et al., 2007; de Mari et al., 2004). Immunotherapy with drugs such as *Staphylococcus* protein A, *Propionibacterium acnes*, or acemannan (see Table 97-3) improves clinical signs of disease in some cats, but controlled studies are lacking.

Chemotherapy should be administered to cats with FeIV-associated neoplasia (see Chapters 77 and 80). Opportunistic agents should be managed as indicated; the upper dose range and duration of antibiotic therapy are generally required. Supportive therapies such as hematinic agents, vitamin B<sub>12</sub>, folic acid, anabolic steroids, and erythropoietin generally have been unsuccessful in the management of nonregenerative anemia. Blood transfusion is required in many cases. Cats with autoagglutinating hemolytic anemia require immunosuppressive therapy, but this may activate virus replication. The prognosis for persistently viremic cats is guarded; the majority die within 2 to 3 years.

# **Prevention and Zoonotic Aspects**

Avoiding contact with FeLV by housing cats indoors is the best form of prevention. Potential fomites such as water bowls and litter pans should not be shared by seropositive and seronegative cats. Testing and removal of seropositive cats can result in virus-free catteries and multiple-cat households.

Because of variations in challenge study methods and the difficulty of assessing the preventable fraction of a disease with a relatively low infection rate, long subclinical phase, and multiple field strains, the efficacy of individual vaccines continues to be in question (see Chapter 94). Vaccination of cats not previously exposed to FeLV should be considered in cats at high risk (i.e., contact with other cats), but owners should be warned of the potential efficacy of less than 100%. Cats with persistent FeLV viremia do not benefit from vaccination. Vaccination is related to the development of fibrosarcoma in some cats (see Chapter 94). Cats developing these tumors may be genetically predisposed (Banerji et al., 2007).

FeLV-infected cats should be housed indoors to avoid infecting other cats and avoid exposure to opportunistic agents. Flea control should be maintained to avoid exposure to hemoplasmas, and *Bartonella* spp. FeLV-infected cats should not be allowed to hunt or be fed undercooked meats to avoid infection by *T. gondii, Cryptosporidium parvum, Giardia* spp., and other infectious agents carried by transport hosts.

Antigens of FeLV have never been documented in the serum of human beings, suggesting that the zoonotic risk is minimal. However, FeLV-infected cats may be more likely than FeLV-naïve cats to pass other zoonotic agents,

such as C. parvum and Salmonella spp., into the human environment.

# CHAPTER

# Polysystemic Mycotic Infections

# CHAPTER OUTLINE

BLASTOMYCOSIS COCCIDIOIDOMYCOSIS CRYPTOCOCCOSIS HISTOPLASMOSIS

# **BLASTOMYCOSIS**

# **Etiology and Epidemiology**

Blastomyces dermatitidis is a saprophytic yeast found primarily in the Mississippi, Missouri, and Ohio River valleys; the mid-Atlantic states; and southern Canada. Two cases in human beings have been reported in Colorado. An extracellular yeast form (5 to 20 pm in diameter) with broad-based budding develops in the vertebrate host (Table 98-1). The infectious mycelial phase occurs in the soil and in culture.

Blastomycosis develops most frequently in areas exposed to high humidity, fog, excavation sites, and sandy, acidic soils near bodies of water. Potential for disease may vary with the virulence of the field strain, the inoculum dose, and the immune status of the host. Most clinical cases occur from point source exposure; multiple cases are diagnosed in an area, and clusters of infection in people and dogs have been reported (MacDonald et al., 2006).

Transmission is from inhalation or contamination of open wounds with spores from the environment. The organism probably replicates in the lungs initially and then spreads hematogenously to other tissues, including the skin and subcutaneous tissues, eyes, bones, lymph nodes, external nares, brain, testes, nasal passages, prostate, liver, mammary glands, vulva, and heart. The organism can be swallowed and passed in feces. Incomplete clearance of the organism by individuals with poor cell-mediated immune responses results in pyogranulomatous inflammation in affected organs, which can cause clinical signs of disease. Subclinical infection is believed to be uncommon in dogs and cats.

# **Clinical Features**

Large-breed, young, male, sporting dogs are infected most commonly by *B. dermatitidis* most likely because of an increased chance for exposure to the organism. Anorexia, cough, dyspnea, exercise intolerance, weight loss, ocular disease, skin disease, depression, lameness, and syncope are the most common presenting complaints.

Fever occurs in approximately 40% of affected dogs. Interstitial lung disease and hilar lymphadenopathy result in cough, dry and harsh lung sounds, and dyspnea; hypertrophic osteopathy occurs in some dogs. Dyspnea from chylothorax caused by cranial vena cava syndrome has been described. Valvular endocarditis occurs as well, and conduction disturbances from myocarditis are detected in some dogs with cardiac blastomycosis (Schmiedt et al., 2006). Lymphadenopathy and cutaneous or subcutaneous nodules, abscesses, plaques, or ulcers occur in 20% to 40% of infected dogs. Splenomegaly is common. Lameness from fungal osteomyelitis of the spine or appendicular skeleton occurs in approximately 30% of dogs with blastomycosis. Infection of the testes, prostate, urinary bladder, and kidneys occurs rarely.

Ocular manifestations are recognized in approximately 30% of dogs with blastomycosis; anterior uveitis, endophthalmitis, posterior segment disease, and optic neuritis occur. Cataracts can result from chronic inflammation or rupture of the lens capsule (Hendrix et al., 2004). Depression and seizures from diffuse or multifocal central nervous system (CNS) involvement occur in some dogs.

Blastomycosis can occur in any cat but is most common in young males. Cats housed indoors and cats allowed outdoors have both been infected (Blondin et al., 2007). Infected cats develop respiratory tract disease, CNS disease, regional lymphadenopathy, dermatologic disease, ocular disease, gastrointestinal tract disease, and urinary tract disease. Pleural or peritoneal effusion resulting in dyspnea or abdominal distension occurs in some cats. Ocular disease usually involves the posterior segment.

#### Diagnosis

Hematologic abnormalities commonly identified in dogs or cats with blastomycosis are normocytic normochromic non-

# **TABLE 98-1**

# Morphologic Appearance of Systemic Canine and Feline Fungal Agents

#### **AGENT** CYTOLOGIC APPEARANCE Extracellular yeast, 5 to 20 .m in diameter; thick, refractile, double-contoured wall; broad-Blastomyces dermatitidis based bud; routine stains are adequate Cryptococcus neoformans Extracellular yeast, 3.5 to 7.0 μm in diameter; thick, unstained capsule; thin-based bud; violet color with light-red capsule with Gram stain; unstained capsule with India ink Coccidiodes immitis Extracellular spherules (20 to 200 µm in diameter) containing endospores; deep red to purple double outer wall with bright red endospores with PAS stain Histoplasma capsulatum Intracellular yeast in mononuclear phagocytes, 2 to 4 µm in diameter, basophilic center with lighter body with Wright's stain Sporothrix schenckii Intracellular yeast in mononuclear phagocytes, 2 to 3 $\mu$ m $\times$ 3 to 6 $\mu$ m in diameter; round, oval, or cigar shaped

regenerative anemia, lymphopenia, and neutrophilic leukocytosis with or without a left shift and monocytosis. Hypoalbuminemia and hyperglobulinemia (i.e., polyclonal gammopathy) caused by chronic inflammation are common serum biochemical abnormalities; hypercalcemia occurs rarely in dogs. Most infected dogs and cats with respiratory disease have diffuse, miliary, or nodular interstitial lung patterns and intrathoracic lymphadenopathy on thoracic radiographs (Fig. 98-1); single masses and pleural effusion from chylothorax sometimes occur. Alveolar lung disease occurs in some cats (Gilor et al., 2006). Bone lesions induced by blastomycosis are lytic with a secondary periosteal reaction and soft tissue swelling.

Serum antibodies develop in some infected animals. Many cats with blastomycosis are negative for serum antibodies by agar gel immunodiffusion (AGID). False-negative results can occur in animals with peracute infection, immunosuppression, or advanced infection that overwhelms the immune system. Antibody titers do not always revert to

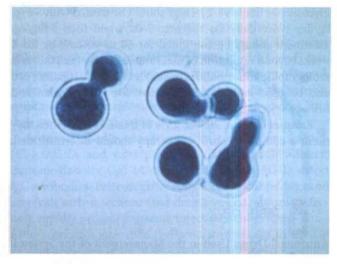

FIG 98-2

negative after successful treatment. Because blastomycosis rarely causes subclinical infection, positive serologic results combined with appropriate clinical signs and radiographic abnormalities allow presumptive diagnosis if the organism cannot be demonstrated. *Blastomyces* antigens and serum antibodies were detected simultaneously in 36 dogs with confirmed infection (Shurley et al., 2005). However, the assay was not specific for *Blastomyces*. Definitive diagnosis of blastomycosis is based on cytologic, histopathologic, or culture demonstration of the organism (Fig. 98-2). Impression smears from skin lesions and aspirates from enlarged lymph nodes and focal lung lesions usually reveal pyogranulomatous inflammation and organisms that can usually be seen at low power. Recovery of organisms from urine is less consistent. Bronchoalveolar lavage is more sensitive than

transtracheal wash for organism demonstration; organisms can also be found in samples obtained by percutaneous lung aspirates. Growth in culture requires 10 to 14 days and is of lower yield than cytology or biopsy.

# **Treatment**

Amphotericin B, ketoconazole, both amphotericin B and ketoconazole, and itraconazole alone are used most frequently for the treatment of blastomycosis in dogs (Table 98-2). Amphotericin B is generally used in animals with lifethreatening disease; the lipid or liposomal encapsulated product is less likely to cause toxicity. If regular amphotericin B is used, the animal should be well hydrated with 0.9% sodium chloride before treatment, and treatment should be discontinued if the blood urea nitrogen level exceeds 50 mg/ dL. Because itraconazole is as effective as amphotericin B and ketoconazole alone or in combination and has fewer adverse effects, it is the drug of choice for the treatment of blastomycosis (see Table 98-2). Dogs should be treated with 5 mg/ kg/day twice daily for the first 5 days and then 5 mg/kg. Treatment should be continued for 60 to 90 days or for 4 weeks beyond resolution of measurable disease (i.e., thoracic radiographic abnormalities or skin lesions). Fluconazole can also be used and may be effective for CNS, ocular, and urinary system blastomycosis.

Relapses occur in 20% to 25% of treated dogs. When they occur a complete course of therapy should be reinstituted.

Posterior segment ocular disease responds well to itraconazole, but anterior uveitis and endophthalmitis often require enucleation of the affected eye. In dogs with ocular blastomycosis resulting in euthanasia or enucleation of the affected eye, difference in the presence of the organism was not noted between treated and untreated dogs (Hendrix et al., 2004). In one study of 23 cats with blastomycosis, successful results were reported for two cats treated with amphotericin B and ketoconazole, one cat treated with amputation, and one cat treated with potassium iodide (Miller et al., 1990). In a more recent study of eight cats, two cats treated with itraconazole and one cat treated with fluconazole had clinical resolution of their disease (Gilor et al., 2006).

# **Zoonotic Aspects and Prevention**

Direct zoonotic transmission from infected animals is unlikely because the yeast phase is not as infectious as the mycelial phase. One veterinarian was infected after material from a pulmonary aspirate from an infected dog was injected intramuscularly, and another developed disease after being bitten by an infected dog. The mycelial phase develops at temperatures lower than body temperature; positive cultures and contaminated bandages are infectious. Multiple reports have been made of canine and human blastomycosis that developed from the same environment exposure. Decreasing potential for exposure by avoiding lakes and creeks in endemic areas is the only way to prevent the disease.

TABLE 98-2

Antifungal Drugs Used in the Management of the Systemic Canine and Feline Fungal Diseases

DRUG	SPECIES	DOSAGE	ORGANISM
Amphotericin B (regular)	D	0.25 mg/kg, IV as test dose, then 0.5 mg/kg, IV, up to 3 times weekly* 0.5-0.8 mg/kg SQ 2-3 times weekly†	Bl, H, Cr, Co
	С	0.25 mg/kg IV up to 3 times weekly,‡ 0.5-0.8 mg/kg SQ 2-3 times weekly†	Bl, H, Cr, Co
Amphotericin B (liposomal or lipid complex)	В	0.5 mg/kg, IV as test dose, then 1.0 mg/kg, IV, 3-5 times weekly§	Bl, H, Cr, Co
Fluconazole	C	50 mg/cat PO q12-24h	Cr, Bl, H, Co
	D	5 mg/kg PO q12-24h	Bl, H, Cr, Co
Flucytosine¶	В	50 mg/kg PO q8h	Cr

	С	50-100 mg/cat/day PO	Bl, Cr, H, Co, Sp

D, dog; C, cat; B, dog and cat; IV, intravenous; PO, oral; Bl, Blastomyces; H, Histoplasma; Cr, Cryptococcus; Co, Coccidioides; Sp, Sporothrix.

<sup>\*</sup>In dogs with normal renal function, dilute in 60-120 mL 5% dextrose and administer IV over 15 minutes; in dogs with renal insufficiency but with a blood urea nitrogen level <50 mg/dL, dilute in 500 mL to 1 L 5% dextrose and administer IV over 3-6 hours. Cumulative dose of at least 12 mg/kg if used alone or 6 mg/kg if combined with another antifungal drug.

<sup>†</sup> Mix in 400 mL (cats) or 500 mL (dogs) of 0.45% saline and 2.5% dextrose solution and administer SQ.

<sup>‡</sup>In cats with normal renal function, dilute in 50-100 mL 5% dextrose and administer IV over 3-6 hours.

<sup>§</sup> Dilute the contents of a vial with 5% dextrose to a final concentration of 1.0 mg/mL and shake for 30 seconds. Draw up needed volume and filter through an 18-gauge Monoject filter needle into 100 mL of 5% dextrose. Infuse intravenously over 15 minutes.

<sup>¶</sup>Should be used in combination with amphatericin B.

# COCCIDIOIDOMYCOSIS

# **Etiology and Epidemiology**

Coccidioides immitis is a dimorphic fungus found deep in sandy alkaline soils in regions with low elevation, low rainfall, and high environmental temperatures, including the southwestern United States, California, Mexico, Central America, and South America. In the United States coccidioidomycosis is diagnosed most frequently in California, Arizona, New Mexico, Utah, Nevada, and southwest Texas. The environmental mycelial phase produces arthrospores (2 to 4 µm wide, 3 to 10 µm long) that enter the vertebrate host by inhalation or wound contamination. Large numbers of arthrospores return to the surface after periods of rainfall and are dispersed by the wind; the prevalence of coccidioidomycosis increases in the years after a high rainfall. Most cases (67%) of feline coccidioidomycosis are diagnosed between December and May. In one study of dogs residing in an endemic area (Arizona), the cumulative probability of infection (evidenced by scroconversion) by 2 years of age was 28%, and the cumulative probability of clinical infection by 2 years of age was 6% (Shubitz et al., 2005).

Inhaled arthrospores induce neutrophilic inflammation followed by infiltrates of histiocytes, lymphocytes, and plasma cells. Infection is cleared if cell-mediated immune responses are normal; most people, dogs, and cats exposed to the organism are subclinically affected. The organism disseminates to mediastinal and tracheobronchial lymph nodes, bones and joints, visceral organs (liver, spleen, kidneys), heart and pericardium, testicles, eyes, brain, and spinal cord of some individuals. Spherules (20 to 200 µm in diameter) containing endospores (see Table 98-1) form in tissues of infected hosts. Endospores are released by cleavage and produce new spherules. Respiratory signs and signs of disseminated disease occur 1 to 3 weeks and 4 months after exposure, respectively.

# **Clinical Features**

Clinical disease in dogs is most common in young, male, large-breed dogs. Dogs that are allowed to roam or walk in the desert in endemic areas are most likely to be exposed (Butkiewicz et al., 2005). Approximately 90% of clinically affected dogs have lameness with swollen, painful bones or joints. Cough, dyspnea, anorexia, weakness, weight loss, lymphadenopathy, lameness, clinical signs of ocular inflammation, and diarrhea are other presenting complaints. Crackles, wheezes, or muffled lung sounds from pleural effusion are common. Restrictive pericarditis presenting with evidence of right heart failure, such as hepatomegaly, pleural effusion, and ascites, can occur (Heinritz et al., 2005). If subcutaneous abscesses, nodules, ulcers, and draining tracts occur, they are usually associated with infected bones. Myocarditis, icterus, renomegaly, splenomegaly, hepatomegaly, orchitis, epididymitis, keratitis, iritis, granulomatous uveitis, and glaucoma are detected in some dogs. Depression, seizures, ataxia, central vestibular disease, cranial nerve deficits,

and behavioral changes are the most common signs of CNS infection.

The median age of cats with coccidioidomycosis is 5 years; no obvious sex or breed predilection exists. The most common clinical manifestations include skin disease (56%), respiratory disease (25%), musculoskeletal disease (19%), and either ophthalmic or neurologic disease (19%) (Greene et al., 1995).

# Diagnosis

Normocytic, normochromic nonregenerative anemia; leukocytosis; leukopenia; and monocytosis are the most common hematologic abnormalities. Hyperglobulinemia (i.e., polyclonal gammopathy), hypoalbuminemia, renal azotemia, and proteinuria occur in some infected animals (Johnson et al., 2003).

Diffuse interstitial lung patterns are more common than bronchial, miliary interstitial, nodular interstitial, or alveolar patterns radiographically in dogs and cats with respiratory coccidioidomycosis. Pleural effusion from pleuritis, right-sided heart failure, or constrictive pericarditis can occur. Hilar lymphadenopathy is common in dogs and cats; however, sternal lymphadenopathy or calcification of lymph nodes is not. Bone lesions usually involve the distal diaphysis, epiphysis, and metaphysis of one or more long bones, and they are more proliferative than lytic.

Serum antibodies are detected by complement fixation (CF), AGID, and tube precipitin (TP) tests; TP detects immunoglobulin (Ig) M antibodies; CF and AGID detect IgG antibodies. False-negative results can occur in dogs and cats with early infections (less than 2 weeks), chronic infection, rapidly progressive acute infection, and primary cutaneous coccidioidomycosis. False-positive results in the CF test can occur as a result of anticomplementary serum, which may be caused by bacterial contaminants or immune complexes. The assays can cross-react with antibodies against H. capsulatum and B. dermatitidis. Serum antibodies develop in dogs with and without clinical signs of disease, and titer magnitude failed to correlate with the presence of illness in one study (Shubitz et al., 2005). Thus results of antibody test results alone should not be used to make a definitive diagnosis. The combination of positive serologic test results and radiographic signs of interstitial lung disease, dermatologic disease, or osteomyelitis in animals from endemic areas can be used to make a presumptive diagnosis if the organism cannot be demonstrated. Titers may persist for months to years after resolution of clinical disease.

Definitive diagnosis requires demonstration of the organism by cytology, biopsy, or culture. The organism is often difficult to demonstrate by cytology; transtracheal aspiration or bronchoalveolar lavage is commonly negative. Extracellular spherules (Fig. 98-3) are most commonly found in lymph node aspirates, draining masses, and pericardial fluid; wet mount examination of unstained smears or periodic acid—Schiff-stained smears are more suitable than are dry mounts.

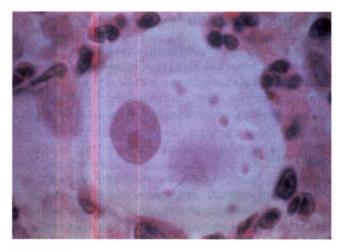

FIG 98-3 Coccidiodes immitis spherule (20 to 200  $\mu$ m in diameter) in muscle tissue.

#### **Treatment**

Ketoconazole is the drug of choice for treatment of coccidioidomycosis in dogs (see Table 98-1), but it commonly leads to inappetence, vomiting, diarrhea, weight loss, and increases in liver enzyme activities in some dogs and cats. In dogs, long-term use of ketoconazole can suppress testosterone and cortisol production and has been associated with cataracts. Amphotericin B should be used if life-threatening disease is present or if response to ketoconazole is poor. Itraconazole can be used in animals with toxicity from ketoconazole.

Fluconazole should be used for animals with meningoencephalitis. Cats and dogs should be treated for 60 to 90 days or until clinical illness has been resolved for at least 1 month. Bone infections are often incurable; therefore repeated treatments are often required. When treated with ketoconazole, itraconazole, or fluconazole, 32 of 44 cats with coccidioidomycosis were asymptomatic during or after treatment (Greene et al., 1995). Relapse occurred in 11 cats during or after treatment. Daily administration of lufenuron, a chitin synthesis inhibitor, has been evaluated in a limited number of dogs with coccidioidomycosis but should not be used in lieu of azoles.

# **Zoonotic Aspects and Prevention**

People exposed to *C. immitis* develop asymptomatic infection or mild, transient respiratory signs. The organism is not transmitted from infected animals to people. However, the mycelial phase occurs outside the vertebrate host, so fomites, such as bandage material and cultures, should be handled carefully. Avoiding endemic areas is the only way to prevent the disease.

# **CRYPTOCOCCOSIS**

# **Etiology and Epidemiology**

Cryptococcus neoformans is a 3.5- to 7.0- m yeastlike organism with worldwide distribution. It has a thick polysaccha-

ride capsule and reproduces by narrow-based budding (see Table 98-1). Cryptococcus neoformans var grubii (serotype A) and C. neoformans var gattii (serotype B) are most commonly associated with disease. Clinical findings with either infection are similar. Many cases have been described in southern California and the eastern coast of Australia. An outbreak of Cryptococcus spp. infections recently occurred in people, dogs, cats, ferrets, and a bird in British Columbia (Lester et al., 2004; MacDougall et al., 2007). Most cases were on Vancouver Island and were caused by C. gattii. The organisms are acquired from the environment; risk factors significantly associated with infection in animals in the British Columbia outbreak included living near a site of soil disturbance such as logging sites, having an above-average level of activity, hunting, and having owners that hiked or visited a botanic garden (Duncan et al., 2006).

The route of transmission for *C. neoformans* is believed to be inhalation. Nasal and pulmonary disease manifestations are common; however, based on culture and serologic studies of healthy animals, an inapparent carrier state also occurs (Malik et al., 1997; Duncan et al., 2005a, 2005b). The organism probably spreads to extrapulmonary sites hematogenously; the CNS may also be infected by direct extension across the cribriform plate from the nasal cavity. Immunity is cell mediated; individuals with incomplete responses do not completely remove the organism, thus resulting in granulomatous lesions. The polysaccharide capsule of the organism inhibits plasma cell function, phagocytosis, leukocyte migration, and opsonization, potentiating infection.

Cryptococcus spp. can be primary pathogens. However, preexisting immunosuppressive conditions are documented in approximately 50% of people with cryptococcosis. Serologic evidence of coinfection with feline immunodeficiency virus or feline leukemia virus occurs in some cats with cryptococcosis. Potentially immunosuppressive conditions such as administration of corticosteroids, ehrlichiosis, heartworm disease, and neoplasia are identified in a small percentage of dogs with cryptococcosis.

# **Clinical Features**

Cryptococcosis is the most common systemic fungal infection of cats and should be considered a differential diagnosis for cats with clinical evidence of upper or lower respiratory tract disease, subcutaneous nodules, lymphadenopathy, intraocular inflammation, fever, or CNS disease. All ages of cats have been infected, but young cats are generally overrepresented. In one study in Australia, Siamese, Himalayan, and Ragdoll breeds were overrepresented (O'Brien et al., 2004). Infection of the nasal cavity, resulting in sneezing and nasal discharge (Fig. 98-4), is reported most frequently. The nasal discharge can be unilateral or bilateral, range from serous to mucopurulent, and often contains blood. Granulomatous lesions extruding from the external nares, facial deformity over the bridge of the nose, and ulcerative lesions on the nasal planum are common. Mandibular lymphadenopathy is detected in most cats with rhinitis. The nasopharynx is the primary site of involvement in some infected cats

FIG 98-4 Severe nasal cryptococcosis in a cat. (Courtesy Dr. Faith Flower, Albuquerque, NM.)

and dogs, resulting in snoring and stertor as the predominant clinical signs. C. gattii has also been detected in pleural effusion (Barrs et al., 2005).

Single or multiple, small (less than 1 cm), cutaneous or subcutaneous masses also have been reported commonly in cats infected with C. neoformans. The masses can be either firm or fluctuant and have a serous discharge if ulcerated. Anterior uveitis, chorioretinitis, or optic neuritis occur in association with ocular infection; lens luxations and glaucoma are common sequelae. Chorioretinitis lesions can be punctate or large; suppurative retinal detachment occurs in some infected cats.

CNS signs of disease result from diffuse or focal meningoencephalitis or focal granuloma formation. Manifestations include depression, behavioral changes, seizures, blindness, circling, ataxia, loss of sense of smell, and paresis depending on the location of the lesion; peripheral vestibular disease can also occur (Beatty et al., 2000). Nonspecific signs of anorexia, weight loss, and fever occur in some infected cats.

Clinical findings in dogs with cryptococcosis depend on the organ systems involved and are similar to those that occur in the cat. Cryptococcosis is diagnosed most commonly in young purebred dogs; Doberman Pinschers, Great Danes, and German Shepherd dogs are commonly affected (Malik et al., 1995; O'Brien et al., 2004). Clinical manifestations include signs of upper or lower respiratory tract infection, disseminated disease including intraabdominal masses, CNS disease, disease of the orbit or eye, skin lesions, nasal cavity disease, and lymph node involvement. Seizures, ataxia, central vestibular syndrome, cranial nerve deficits, and clinical signs of cerebellar disease are the most common CNS manifestations in dogs. Dogs with Cryptococcus

spp.-associated pyelonephritis (Newman et al., 2003) and gastrointestinal disease (Graves et al., 2005) have been reported.

# **Diagnosis**

Nonregenerative anemia and monocytosis are the most common hematologic abnormalities; neutrophil counts and biochemical panels are generally normal. In dogs with CNS involvement, cerebrospinal fluid (CSF) protein concentrations vary from normal to 500 mg/dL, and cell counts vary from normal to 4500/µL; neutrophils and mononuclear cells predominate, but eosinophils are present in some cases. Radiographic changes consistent with cryptococcosis include increased soft tissue density in the nasal cavity caused by fungal granuloma formation as well as nasal bone deformity and lysis. Hilar lymphadenopathy and diffuse to miliary pulmonary interstitial patterns are common thoracic radiographic abnormalities.

Because circulating C. neoformans antibodies can be detected in both healthy and diseased animals, their presence does not document clinical disease. In addition, in one study all infected cats were seronegative (Flatland et al., 1996). Cryptococcal antigen can be detected in serum, aqueous humor, or CSF by latex agglutination (LA); serum antigen tests are positive in most cats and dogs with cryptococcosis. Animals with acute disease, chronic low-grade infections, drug-induced remission, or localized disease can be LA negative. The LA performed on CSF is positive in almost all animals with CNS cryptococcosis. Cryptococcal antigen can also be detected in subclinical carriers (Duncan et al., 2005a, 2005b).

A definitive diagnosis of cryptococcosis is based on positive antigen testing, or cytologic, histopathologic, or culture demonstration of the organism (Fig. 98-5) combined with appropriate clinical manifestations of disease. The organism is found during cytologic evaluation of nasal lesions, cutaneous lesions, lymph node aspirates, CSF, and bronchoalveolar lavage fluid in most affected animals; it can also be cultured. The organism can be cultured from the nasal cavity of some asymptomatic animals, so positive culture results do not always correlate to disease. One study evaluating subclinical carriage of C. gattii showed some animals eliminated the infection, some remained persistently colonized, and some progressed to clinical illness (Duncan et al., 2005a).

#### **Treatment**

Dogs and cats with cryptococcosis have been treated with amphotericin B, ketoconazole, itraconazole, fluconazole, and 5-flucytosine alone and in various combinations (see Table 98-2). Amphotericin B is usually not indicated unless lifethreatening disseminated disease requiring rapid response to therapy is required. If amphotericin B is deemed necessary, lipid or liposomal encapsulated amphotericin is likely optimal because fewer adverse effects are associated with these formulations compared with regular amphotericin B. However, for owners who cannot afford this therapy, a lessexpensive subcutaneous protocol for administration of

FIG 98-5 Cytologic appearance of *Cryptococcus neoformans*. The organism is 3.5 to 7.0  $\mu$ m in diameter and has a thick polysaccharide capsule. (Courtesy Dr. Dennis Macy, College of Veterinary Medicine and Biomedical Sciences, Colorado State University.)

regular amphotericin B has been used successfully for the treatment of cryptococcosis in dogs and cats and may be effective for other systemic fungi that are susceptible to the drug (Malik et al., 1996a; see Table 98-2).

Ketoconazole, itraconazole, or fluconazole are used as single agents in dogs or cats without life-threatening disease. Ketoconazole commonly leads to inappetence, vomiting, diarrhea, weight loss, and increases in liver enzyme activities in some dogs and cats. In dogs, long-term use of ketoconazole can suppresses testosterone and cortisol production and has been associated with cataracts. Because of these problems, ketoconazole is used less frequently than itraconazole and fluconazole. Fluconazole should be considered for dogs or cats with ocular or CNS infection. If clinical signs of toxicity develop (inappetence; drug eruptions) or increased activity of alanine aminotransferase is detected, drug therapy should be stopped and then reinstituted at 50% of the original dose after signs of toxicity abate.

Flucytosine crosses the blood-brain barrier better than ketoconazole or amphotericin B, so it has been used primarily for the treatment of CNS cryptococcosis. It must be used in combination with other antifungal drugs and has many adverse effects, including vomiting, diarrhea, hepatotoxicity, cutaneous reactions, and bone marrow suppression.

Clinical signs of nasal and cutaneous cryptococcosis generally resolve with treatment, but dogs or cats with CNS or ocular disease are less likely to respond. Treatment should continue for at least 1 to 2 months past resolution of clinical disease. Serum and CSF LA antigen titers can diminish with therapy and have been used to monitor response. Antigen titers fail to decrease in some animals without clinical evi-

dence of disease, suggesting persistence of the organism in tissues.

# **Zoonotic Aspects and Prevention**

People and animals can have the same environmental exposure to *Cryptococcus* spp., but zoonotic transfer from contact with infected animals is unlikely. Prevention is achieved by decreasing potential for exposure.

## HISTOPLASMOSIS

# **Etiology and Epidemiology**

Histoplasma capsulatum is a saprophytic dimorphic fungus found in the soil in all regions with tropical and subtropical climates; histoplasmosis is diagnosed most frequently in the Mississippi, Missouri, and Ohio River valleys and in the mid-Atlantic states. The organism has also been associated with disease in a dog in Australia, a dog in Japan, and two indoor cats in California (Johnson et al., 2004). The microconidia (2 to 4  $\mu m$ ) and macroconidia (5 to 18  $\mu m$ ) of the mycelial phase are found in the environment. In the vertebrate host, the 2- to 4-11m yeast phase is found in the cytoplasm of mononuclear phagocytes (see Fig. 98-6 and Table 98-1).

Histoplasma capsulatum is concentrated most heavily in soil contaminated with bird or bat excrement. Point sources for infection are found in endemic areas; two dogs and 20 people developed pulmonary histoplasmosis after removing a tree that had served as a bird roost (Ward et al., 1979). Subclinical infections are common in dogs. Dogs in endemic areas are commonly exposed but the incidence of disease is low. Immunosuppression may predispose to clinical infection in dogs and cats.

Infection is by ingestion or inhalation of microconidia from the environment. The organism is engulfed by mononuclear phagocytes, transformed to the yeast phase, and transported throughout the body in the blood and lymph. Granulomatous inflammation results in persistently infected organs and clinical signs of disease. Disseminated disease is common in cats.

# **Clinical Features**

Most dogs with histoplasmosis are outdoor sporting breeds younger than 7 years. Subclinical infection, pulmonary infection, and disseminated infection are recognized most frequently. Most affected dogs are presented for evaluation of anorexia, fever, depression, weight loss, cough, dyspnea, or diarrhea. Large-bowel diarrhea is most common, but small-bowel diarrhea, mixed-bowel diarrhea, and protein-losing enteropathy occur in some.

Physical examination abnormalities often include depression, increased bronchovesicular sounds, respiratory wheezes, fever, evidence of diarrhea, pale mucous membranes, hepatomegaly, splenomegaly, icterus, ascites, and intraabdominal lymph node enlargement. Airway obstruction from massive hilar lymphadenopathy occurs in some dogs (Schulman et al., 1999). Lameness from bone infection or polyarthritis,

peripheral lymphadenopathy, chorioretinitis, CNS disease, and skin disease occur occasionally. Subcutaneous nodules rarely drain or ulcerate and are less common than in dogs with cryptococcosis or blastomycosis.

Infected cats are either normal or develop disseminated disease. Most clinically affected cats are younger than 4 years, and some are coinfected with feline leukemia virus. Depression, weight loss, anorexia, lameness, and dyspnea are common presenting complaints. Weight loss can be severe and develop in as little as 2 weeks. Fever (103.5° to 105° F), pale mucous membranes, abnormal lung sounds, oral erosions or ulcers, peripheral or visceral lymphadenopathy, icterus, soft tissue swelling around osseous lesions, hepatomegaly, skin nodules and, rarely, splenomegaly are physical examination abnormalities potentially consistent with histoplasmosis. Disseminated disease has a grave prognosis in cats. Osseous histoplasmosis is most common in bones of the appendicular skeleton distal to the stifle or elbow joints, and one or more limbs can be involved. Feline ocular histoplasmosis manifests with conjunctivitis, chorioretinitis, retinal detachment, or optic neuritis and may induce glaucoma and blindness. Other than depression, CNS signs are uncommon.

# **Diagnosis**

A variety of nonspecific clinicopathologic and radiographic abnormalities are associated with histoplasmosis. Normocytic, normochromic, nonregenerative anemia is the most common hematologic abnormality in both dogs and cats. Neutrophil counts can be normal, increased, or decreased. Unlike the other systemic fungi, *H. capsulatum* is occasionally seen in circulating cells, particularly on examination of a buffy coat smear; mononuclear cell infection is most common, followed by eosinophils. Thrombocytopenia from disseminated intravascular coagulation or microangiopathic destruction occurs in approximately 50% of dogs and some cats. Some affected cats develop pancytopenia from bone marrow infection. Hypoproteinemia and increased activities of alkaline phosphatase and alanine aminotransferase occur in some infected animals.

Lysis predominates in animals with bone infection; periosteal and endosteal new bone production occurs in some cases. In dogs with pulmonary infection, radiographic abnormalities include diffuse interstitial, miliary-to-nodular interstitial disease; hilar lymphadenopathy; pleural effusion; and calcified pulmonary parenchyma caused by chronic disease. In some dogs massive hilar lymphadenopathy is the only radiographic finding. Alveolar lung disease, tracheobronchial lymphadenopathy, and calcified lymph nodes are uncommon in cats. Colonoscopic findings in dogs with gastrointestinal infection include increased mucosal granularity, friability, ulceration, and thickness.

Several tests have been evaluated for the detection of circulating antibodies against *H. capsulatum* in the serum of dogs and cats, but the sensitivity and specificity are poor for all. Serologic diagnosis is unreliable and should be used only to establish a presumptive diagnosis when the organism

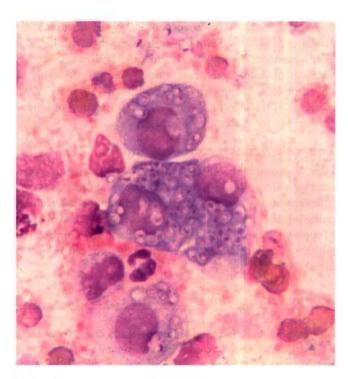

FIG 98-6
Histoplasma capsulatum (2 to 4 μm in diameter) in mononuclear cells. (Courtesy Dr. Dennis Macy, College of Veterinary Medicine and Biomedical Sciences, Colorado State University.)

cannot be demonstrated by cytology, histopathology, or culture and the clinical signs are suggestive of the disease.

Definitive diagnosis requires demonstration of the organism by cytology, biopsy, or culture (Fig. 98-6). The organism is found most frequently in rectal scrapings or biopsies from dogs with large-bowel diarrhea, in bone marrow or buffy coat cells from cats with disseminated disease, and in other locations (e.g., lymph nodes, lung, spleen, liver, skin nodules). The organism has also been identified in pleural and peritoneal effusions and in CSF.

## **Treatment**

Because of its effectiveness and minimal toxicity, itraconazole is the initial drug of choice for dogs and cats with histoplasmosis (see Table 98-2). Animals should be treated for 60 to 90 days or until clinical evidence of disease has been resolved for at least 1 month. Amphotericin B can be used in animals with life-threatening disease or in those unable to absorb oral medications because of intestinal disease. Ketoconazole and fluconazole are also effective in some animals. However, ketoconazole has more adverse effects than itraconazole, and some cases that do not respond to fluconazole respond to intraconazole. The overall success rate for the treatment of histoplasmosis in cats was 33% in one study (Clinkenbeard et al., 1989c). In another study, all eight cats treated with itraconazole (5 mg/kg PO q12h) were eventually cured (Hodges et al., 1994). Pulmonary disease in dogs has a fair to good prognosis, whereas disseminated disease has a poor prognosis.

Administration of glucocorticoids with or without antifungal drugs lessened clinical signs associated with chronic hilar lymphadenopathy much more quickly than did administration of antifungal drugs alone and did not result in disseminated histoplasmosis (Schulman et al., 1999). However, if the infection is active, administration of glucocorticoids may exacerbate clinical disease.

# **Zoonotic Aspects and Prevention**

Like blastomycosis, direct zoonotic transmission from infected animals is unlikely because the yeast phase is not as infectious as the mycelial phase. Care should be taken when culturing the organism. Prevention includes the avoidance of potentially contaminated soil. Organism numbers in contaminated areas can be decreased by application of 3% formalin.

TOXOPLASMOSIS, CANINE
AMERICAN TRYPANOSOMIASIS

## **BABESIOSIS**

## **Etiology and Epidemiology**

Babesiosis in dogs is most commonly associated with Babesia canis and B. gibsoni, protozoans that parasitize red blood cells (RBCs), leading to progressive anemia. B. canis has worldwide distribution including Africa, Asia, Australia, Europe, Central America, South America, Japan, and the United States. Three subspecies of B. canis have been proposed to be separate species. B. canis rossi is transmitted by Haemaphysalis leachi and is the most pathogenic; B. canis canis is transmitted by Dermacentor reticulatus and is moderately pathogenic; B. canis vogeli is the least pathogenic and is transmitted by *Rhipicephalus sanguineus* (brown dog tick). Babesia canis vogeli is the most common B. canis subspecies infecting dogs in the United States. B. gibsoni infects dogs in the United States, Japan, Sri Lanka, Korea, Malaysia, northern and eastern Africa, Australia, and southern Europe. B. gibsoni strains, of which there are at least three (Asia, California, and Theileria annae, a B. gibsoni-like organism common in dogs in northern Spain), vary genetically (Garcia 2006). Rhipicephalus sanguineus is a proposed vector for B. gibsoni in the United States. Presence of B. gibsoni DNA in dog blood has been associated with a history of a dog bite, especially by an American Pit Bull Terrier, suggesting that fighting is a route of transmission. Babesia spp. infections were detected in 29 states and Ontario (Birkenheuer et al., 2005). Other novel *Babesia* spp. that genetically vary considerably from other *B. canis* or *B. gibsoni* isolates have been described in the United States; however, the prevalence rates for these infections is unknown (Kocan et al., 2001; Meinkoth et al., 2002; Birkenheuer et al. 2004a). None of the *Babesia* spp. that infect cats (*B. cati* [India], *B. felis* [Africa, southern Asia, Europe], *B. herpailuri* [South America, Africa], *B. canis presentii* [Israel]) have been recognized in the United States. *Babesia* spp. can also be transmitted by blood transfusions.

After infection with pathogenic strains of B. canis or B. gibsoni, the incubation period varies from several days to several weeks. The degree of parasitemia varies by the organism studied but can be detected transiently in some dogs as soon as day 1 (Boozer & Macintire, 2003). The organisms replicate intracellularly in RBCs, resulting in intravascular or extravascular hemolytic anemia. Immune-mediated reactions against the parasites or altered self-antigens worsen the hemolytic anemia and commonly result in a positive direct Coombs test. Activation of macrophages leads to fever and hepatosplenomegaly. Severe hypoxia occurs because of rapid breakdown of RBCs. Disseminated intravascular coagulation occurs in some infected dogs during acute infection. The severity of disease depends on the species and strain of Babesia and the host's immune status; chronic, subclinical infection can be common with some. Administration of glucocorticoids or splenectomy may activate chronic disease. Presence of coinfections, such as Bartonella spp., may increase the pathogenic potential (Kordick et al., 1999; Tuttle et al., 2003).

#### **Clinical Features**

In the United States, subclinical *Babesia* spp. infections are most common. Peracute or acute *Babesia* spp. infections result in anemia and fever, leading to pale mucous membranes, tachycardia, tachypnea, depression, anorexia, and weakness. Icterus, petechiae, and hepatosplenomegaly are present in some dogs depending on the stage of infection and the presence of disseminated intravascular coagulation. Severe anemia, disseminated intravascular coagulation, metabolic acidosis, and renal disease are most common during acute infection and are generally most severe with *B. canis* 

rossi infections in South Africa. The main differential diagnosis for acute babesiosis is primary immune-mediated hemolytic anemia. Chronically infected dogs commonly have weight loss and anorexia. Ascites, gastrointestinal signs, CNS disease, edema, and clinical evidence of cardiopulmonary disease occur in some dogs with atypical infection.

# Diagnosis

Regenerative anemia, hyperbilirubinemia, bilirubinuria, hemoglobinuria, thrombocytopenia, metabolic acidosis, azotemia, polyclonal gammopathy, and renal casts are common in dogs infected with pathogenic Babesia spp. Presence of the organism in RBCs detected by Wright's or Giemsa stains on thin blood smears (see Chapter 92) can be used to support the diagnosis, but parasitemia can be intermittent, giving falsely negative results; capillary blood is the preferred source for blood smear evaluation. B. canis is typically found as paired, piriform bodies measuring 2.4 × 5.0 µm. B. gibsoni is typically found as single or paired annular bodies measuring 1.0 × 3.2 µm. Serologic and polymerase chain reaction (PCR) assays are also available to help aid in the diagnosis. Indirect fluorescent antibody tests for B. canis and B. gibsoni are available commercially. However, serologic cross-reactivity can exist between B. canis and B. gibsoni, so antibody test results cannot be used to determine the infective species definitively. Demonstration of increasing titers over 2 to 3 weeks is consistent with recent or active infection. No standardization between laboratories exists, so suggested positive cutoff titers vary. False-negative serologic test results can occur in some dogs, particularly those with peracute disease or concurrent immunosuppression. A titer above 1:320 is suggested as diagnostic for B. gibsoni, but not all infected dogs achieve this titer magnitude (Birkenheuer et al., 1999). Many dogs are seropositive but clinically normal, so serology alone cannot be used to make a definitive diagnosis of clinical babesiosis. Positive results in PCR assays performed on blood prove current infection but positive results do not always correlate with clinical illness.

# Treatment

Supportive care, including blood transfusions, sodium bicarbonate therapy for acidosis, and fluid therapy, should be administered as indicated. A number of drugs, including diminazene aceturate, phenamidine, pentamidine isethionate, parvaquone, atovaquone, and niridazole, have also been used in an attempt to treat different Babesia spp. infections. In the United States, if clinical disease associated with B. canis is suspected, imidocarb diproprionate may be effective when administered (5 to 6.6 mg/kg SC or intramuscularly [IM]) twice, 14 days apart or (7.5 mg/kg, SC or IM) once. Adverse effects include transient salivation, diarrhea, dyspnea, lacrimation, and depression. Imidocarb is not as effective for the treatment of B. gibsoni infection. In the United States, if clinical disease associated with B. gibsoni is suspected, azithromycin (10 mg/kg PO q24h for a minimum of 10 days) or clindamycin hydrochloride (12.5 mg/kg PO q12h for at least 10 days) may lessen clinical disease if other drugs are not available. Azithromycin (as described) and atovaquone (13.3 mg/kg PO q8h for at least 10 days) is currently recommended for the treatment B. gibsoni infections, but this combination does not always result in elimination of infection (Birkenheuer et al., 2004b; Jefferies et al., 2007). Because no drugs are known to eliminate infection consistently, treatment of healthy, seropositive dogs is unlikely to be of benefit.

# **Zoonotic Aspects and Prevention**

No evidence currently exists to suggest that Babesia spp. infecting dogs and cats can cause human disease. However, some Babesia spp. infections of people are genetically similar to those infecting dogs, and the organism should be considered important vector-borne diseases of people. Ticks should be controlled if possible. If controlling ticks is difficult in a B. canis-infected kennel, one dose of imidocarb at 7.5 mg/kg IM may eliminate the carrier state. Minimal cross-protection exists between species; a dog that has recovered from babesiosis may still become ill if infected with another species. Thus tick control must be maintained in endemic areas. Administration of immunosuppressive drugs and splenectomy should be avoided in previously infected dogs. Dogs used as blood donors should be assessed for infection by PCR or serologic screening and positive dogs excluded from the program. Dog bites should be avoided. A B. canis vaccine is available in Europe. For blood donor programs, high-risk breeds (Greyhound, American Pit Bull Terrier) or dogs from endemic areas should be screened for Babesia spp. infection by serology or PCR assays, and positive dogs should be excluded from the program (Wardrop et al., 2005).

# **CYTAUXZOONOSIS**

# **Etiology and Epidemiology**

Cytauxzoon felis is a protozoal disease of cats in the southeastern, mid-Atlantic, and south-central United States that is usually fatal. Large-scale prevalence rates have not been performed, but one study of 961 cats in Florida, North Carolina, and Tennessee showed a prevalence rate of 0.3% (Haber et al., 2007). Isolates from domestic cats have been genetically similar between studies (Birkenheuer et al., 2006b). Bobcats are usually subclinically affected and may therefore be the natural host of the organism. The organism can be passed experimentally from infected bobcats to domestic cats by Dermacentor variabilis (American dog tick); clinical illness occurs after an incubation period of 5 to 20 days. After infection, schizonts and macroschizonts form in mononuclear phagocytes. The infected macrophages line the lumen of veins throughout the body. Merozoites released from the infected macrophages infect erythrocytes. Clinical disease results from obstruction of blood flow through tissues by the mononuclear infiltrates and from hemolytic anemia. Domestic cats occasionally survive infection, suggesting that variants that are less virulent to cats also exist (Walker et al., 1995; Meinkoth et al., 2000; Haber et al., 2007).

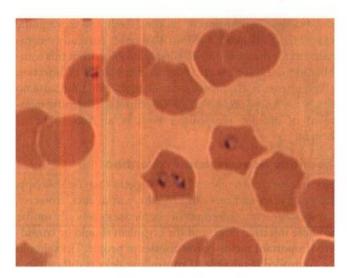

FIG 99-1 Cytauxzoon felis in the red blood cells of a cat. (Courtesy Dr. Terry M. Curtis, Gainesville, FL.)

# **Clinical Features**

Most cases of cytauxzoonosis are in cats allowed to go outdoors. Fever, anorexia, dyspnea, depression, icterus, pale mucous membranes, and death are the most common clinical findings. A primary differential diagnosis is mycoplasmosis. Ticks are rarely identified on affected cats.

# Diagnosis

Regenerative anemia, pancytopenia, and neutrophilic leukocytosis are the most common hematologic findings; thrombocytopenia occurs in some cats. Hemoglobinemia, hemoglobinuria, hyperbilirubinemia, and bilirubinuria are uncommon. Antemortem diagnosis is based on demonstration of the erythrocytic phase on thin blood smears (Fig. 99-1) stained with Wright's or Giemsa stains (see Chapter 92). Infected macrophages can be detected cytologically in bone marrow, spleen, liver, or lymph node aspirates. The organism is easily identified on histopathologic evaluation of most organs. Serologic testing is not commercially available. PCR can be used to amplify organism DNA from blood.

# **Treatment**

Supportive care includes fluid therapy and blood transfusion administered as indicated. Diminazene (five cats) (2.0 mg/kg IM twice, 7 days apart) or imidocarb (one cat) (2 mg/kg IM twice, 14 days apart) was used in cats that survived infection (Greene et al., 1999). Historically, parvaquone (10 to 30 mg/kg IM or SC q24h) administered for 2 to 3 days, buparvaquone (10 mg/kg IM or SC q24h) administered for 2 to 3 days, or thiacetarsemide (0.1 mg/kg IV q12h) administered for 2 days have been attempted. Diminazene, parvaquone, and buparvaquone are not routinely available; thiacetarsemide is toxic for cats and should not be used in this species. If no other drug is available, enrofloxacin at 5.0 mg/kg PO

or SC q12h for 7 to 10 days could be attempted. Azithromycin and atovaquone as used for *B. gibsoni* may be effective.

# **Zoonotic Aspects and Prevention**

Cytauxzoon felis is not known to be zoonotic. The disease can only be prevented by avoiding exposure. Ticks should be controlled, and cats in endemic areas should be housed during periods of peak tick activity.

# **HEPATOZOONOSIS**

# **Etiology and Epidemiology**

Hepatozoonosis in dogs is caused by the protozoal agents Hepatozoon canis and H. americanum. In North America H. americanum predominates, is transmitted by Amblyomma maculatum (Gulf Coast tick), and is most common in the Texas Gulf Coast, Mississippi, Alabama, Georgia, Florida, Louisiana, and Oklahoma. In Africa, southern Europe, and Asia, H. canis predominates and is transmitted by Rhipicephalus sanguineus (brown dog tick). A Hepatozoon species is occasionally found in the blood of cats in Europe. Clinical disease associations are currently unclear, but the cats are commonly coinfected with feline leukemia virus or feline immunodeficiency virus. Vertebrate hosts develop macrogametes and microgametes in neutrophils and monocytes. The tick ingests the organism during a blood meal and oocysts develop. After a dog ingests an infected tick, sporozoites are released and infect mononuclear phagocytes and endothelial cells of the spleen, liver, muscle, lungs, and bone marrow and ultimately form cysts containing macromeronts and micromeronts. Micromeronts develop into micromerozoites, which infect leukocytes and develop into gamonts. Tissue phases induce pyogranulomatous inflammation, resulting in clinical disease. Glomerulonephritis or amyloidosis may occur as a result of chronic inflammation and immune complex disease. Infected dogs can serve as a source of infection for ticks for months to years (Ewing et al., 2003).

# **Clinical Features**

H. americanum can be a primary pathogen, resulting in clinical illness without concurrent immune deficiency. Clinically affected dogs have been in all age groups, but disease is most commonly recognized in puppies. Fever, weight loss, and severe hyperesthesia over the paraspinal regions are common findings. Anorexia, pale mucous membranes from anemia, depression, oculonasal discharge, and bloody diarrhea occur in some dogs. Clinical signs can be intermittent and recurrent.

# **Diagnosis**

Neutrophilic leukocytosis (20,000 to 200,000 cells/ L) with a left shift is the most common hematologic finding. Thrombocytopenia is unusual unless coinfection with *Ehrlichia canis* or *Anaplasma* spp. occurs. Normocytic, normochromic, nonregenerative anemia is common and is likely from

chronic inflammation. Increased activity of alkaline phosphatase but not creatine kinase occurs in *H. americanum*—infected dogs. Hypoalbuminemia, hypoglycemia and, rarely, polyclonal gammopathy occur in some dogs. Periosteal reactions from the inflammatory reaction directed at tissue phases in muscle can occur in any bone except the skull, are most common in young dogs, do not occur in every case, and are not pathognomonic for hepatozoonosis. Definitive diagnosis is based on identification of gamonts in neutrophils or monocytes in Giemsa or Leishman's stained blood smears or by demonstration of the organism in muscle biopsy sections. PCR assays may be used to aid in the diagnosis in the future.

#### **Treatment**

No therapeutic regimen has been shown to eliminate *H. canis* or *H. americanum* infection from tissues. However, clinical disease resolves rapidly with several drug protocols. For treatment of *H. americanum*, the combination of trimethoprim-sulfadiazine (15 mg/kg PO q12h), pyrimethamine (0.25 mg/kg PO q24h), and clindamycin (10 mg/kg PO q8h) for 14 days is highly successful in the acute stage (Macintire et al., 2001). Use of decoquinate (10 to 20 mg/kg q12h) with food lessens the likelihood of recurrence of clinical disease and prolongs survival time. Imidocarb dipropionate (5 to 6 mg/kg IM or SC) administered once or twice 14 days apart is the drug of choice for treatment of *H. canis* and may also be effective for *H. americanum*. Administration of nonsteroidal antiinflammatory agents may lessen discomfort for some dogs.

# **Zoonotic Aspects and Prevention**

No evidence exists for zoonotic transfer of *H. americanum* or *H. canis* from infected dogs to people. Tick control is the best form of prevention. Glucocorticoid administration should be avoided because it may exacerbate clinical disease.

# **LEISHMANIASIS**

# Etiology and Epidemiology

Leishmania spp. are flagellates that cause cutaneous, mucocutaneous, and visceral diseases in dogs, human beings, and other mammals. Rodents and dogs are primary reservoirs of Leishmania spp., people and cats are probably incidental hosts, and sandflies are the vector in most endemic regions other than the United States. Leishmaniasis was considered unimportant in the United States until recently, with cases only reported occasionally. In 1999 L. donovani infection was confirmed in multiple dogs in a Foxhound kennel in New York state (Gaskin et al., 2002). Further investigation of more than 12,000 foxhounds and other canids documented L. donovani infection in 18 states and two Canadian provinces (Duprey et al., 2006) (Fig. 99-2). Infection of canids other than Foxhounds appears to be uncommon. In other countries flagellated promastigotes develop in the sandfly and are

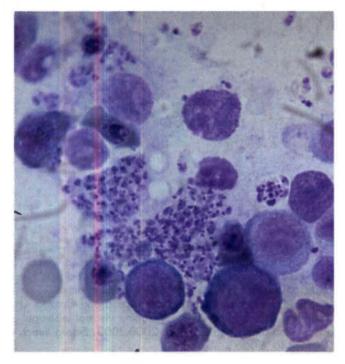

#### FIG 99-2

Distribution of hunt clubs with confirmed cases of visceral leishmaniasis, United States and Canada. States in which hunt clubs or kennels had 1 or more dogs infected with Leishmania infantum are shaded. Leishmania-positive Foxhounds were also found in Nova Scotia and Ontario. (Reprinted from Duprey ZH et al: Canine visceral leishmaniasis, United States and Canada, 2000-2003, Emerg Infect Dis 12:440, 2006.)

injected into the vertebrate host when the sandfly feeds. Promastigotes are engulfed by macrophages and disseminate through the body. After an incubation period of 1 month to 7 years, amastigotes (nonflagellate) form and cutaneous lesions develop; sandflies are infected during feeding. In Foxhounds in the United States transmission appeared to be primarily from dog to dog (Duprey et al., 2006). Transmission by fighting, shared needles, blood transfusions, breeding, and congenital transmission can occur (Duprey et al., 2006; de Freitas et al., 2006). The intracellular organism induces extreme immune responses; polyclonal gammopathies (and occasionally monoclonal); proliferation of macrophages, histiocytes, and lymphocytes in lymphoreticular organs; and immune complex formation resulting in glomerulonephritis and polyarthritis are common.

#### Clinical Features

Dogs generally develop visceral leishmaniasis. A subclinical phase of infection may persist for months or years. Weight loss in the face of a normal to increased appetite, polyuria, polydipsia, muscle wasting, depression, vomiting, diarrhea, cough, petechiae, ecchymosis, epistaxis, sneezing, and melena are common presenting complaints. Splenomegaly, lymphadenopathy, facial alopecia, fever, rhinitis, dermatitis, increased lung sounds, icterus, swollen painful joints, uveitis, and conjunctivitis are commonly identified on physical examination. Cutaneous lesions are characterized by hyperkeratosis, scaling, thickening, mucocutaneous ulcers, and intradermal nodules on the muzzle, pinnae, ears, and foot pads. Bone lesions are detected in some dogs. Most dogs die or are euthanized as a consequence of chronic kidney disease. Cats are usually subclinically infected; one cat in Texas had cutaneous nodules on the pinna.

# **Diagnosis**

The principal clinicopathologic abnormalities include hyperglobulinemia, hypoalbuminemia, proteinuria, increased liver enzyme activities, thrombocytopenia, azotemia, lymphopenia, and leukocytosis with left shift. The hyperglobulinemia is usually polyclonal, but an IgG monoclonal gammopathy was reported in a dog (Font et al., 1994). Neutrophilic polyarthritis occurs in some dogs as a manifestation of a type III hypersensitivity reaction. Demonstration of amastigotes (2.5 to 5.0 µm ×1.5 to 2.0 µm) in lymph node aspirates, bone marrow aspirates, or skin imprints stained with Wright's or Giemsa stain gives a definitive diagnosis (Fig. 99-3). The organism can also be identified by histopathologic or immunoperoxidase evaluation of skin or organ biopsy, culture, inoculation of hamsters, or PCR. Antibodies against Leishmania can be detected in serum; IgG titers develop 14 to 28 days after infection and decline 45 to 80 days after treatment. Serologic cross-reactivity occurs between Trypanosoma cruzi and Leishmania. Because dogs are unlikely to eliminate infection spontaneously, most true-positive antibody test dogs are currently infected. PCR can be performed on ethylenediamine tetraacetic acid anticoagulated blood, bone marrow, or lymph node aspirates. Real-time PCR assays can be used to monitor response to therapy (Francino et al., 2006).

#### **Treatment**

Although clinical signs of disease often improve with drug administration, the prognosis for visceral leishmaniasis in dogs is variable; most cases are recurrent. No drug or drug combination has been used to clear Leishmania from the body successfully. The combination of antimony and allopurinol (15 mg/kg PO q12h) was superior to treatment with either drug alone (Denerolle et al., 1999), but even long-term therapy does not always eliminate infection (Manna et al., 2007). Because antimony drugs are not available in the United States, infected dogs should be started on allopurinol therapy initially. In one study, marbofloxacin was effective in vitro and may be considered for the treatment of infected dogs if other drugs are not available (Vouldoukis et al., 2006). Liposomal or lipid-emulsified amphotericin B at varying doses (0.8 to 3.3 mg/kg IV for varying numbers of treatments) has been prescribed with good clinical results, but recurrences can still occur (Oliva et al., 1995; Corcadillas et al., 2003). Dogs with chronic kidney disease have a poor prognosis, but a recent study showed administration of allopurinol to be beneficial (Plevraki et al., 2006).

# **Zoonotic Aspects and Prevention**

The primary zoonotic risk for canine leishmaniasis is from dogs acting as a reservoir host for the organism. Direct contact with amastigotes in draining lesions is unlikely to result in human infection. None of the 185 persons with potential exposure to infected Foxhounds had evidence of infection (Duprey et al., 2006). Avoidance of infected sandflies is the only means of prevention. If in endemic areas, house animals during night hours and control breeding places of sandflies. Use of 10% imidacloprid/50% permethrin may lessen transmission in sandfly-endemic areas (Otranto et al., 2007). A vaccine is available for use with dogs in some countries (Dantas-Torres, 2006). For blood donor programs, high-risk breeds (e.g., Foxhounds) or dogs from endemic areas should be screened for Leishmania spp. infection by serology or PCR assays, and positive dogs should be excluded from the program (Wardrop et al., 2005).

#### NEOSPOROSIS

# **Etiology and Epidemiology**

*Neospora caninum* is a coccidian previously confused with *T*. gondii because of similar morphology. The sexual cycle is completed in the gastrointestinal tract of dogs and results in the passage of oocysts in feces. Oocyst shedding can continue for several months in some dogs (McGarry et al., 2003). Sporozoites develop in oocysts within 24 hours of passage. Tachyzoites (rapidly dividing stage) and tissue cysts containing hundreds of bradyzoites (slowly dividing stage) are the other two life stages. Dogs are infected by ingestion of bradyzoites but not tachyzoites. Infection has been documented after ingestion of infected bovine placental tissue. Dogs can become infected from ingesting intermediate hosts such as white-tailed deer (Gondim et al., 2004). Thus free-roaming dogs may be at increased risk of infection. Transplacental infection has been well documented; dams that give birth to infected offspring can repeat transplacental infection during

subsequent pregnancies. Because repeated transplacental infections occur, puppies from a bitch who previously birthed infected puppies are at an increased risk. Canine neosporosis has been reported in many countries around the world. Seroprevalence of infection has varied from 0% to 100% depending on the country and lifestyle of the dog (Dubey et al., 2007a). The pathogenesis of the disease is primarily related to the intracellular replication of tachyzoites. Although organism replication occurs in many tissues, including the lungs, in dogs clinical illness is primarily neuromuscular.

Encephalomyelitis and myositis develop in experimentally infected kittens and seropositive, naturally exposed cats have been detected (Bresciani et al., 2007), but clinical disease in naturally infected cats has not been reported. *N. caninum* seropositive, nondomestic felids also have been reported (Spencer et al., 2003).

Administration of glucocorticoids may activate bradyzoites in tissue cysts, resulting in clinical illness.

#### **Clinical Features**

Ascending paralysis with hyperextension of the hindlimbs in congenitally infected puppies is the most common clinical manifestation of the disease. Muscle atrophy occurs in many cases. Polymyositis and multifocal CNS disease can occur alone or in combination. Clinical signs can be evident soon after birth or may be delayed for several weeks. Neonatal death is common. Although disease tends to be most severe in congenitally infected puppies, dogs as old as 15 years have been clinically affected. In one dog presented primarily for respiratory disease, cough was the principal sign. Myocarditis, dysphagia, ulcerative dermatitis, pneumonia, and hepatitis occur in some dogs. Whether clinical disease in older dogs is from acute, primary infection or exacerbation of chronic infection is unknown. Administration of glucocorticoids may activate bradyzoites in tissue cysts, resulting in clinical illness. Disease is caused by intracellular replication of Neospora caninum tachyzoites. Infection of CNS structures causes mononuclear cell infiltrates, which suggests an immune-mediated component to the pathogenesis of disease. Intact tissue cysts in neural structures are generally not associated with inflammation, but ruptured tissue cysts induce inflammation. Untreated disease generally results in death.

# **Diagnosis**

Hematologic and biochemical findings are nonspecific. Myositis commonly results in increased creatine kinase and aspartate aminotransferase activities. CSF abnormalities include increased protein concentration (20 to 50 mg/dL) and a mild, mixed inflammatory cell pleocytosis (10 to 50 cells/ L) consisting of monocytes, lymphocytes, neutrophils and, rarely, eosinophils. Interstitial and alveolar patterns can be noted on thoracic radiographs.

Definitive diagnosis is based on demonstration of the organism in CSF or tissues. Tachyzoites are rarely identified on cytologic examination of CSF, imprints of dermatologic lesions, and bronchoalveolar lavage. Mixed inflammation with neutrophils, lymphocytes, eosinophils, plasma cells,

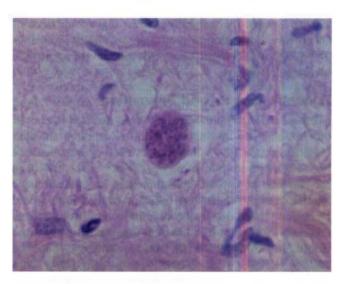

FIG 99-4
Neospora caninum cyst filled with bradyzoites in canine central nervous system tissue.

macrophages, and tachyzoites was noted on transthoracic aspirate of one dog with lung disease. *Neospora caninum* tissue cysts have a wall thicker than 1  $\mu$ m; *T. gondii* tissue cysts have a wall thinner than 1  $\mu$ m (Fig. 99-4). Oocysts can be detected in feces by microscopic examination after flotation or by PCR. The organism can be differentiated from *T. gondii* by electron microscopy, immunohistochemistry, and PCR. A multiplex PCR assay that detects both *T. gondii* and *N. caninum* for use with tissues or CSF has been reported (Schatzerg et al., 2003)

A presumptive diagnosis of neosporosis can be made by combining appropriate clinical signs of disease and positive serology or presence of antibodies in CSF with the exclusion of other etiologies inducing similar clinical syndromes, particularly *T. gondii*. Serologic cross-reactivity between *T. gondii* and *N. caninum* exist in some assays (Silva et al., 2007). IgG antibody titers of at least 1:200 have been detected in most dogs with clinical neosporosis; minimal serologic cross-reactivity occurs with *T. gondii* at titers of 1:50 or higher when using the immunofluorescent assay test.

#### **Treatment**

Although many dogs with neosporosis die, some have survived after treatment with trimethoprim-sulfadiazine combined with pyrimethamine; sequential treatment with clindamycin hydrochloride, trimethoprim-sulfadiazine, and pyrimethamine; or clindamycin alone. Administration of trimethoprim-sulfadiazine (15 mg/kg PO q12h) with pyrimethamine (1 mg/kg PO q24h) for 4 weeks or clindamycin (10 mg/kg PO q8h) for 4 weeks was recommended for the treatment of canine neosporosis. In one recent study of naturally infected beagle puppies, administration of clindamycin alone (75 mg/puppy at 9 weeks of age, PO, q12h [dose doubled at 13 weeks] for 6 months) lessened clinical signs of disease but did not eliminate the infection (Dubey et al.,

2007b). Treatment of clinically affected dogs should be initiated before the development of extensor rigidity, if possible. The prognosis for dogs presented with severe neurologic involvement is grave.

# **Zoonotic Aspects and Prevention**

Neospora caninum antibodies have been detected in people, but in one study no link was found to repeated abortion (Peterson et al., 1999). In addition, the organism has not been isolated from human tissues (Dubey et al., 2007a), so the zoonotic potential is still unproven. An epidemiologic link has been shown between dogs and cattle; efforts should be made to lessen dog fecal contamination of livestock feed, and dogs should not be allowed to ingest bovine placentas. Consuming raw meat is a risk factor for dogs and should be avoided (Reichel et al., 2007). Hunting behavior of dogs should be restricted if possible. Bitches that whelp clinically affected puppies should not be bred. Glucocorticoids should not be administered to seropositive animals, if possible, because a potential exists for activation of infection.

# FELINE TOXOPLASMOSIS

# **Etiology and Epidemiology**

Toxoplasma gondii is one of the most prevalent parasites infecting warm-blooded vertebrates. Only cats complete the coccidian life cycle and pass environmentally resistant oocysts in feces. Sporozoites develop in oocysts after 1 to 5 days of exposure to oxygen and appropriate environmental temperature and humidity. Tachyzoites disseminate in blood or lymph during active infection and replicate rapidly intracellularly until the cell is destroyed. Bradyzoites are the slowly dividing, persistent tissue stage that form in the extraintestinal tissues of infected hosts as immune responses attenuate tachyzoite replication. Tissue cysts form readily in the CNS, muscles, and visceral organs. Bradyzoites may persist in tissues for the life of the host.

Infection of warm-blooded vertebrates occurs after ingestion of any of the three life stages of the organism or transplacentally. Most cats are not coprophagic and so are infected most commonly by ingesting T. gondii bradyzoites during carnivorous feeding; oocysts are shed in feces from 3 to 21 days. Sporulated oocysts can survive in the environment for months to years and are resistant to most disinfectants (Fig. 99-5). Results of a recent study confirm that the T. gondii oocyst shedding prepatent period is stage dependent (ingestion of bradyzoites has a shorted prepatent period than ingestion of sporozoites) and not dose dependent (Dubey, 2006). In addition, transmission of T. gondii is most efficient when cats consume tissue cysts (carnivorism) and when intermediate hosts consume oocysts (fecal-oral transmission). T. gondii infection of rodents changes the behavior of the prey species, making it less averse to cats, potentially increasing the likelihood the definitive host (felid) will become infected and potentiate the sexual phase of the organism (Vyas et al., 2007). Approximately 30% to 40% of

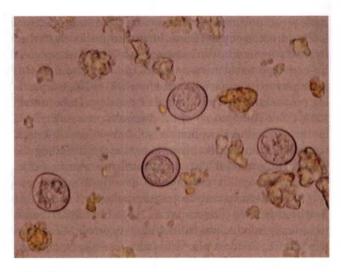

FIG 99-5 Unstained *Toxoplasma gondii* unsporulated oocysts. The oocysts are  $10 \times 12 \ \mu m$ .

cats and people in the United States are seropositive and are presumed to be infected. In a recent study of clinically ill cats, *T. gondii* antibodies were detected in 31.6% of the 12,628 cats tested (Vollaire et al., 2005).

#### **Clinical Features**

Approximately 10% to 20% of experimentally inoculated cats develop self-limiting, small-bowel diarrhea for 1 to 2 weeks after primary oral inoculation with *T. gondii* tissue cysts; this is presumed to be from enteroepithelial replication of the organism. However, detection of *T. gondii* oocysts in feces is rarely reported in studies of naturally exposed cats with diarrhea. *T. gondii* enteroepithelial stages were found in intestinal tissues from two cats with inflammatory bowel disease. Positive response to anti-*Toxoplasma* drugs in these two cats suggests that toxoplasmosis may occasionally induce inflammatory bowel disease. Eosinophilic fibrosing gastritis was recently described in a *T. gondii*—infected cat (McConnell et al., 2007).

Fatal extraintestinal toxoplasmosis can develop from overwhelming intracellular replication of tachyzoites after primary infection; hepatic, pulmonary, CNS, and pancreatic tissues are commonly involved. Kittens infected by the transplacental or transmammary routes develop the most severe signs of extraintestinal toxoplasmosis and generally die of pulmonary or hepatic disease. Common clinical findings in cats with disseminated toxoplasmosis include depression, anorexia, and fever followed by hypothermia, peritoneal effusion, icterus, and dyspnea. If a host with chronic toxoplasmosis is immunosuppressed, bradyzoites in tissue cysts can replicate rapidly and disseminate again as tachyzoites; this is common in people with acquired immunodeficiency syndrome (AIDS). Disseminated toxoplasmosis has been documented in cats concurrently infected with feline leukemia, feline immunodeficiency, or feline infectious peritonitis viruses as well as after cyclosporine administration for skin

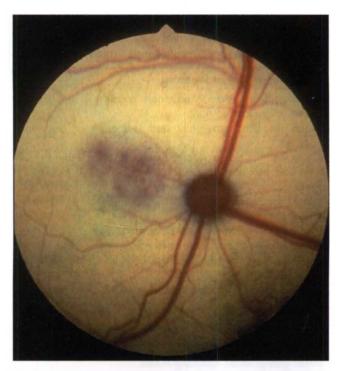

FIG 99-6
Punctate chorioretinitis caused by *Toxoplasma gondii* in an experimentally inoculated cat.

disease or after renal transplantation (Bernstein et al., 1999; Barrs et al., 2006).

Sublethal, chronic toxoplasmosis occurs in some cats. *T. gondii* infection should be on the differential diagnosis list for cats with anterior or posterior uveitis, cutaneous lesions, fever, muscle hyperesthesia, myocarditis with arrhythmias, weight loss, anorexia, seizures, ataxia, icterus, diarrhea, or pancreatitis (Fig. 99-6). Based on results of *T. gondii*–specific aqueous humor antibody and PCR studies, toxoplasmosis appears to be a common infectious cause of uveitis in cats. Kittens infected transplacentally or lactationally commonly develop ocular disease. Immune complex formation and deposition in tissues and delayed hypersensitivity reactions may be involved in chronic, sublethal clinical toxoplasmosis. Because none of the anti-*Toxoplasma* drugs totally clear the body of the organism, recurrence of disease is common.

# **Diagnosis**

Cats with clinical toxoplasmosis can have a variety of clinicopathologic and radiographic abnormalities, but none documents the disease. Nonregenerative anemia, neutrophilic leukocytosis, lymphocytosis, monocytosis, neutropenia, eosinophilia, proteinuria, and bilirubinuria as well as increases in serum protein and bilirubin concentrations, creatinine kinase, alanine aminotransferase, alkaline phosphatase, and lipase activities occur in some cats. Pulmonary toxoplasmosis most commonly causes diffuse interstitial to alveolar patterns or pleural effusion. Mass lesions may be detected on computed tomography or magnetic resonance

imaging examinations. CSF protein concentrations and cell counts are often higher than normal. The predominant white blood cells in CSF are small mononuclear cells, but neutrophils also are commonly found.

The antemortem definitive diagnosis of feline toxoplasmosis can be made if the organism is demonstrated; however, this is uncommon, particularly in association with sublethal disease. Bradyzoites or tachyzoites are rarely detected in tissues, effusions, bronchoalveolar lavage fluids, aqueous humor, or CSF. Detection of  $10 \times 12~\mu m$  oocysts in feces in cats with diarrhea suggests toxoplasmosis but is not definitive because *Besnoitia* and *Hammondia* infections of cats produce morphologically similar oocysts.

T. gondii-specific antibodies (IgM, IgG, IgA), antigens, and immune complexes can be detected in the serum of normal cats as well as in those with clinical signs of disease, so antemortem diagnosis of clinical toxoplasmosis is impossible based on these tests alone. Of the serum tests, IgM correlates the best with clinical feline toxoplasmosis because this antibody class is rarely detected in serum of healthy cats. The antemortem diagnosis of clinical toxoplasmosis can be tentatively based on the combination of the following:

- Demonstration of antibodies in serum, which documents exposure to *T. gondii*
- Demonstration of an IgM titer above 1:64 or a fourfold or greater increase in IgG titer, which suggests recent or active infection
- · Clinical signs of disease referable to toxoplasmosis
- Exclusion of other common causes for the clinical syndrome
- · Positive response to appropriate treatment

Some cats with clinical toxoplasmosis will have reached their maximal IgG titer or have undergone antibody class shift from IgM to IgG by the time they are serologically evaluated, so the failure to document an increasing IgG titer or a positive IgM titer does not exclude the diagnosis of clinical toxoplasmosis. Because some healthy cats have extremely high serum antibody titers and some clinically ill cats have low serum antibody titers, the magnitude of titer is relatively unimportant in the clinical diagnosis of toxoplasmosis. Because the organism cannot be cleared from the body, most cats will be antibody positive for life, so repeating serum antibody titers after the clinical disease has resolved is not necessary.

The combination of aqueous humor or CSF *T. gondii*-specific antibody detection and organism DNA detection by PCR is the most accurate way to diagnose ocular or CNS toxoplasmosis (e.g., Diagnostic Laboratory, College of Veterinary Medicine and Biomedical Sciences, Colorado State University, Fort Collins). Whereas *T. gondii*-specific IgA, IgG, and organism DNA can be detected in aqueous humor and CSF of both normal and clinically ill cats, *T. gondii*-specific IgM has only been detected in the aqueous humor or CSF of clinically ill cats and therefore may be the best indicator of clinical disease. Because *T. gondii* DNA can be detected

in the blood of healthy cats, positive PCR results do not correlate to clinical disease (Burney et al., 1999).

#### **Treatment**

Supportive care should be instituted as needed. Clindamycin hydrochloride (10 to 12 mg/kg PO q12h) administered for 4 weeks or a trimethoprim-sulfonamide combination (15 mg/ kg PO q12h) administered for 4 weeks has been used most frequently by the author for the treatment of clinical feline toxoplasmosis. Azithromycin (10.0 mg/kg PO q24h) has been used successfully in a limited number of cats, but the optimal duration of therapy is unknown. Pyrimethamine combined with sulfa drugs is effective for the treatment of human toxoplasmosis but commonly results in toxicity in cats. Cats with systemic clinical signs of toxoplasmosis, such as fever or muscle pain combined with uveitis, should be treated with anti-Toxoplasma drugs in combination with topical, oral, or parenteral corticosteroids to avoid secondary lens luxations and glaucoma. T. gondii-seropositive cats with uveitis that are otherwise normal can be treated with topical glucocorticoids alone unless the uveitis is recurrent or persistent. In these situations, administration of a drug with anti-T. gondii activity may be beneficial.

Clinical signs not involving the eyes or the CNS usually resolve within the first 2 to 3 days of clindamycin or trimethoprim-sulfonamide administration; ocular and CNS toxoplasmosis responds more slowly to therapy. If fever or muscle hyperesthesia does not decrease after 3 days of treatment, other causes should be considered. Recurrence of clinical signs may be more common in cats treated for less than 4 weeks. No evidence suggests that any drug can totally clear the body of the organism, so recurrences are common and infected cats will always be seropositive. The prognosis is poor for cats with hepatic or pulmonary disease caused by organism replication, particularly in those that are immunocompromised.

#### **Zoonotic Aspects and Prevention**

T. gondii is a major zoonosis. Primary infection of mothers during gestation can lead to clinical toxoplasmosis in the fetus; stillbirth, CNS disease, and ocular disease are common clinical manifestations. Primary infection in immunocompetent individuals results in self-limiting fever, malaise, and lymphadenopathy. As T-helper cell counts decline, approximately 10% of people with AIDS develop toxoplasmic encephalitis from activation of bradyzoites in tissue cysts.

People most commonly acquire toxoplasmosis transplacentally or by ingesting sporulated oocysts or tissue cysts. To prevent toxoplasmosis, avoid eating undercooked meats or ingesting sporulated oocysts (Box 99-1). In a recent study of 6282 meat samples from 698 retail meat stores, *T. gondii* was detected by bioassay in cats in none of the beef or chicken samples tested and only a small number of pork samples (Dubey et al., 2005). Although owning a pet cat was epidemiologically associated with acquiring toxoplasmosis in one study of pregnant women, touching individual cats is prob-

## Prevention of Human Toxoplasmosis

#### **Prevention of Oocyst Ingestion**

Avoid feeding undercooked meats to cats.

Do not allow cats to hunt.

Clean the litter box daily and incinerate or flush the faces.

Clean the litter box periodically with scalding water or use a litter box liner.

Wear gloves when working with soil.

Wash hands thoroughly with soap and hot water after gardening.

Wash fresh vegetables well before ingestion.

Keep children's sandboxes covered.

Boil water for drinking that has been obtained from the general environment.

Control potential transport hosts.

Treat oocyst shedding cats with anti-Toxoplasma drugs.

#### **Prevention of Tissue Cyst Ingestion**

Cook all meat products to 66° C.

Wear gloves when handling meats.

Wash hands thoroughly with soap and hot water after handling meats.

Freeze all meat for a minimum of 3 days before cooking.

ably not a common way to acquire toxoplasmosis for the following reasons:

- Cats generally only shed oocysts for days to several weeks after primary inoculation.
- Repeat oocyst shedding is rare, even in cats receiving glucocorticoids, cyclosporine, or in those infected with feline immunodeficiency virus or feline leukemia virus.
- Cats with toxoplasmosis inoculated with tissue cysts 16 months after primary inoculation did not shed oocysts.
- Cats are quite fastidious and usually do not allow feces to remain on their skin for periods long enough to lead to oocyst sporulation; the organism was not isolated from the fur of cats shedding millions of oocysts 7 days previously.
- Increased risk of acquired toxoplasmosis was not associated with cat ownership in people with AIDS or in veterinary health care providers.

However, because some cats will repeat oocyst shedding when exposed a second time, feces should always be handled carefully. If a fecal sample from a cat is shown to contain oocysts measuring  $10 \times 12~\mu m$ , the organism is assumed to be *T. gondii*. The feces should be collected daily until the oocyst shedding period is complete; administration of clindamycin (25 to 50 mg/kg PO divided q12h) or sulfonamides (100 mg/kg PO divided q12h) can reduce levels of oocyst shedding.

Because human beings are not commonly infected with *T. gondii* from contact with individual cats, testing healthy cats for toxoplasmosis is not recommended. Fecal examination is an adequate procedure to determine when cats are actively shedding oocysts but cannot predict when a cat has shed oocysts in the past. No serologic assay accurately predicts when a cat shed *T. gondii* oocysts in the past, and most cats that are shedding oocysts are seronegative. Most seropositive cats have completed the oocyst shedding period and are unlikely to repeat shedding; most seronegative cats would shed the organism if infected. If owners are concerned that they may have toxoplasmosis, they should see their physician for testing.

# CANINE TOXOPLASMOSIS

# **Etiology and Epidemiology**

Dogs do not produce *T. gondii* oocysts like cats, but they can mechanically transmit oocysts after ingesting feline feces. The tissue phases of *T. gondii* infection occur in dogs and can induce clinical disease. Approximately 20% of dogs in the United States are seropositive for *T. gondii* antibodies. Before 1988 many dogs diagnosed with toxoplasmosis based on histologic evaluation were truly infected with *Neospora caninum* (see Neosporosis section).

#### **Clinical Features**

Respiratory, gastrointestinal, or neuromuscular infection resulting in fever, vomiting, diarrhea, dyspnea, and icterus occurs most commonly in dogs with generalized toxoplasmosis. Generalized toxoplasmosis is most common in immunosuppressed dogs, such as those with canine distemper virus infection or those receiving cyclosporine to prevent rejection of a transplanted kidney. Neurologic signs depend on the location of the primary lesions and include ataxia, seizures, tremors, cranial nerve deficits, paresis, and paralysis. Dogs with myositis present with weakness, stiff gait, or muscle wasting. Rapid progression to tetraparesis and paralysis with lower motor neuron dysfunction can occur. Some dogs with suspected neuromuscular toxoplasmosis probably had neosporosis. Myocardial infection resulting in ventricular arrhythmias occurs in some infected dogs. Dyspnea, vomiting, or diarrhea occurs in dogs with polysystemic disease. Retinitis, anterior uveitis, iridocyclitis, and optic neuritis occur in some dogs with toxoplasmosis, but they are less common than in cats. Cutaneous disease has also been detected (Webb et al., 2005).

# Diagnosis

As in cats, hematologic, biochemical, urinalysis, and radiographic abnormalities are not specific. Increased protein concentrations and mixed inflammatory cell infiltrates occur in dogs with CNS toxoplasmosis.

Demonstration of the organism associated with inflammation in tissues or exudates can lead to a definitive diagnosis. More commonly an antemortem diagnosis is based on the combination of appropriate clinical signs, exclusion of other likely etiologies, positive serum antibody tests, exclusion of *N. caninum* infection by serologic testing, and response to an anti-*Toxoplasma* drug. Interpretation of serum, aqueous humor, and CSF antibody and PCR test results is as discussed for toxoplasmosis in cats.

# **Therapy**

Clindamycin hydrochloride (10-12 mg/kg PO q12h) has been used most frequently for treatment of canine toxoplasmosis by the author. Trimethoprim-sulfa (15 mg/kg PO q12h) is an alternative protocol. Treatment should be continued for a minimum of 4 weeks. If uveitis occurs, topical glucocorticoid treatment should also be used.

# **Zoonotic Aspects and Prevention**

Dogs do not complete the enteroepithelial phase of *T. gondii* but can mechanically transmit oocysts after ingesting feline feces. Like all other warm-blooded vertebrates, dogs are infected by the ingestion of sporulated oocysts or tissue cysts. Toxoplasmosis in dogs can be prevented by not allowing dogs to be coprophagic and to feed only cooked meat and meat byproducts.

#### AMERICAN TRYPANOSOMIASIS

# Etiology and Epidemiology

Trypanosoma cruzi is a flagellate that infects many mammals and causes American trypanosomiasis. The disease is diagnosed primarily in South America, but several cases have been detected in dogs of North America. Infected reservoir mammals (dogs, cats, raccoons, opossums, armadillos) and vectors (reduviid [kissing] bugs) are found in the United States, but infection in dogs or people is rare; this may relate to differences in vector behavior and sanitation standards in the United States. In one study in Texas the number of serologically positive dogs increased between 1987 and 1996 (Meurs et al., 1998). Foxhounds infected with Leishmania spp. were recently shown to be coinfected with T. cruzi (Duprey et al., 2006) (Fig. 99-7). The organism has three life stages: trypomastigotes (flagellated stage found free in blood), amastigotes (nonflagellated intracellular form), and epimastigotes (flagellated form found in the vector). When infected kissing bugs defecate during feeding, epimastigotes enter the vertebrate host, infect macrophages and myocytes, and transform into amastigotes. Amastigotes divide by binary fission until the host cell ruptures, releasing trypomastigotes into the circulation. The vector is then infected by ingesting trypomastigotes during a blood meal. Transmission can also occur transplacentally by vector ingestion, blood transfusion, or ingestion of infected tissues or milk. Peak parasitemia occurs 2 to 3 weeks after infection, causing acute disease. Disease in dogs is primarily a cardiomyopathy that develops from parasiteinduced damage to myocardial cells or immune-mediated reactions.

Distribution of hunt clubs with *Trypanosoma cruzi*–positive hounds, United States and Canada. States in which hunt clubs or kennels had 1 or more dogs infected with *T. cruzi* are shaded. A *T. cruzi*–positive hunt club was also found in Ontario. {Reprinted from Duprey ZH et al: Canine visceral leishmaniasis, United States and Canada, 2000-2003,

#### **Clinical Features**

Emerg Infect Dis 12:440, 2006.)

Exercise intolerance and weakness are nonspecific presenting complaints that relate to myocarditis or heart failure during acute infection. Generalized lymphadenopathy, pale mucous membranes, tachycardia, pulse deficits, hepatomegaly, and abdominal distension can be detected on physical examination. Anorexia, diarrhea, and neurologic signs occasionally occur. Dogs that survive acute infection can present for evaluation of chronic dilative cardiomyopathy. In one study of 11 dogs with chronic infection, right-sided cardiac disease, conduction disturbances, ventricular arrhythmias, and supraventricular arrhythmias were most common (Meurs et al., 1998).

#### Diagnosis

Common clinicopathologic abnormalities include lymphocytosis and increased activities of liver enzymes and creatine kinase. Thoracic radiographic, abdominal radiographic, and echocardiographic findings are consistent with cardiac disease and failure but are not specific for trypanosomiasis. The primary electrocardiographic findings are ventricular premature contractions, heart block, and T-wave inversion. Definitive diagnosis is based on organism demonstration. Trypomastigotes (one flagellum, 15 to 20 µm long) can be identified during acute disease on thick blood film (see Chapter 92) or buffy coat smears stained with Giemsa or Wright's stain. The organism is sometimes detected in lymph node aspirates or abdominal effusions. Histopathologic evaluation of cardiac tissue may reveal amastigotes (1.5 to 4.0 μm). Trypomastigotes can also be cultured from blood or grown by bioassay in mice. PCR assays can also be used to prove infection (Nabity et al., 2006).

#### **Treatment**

Nifurtimox has been prescribed most frequently for Chagas disease but are toxic and not routinely available in the United States. In a recent study of allopurinol for the treatment of *T. cruzi* infection in an experimentally infected mouse model, a positive response was noted. Thus treating clinically affected dogs with allopurinol as described for *Leishmania* may be prudent. Glucocorticoid therapy may improve survival of infected dogs. Therapy for arrhythmias or heart failure should be instituted as needed. Most dogs that survive acute infection develop dilative cardiomyopathy. Survival time in 11 dogs ranged from 0 to 60 months (Meurs et al., 1998).

# **Zoonotic Aspects and Prevention**

Infected dogs can serve as a reservoir of *T. cruzi* for vectors, and blood from infected dogs can be infectious to human beings. Vector control is the primary means of prevention. In one recent study use of deltamethrin-treated collars reduced *Triatoma infestans* feeding success on dogs (Reithinger et al., 2005). Dogs should be kept from other reservoir hosts, such as opossums, and should not be fed raw meat. Potential blood donors from endemic areas should be serologically screened. For blood donor programs, high-risk breeds (e.g., Foxhounds) or dogs from endemic areas should be screened for *T. cruzi* infection by serology or PCR assays, and positive dogs should be excluded from the program (Wardrop et al., 2005).

Zoonotic diseases are defined as being common to, shared by, or naturally transmitted between humans and other vertebrates. Most of the agents discussed in this chapter can infect and cause disease in immunocompetent people, but disease is generally more prevalent or more severe in immunodeficient people. Immunosuppression is common in humans. People with acquired immunodeficiency syndrome (AIDS) are discussed most frequently, but the population also includes the very old, the very young, and those receiving chemotherapy for immune-mediated diseases, organ transplantation, or neoplasia. Immunosuppressed people are sometimes advised to give up their pets. However, humans are unlikely to contract zoonotic diseases from contact with their pets, so in most cases this is not necessary. The Centers for Disease Control and Prevention online publication Preventing Infections from Pets: A Guide for People with HIV Infection states, "You do not have to give up your pet" (http:// www.cdc.gov/hiv/pubs/brochure/oi\_pets.htm). I believe that all human and other animal health care providers should provide accurate information to pet owners concerning the risks and benefits of pet ownership so that an informed decision about acquiring and keeping pets can be made (Grant et al., 1999).

Many infectious agents can infect humans by direct contact with pets, their exudates, or their excrement. These agents are the most important to veterinary health care providers and to dog and cat owners and are discussed in this chapter by likely route of exposure. For some zoonoses, including Rickettsia rickettsii, Ehrlichia spp., Bartonella spp., and Borrelia burgdorferi, the pet brings the vector of the organism into the environment, resulting in exposure of the person. With other zoonoses, including Histoplasma capsulatum, Coccidioides immitis, Blastomyces dermatitidis, and Cryptococcus neoformans, the owner and pet are infected by shared environmental exposure to the agent.

Following is a brief description of the more common canine and feline zoonoses encountered in small animal practice. General guidelines for the avoidance of zoonotic transfer of disease for veterinarians and pet owners are listed in Boxes 100-1 and 100-2, respectively.

# **ENTERIC ZOONOSES**

Multiple infectious agents of the gastrointestinal tract can be shared between animals and humans. Prevalences recently reported in two studies in cats and one in dogs are listed in Table 100-1. These findings emphasize that diagnostic workups for enteric infections are indicated because of potential human health risks. The minimal diagnostic plan to assess for enteric zoonoses includes a fecal flotation, fecal wet mount, rectal cytology, and *Cryptosporidium* spp. screening procedure. Fecal culture should be considered if infection with *Salmonella* spp. or *Campylobacter* spp. is on the list of differential diagnoses.

# **NEMATODES**

Visceral larva migrans can be induced by infection of humans with *Toxocara cati, Toxocara canis*, or *Baylisascaris procyonsis* (Table 100-2). In the United States infection of humans is

# BOX 100-1

# General Guidelines for Veterinarians to Avoid Zoonotic Transfer of Disease

- Veterinarians and their staff should familiarize themselves with zoonotic issues and take an active role in discussing the health risks and benefits of pet ownership with clients so that logical decisions concerning ownership and management of individual animals can be made.
- The veterinary clinic should communicate that the staff understands conditions associated with immune deficiency, is discreet, and is willing to help; signs or posters can be effective for this purpose.
- Pet owners should be provided information concerning veterinary or public health aspects of zoonoses, but veterinarians should not diagnose diseases in humans or discuss specific treatments.
- Clinically ill pet owners should always be referred to a physician for additional information and treatment.
- Veterinarians and physicians have different experiences concerning zoonoses; veterinarians should volunteer to speak to the pet owner's physician to clarify zoonotic issues when indicated.
- When public health-related advice is offered, it should be documented in the medical record.
- When reportable zoonotic diseases are diagnosed, appropriate public health officials should be contacted.
- Diagnostic plans to assess for presence of organisms with zoonotic potential should be offered, particularly to owners with clinically ill pets.
- All dogs and cats should be vaccinated for rabies.
- Dogs and cats should be routinely administered drugs that kill hookworms and roundworms.
- Flea and tick control should be maintained at all
- Veterinary clinic staff members should teach owners techniques to avoid being bitten or scratched.

still common; an estimated 3 million to 6 million people in the United States are infected with Toxocara larva migrans each year, and the average seroprevalence of antibodies against Toxocara is 3.5% in the general human population (Schantz, 1989). These common roundworms are passed as eggs in feces. The eggs larvate and become infectious after 1 to 3 weeks and can survive in the environment for months. Humans are infected after ingesting larvated eggs. Dogs are considered more of a significant problem than cats for the spread of eggs. However, areas such as children's sandboxes may be contaminated with T. cati because of the defecation habits of cats. Human infection after direct contact with dogs or cats is extremely unlikely because the eggs are not immediately infectious.

Dogs and cats can be subclinically affected or may develop poor haircoats, poor weight gain, and gastrointestinal signs. After ingestion of infectious eggs, larvae penetrate the intes-

# BOX 100-2

# General Guidelines for Pet Owners to Avoid Zoonotic Transfer of Disease

- If a new pet is to be adopted, the dog or cat least likely to be a zoonotic risk is a clinically normal, arthropodfree, adult animal from a private family.
- Once the animal to be adopted is identified, it should be quarantined from any immunocompromised person until a thorough physical examination and zoonoses risk assessment is performed by a veterinarian.
- Veterinary care should be sought for all clinically ill
- Physical examination and fecal examination should be performed at least once or twice yearly.
- Fecal material produced in the home environment should be removed daily, preferably by someone other than an immunocompromised individual.
- Use litterbox liners and periodically clean the litterbox with scalding water and detergent.
- Do not allow dogs or cats to drink from the toilet.
- Wear gloves when gardening and wash hands thoroughly when finished.
- Filter or boil water from sources in the environment.
- Wash your hands after handling animals.
- Do not handle animals that you are unfamiliar with.
- Clinically ill animals should not be handled by immunocompromised people, if possible.
- Pets should be maintained within the home environment to lessen exposure to other animals that may carry zoonotic agents, exposure to excrement of other animals, and exposure to fleas and ticks.
- Pets should only be fed commercially processed food.
- People should not share food utensils with pets.
- Avoid being licked by animals.
- Claws of cats should be clipped frequently to lessen the risk of skin penetration.
- To lessen the risk of bites and scratches, do not tease or physically restrain dogs and cats.
- If bitten or scratched by a dog or cat, seek medical
- Control potential transport hosts, such as flies and cockroaches, that may bring zoonotic agents into the
- Cook meat for human consumption to 80°C for 15 minutes minimum (medium-well).
- Wear gloves when handling meat and wash hands thoroughly with soap and water when finished.

tinal wall and migrate through the tissues. Eosinophilic granulomatous reactions involving the skin, lungs, central nervous system (CNS), or eyes then occur, potentially leading to clinical signs of disease. Clinical signs and physical examination abnormalities in affected individuals include skin rash, fever, failure to thrive, CNS signs, cough, pulmonary infiltrates, and hepatosplenomegaly. Peripheral eosinophilia is common. Ocular larva migrans most commonly involves the retina and can cause reduced vision; uveitis and

Uncinaria stenocephala	В	As for Ancylostoma spp.

D, Dog; C, cat; B, dog and cat.
\* Zoonotic potential undetermined; dogs are rarely infected by the ciliate Balantidium coli.

endophthalmitis can also occur. Visceral larva migrans is most common in children between 1 and 4 years of age, whereas ocular larva migrans is most common in older children. Diagnosis in human beings is confirmed by biopsy or can be presumed in cases with classic clinical manifestations, eosinophilia, and positive serology.

Ancylostoma caninum, Ancylostoma braziliense, Ancylostoma tubaeformis, Uncinaria stenocephala, and Strongyloides stercoralis have been associated with cutaneous larva migrans in the United States. After the passage of hookworm eggs into the environment in feces, infectious larvae are released after incubating for 1 to 3 days; humans are infected by skin penetration. In addition, eosinophilic enteritis in humans was reported after ingestion of larvated A. caninum eggs.

Animals are either subclinically ill or have nonspecific signs such as poor haircoats, failure to gain weight, vomiting, or diarrhea. Heavily infected puppies and kittens may have pale mucous membranes from blood loss anemia. In humans the larvae cannot penetrate the dermoepidermal junction and usually die in the epidermis. Clinical signs are related to migration of the larvae, which results in an erythematous, pruritic cutaneous tunnel. Cutaneous signs usually resolve within several weeks. Abdominal pain is the most common clinical sign in humans with *A. caninum* intestinal infection.

*Trichuris vulpis*, the dog whipworm, is most commonly associated with large-bowel diarrhea in dogs. The organism has been detected in feces in some people and has rarely been associated with gastrointestinal signs of disease (Dunn 2002).

Prevention of hookworms and roundworms is achieved by control of animal excrement in human environments. All puppies and kittens should have a fecal flotation performed and should be routinely treated with an anthelmintic that has efficacy against roundworms and hookworms. The Companion Animal Parasite Council (http://www.capcvet. org) recommends that puppies and their mothers be treated at 2, 4, 6, and 8 weeks of age and that kittens and their mothers be treated at 6, 8, and 10 weeks of age. These guidelines are particularly important for areas and animals with heavy parasite burdens. If the puppies and kittens are not presented to the veterinary clinic until vaccination age or are from areas with low prevalence rates for infection, I administer an appropriate anthelmintic such as pyrantel pamoate at each vaccination appointment. Roundworm and hookworm infections are occasionally occult, so all puppies or kittens should receive an anthelmintic whether or not eggs are detected on microscopic examination of feces. In most areas of the country monthly deworming should be considered. Administration of heartworm preventatives that also control hookworms and roundworms is an easy way to provide strategic deworming year-round.

#### **CESTODES**

Dipylidium caninum, Echinococcus granulosa, and Echinococcus multilocularis are cestodes that can infect humans. Wild carnivores are more common definitive hosts of Echinococcus spp. and shed infective eggs into the environment. E. granulosa eggs can be transmitted in feces of dogs after inges-

tion of infected sheep or rabbit tissues; E. multilocularis can be transmitted in feces of dogs or cats after ingestion of an infected rodent. Transmission to humans occurs after ingestion of the intermediate host (flea, Dipylidium) or eggs (Echinococcus spp.). Infection of dogs and cats with cestodes is generally subclinical. Dipylidium infection is most common in children and can lead to diarrhea and pruritus ani. In humans, after ingestion of eggs, which are immediately infectious, Echinococcus enters the portal circulation and spreads throughout the liver and other tissues. E. multilocularis is most common in the northern and central parts of North America but seems to be spreading with the fox population (most common definitive host). Prevention or control of cestodes is based on sanitation procedures and use of taeniacides. Praziquantel is labeled for the treatment of Echinococcus spp. Restricting hunting behavior of dogs and cats and feeding only processed or cooked foods should lessen potential exposure to Echinococcus spp. Monthly administration of praziquantel should be considered in dogs and cats allowed to hunt in endemic areas. Flea control should be maintained to lessen risk of D. caninum infection.

#### COCCIDIANS

Cryptosporidium spp. inhabit the respiratory and intestinal epithelium of many vertebrates, including birds, mammals, reptiles, and fish. Once thought to be a commensal, Cryptosporidium spp. are now known to cause gastrointestinal tract disease in several mammalian species, including rodents, dogs, cats, calves, and humans. The organisms have an enteric life cycle similar to that of other coccidians that culminates in the production of thin-walled, autoinfective oocysts and thick-walled, environmentally resistant oocysts that are passed in feces (Fig. 100-1). Oocysts (4 to 6 µm in diameter) are passed sporulated and are immediately infectious to other hosts. Multiple species of Cryptosporidium spp. exist, including C. parvum, C. hominis, C. felis, and C. canis. Although some Cryptosporidium infect multiple animal

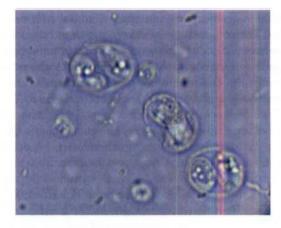

FIG 100-1
Cryptosporidium parvum and Toxoplasma gondii oocysts on a fecal flotation. The C. parvum oocysts are approximately 4 × 5 µm, and the T. gondii oocysts are approximately 10 × 12 µm.

species, others have a limited host range. However, strains that infect both pets and people cannot be differentiated by light microscopy from those that infect only pets, so all *Cryptosporidium* spp. should be considered potentially zoonotic. The most common *Cryptosporidium* spp. isolated from dogs and cats are the host-adapted *C. canis* and *C. felis*, respectively.

The prevalence of *Cryptosporidium* spp. oocysts in dog and cat feces approximates that of *Giardia* (see Table 100-1), leading to the recommendation that all dogs or cats with diarrhea in the homes of immunosuppressed people be assessed for this infection. In the United States the seroprevalence of immunoglobulin G (IgG) antibodies in serum is 8.6% in cats and up to 58% in humans. In dogs and cats with diarrhea, *Cryptosporidium* spp. DNA was amplified from feces of 16.8% and 29%, respectively (Scorza et al., 2006). These results suggest that exposure to *Cryptosporidium* spp. is quite common in pets and people.

Person-to-person contact with oocysts by fecal-oral contamination and ingestion of contaminated water are the most likely routes of exposure. *C. parvum* infection of humans after exposure to infected calves has been recognized for years. Human infection associated with contact with infected dogs and cats has been reported but is thought to be unusual. In one study cat or dog ownership was not statistically associated with cryptosporidiosis in human immunodeficiency virus (HIV)-infected people (Glaser et al., 1999).

Infection of dogs and cats by *Cryptosporidium* spp. is usually subclinical, but small-bowel diarrhea occurs in some cases. Immunosuppression may potentiate disease; several dogs and cats had concurrent feline leukemia virus infection, canine distemper virus infection, or intestinal lymphoma. Clinical cryptosporidiosis is characterized by small-bowel diarrhea and is generally self-limiting in immunocompetent people, but fatal infection is common in those with AIDS. From 10% to 20% of humans with AIDS will be infected by *C. parvum* during the course of their illness.

The small size (approximately 4 to 6 µm in diameter) of Cryptosporidium spp. oocysts leads to difficulty in diagnosis. Routine salt solution flotation and microscopic examination at ×100 magnification commonly lead to false-negative results. The combination of concentration techniques with fluorescent antibody staining or acid-fast staining appears to be more sensitive. Multiple enzyme-linked immunosorbent assays for the detection of C. parvum antigen in feces are commercially available but do not accurately detect C. felis or C. canis. Polymerase chain reaction (PCR) is the most sensitive test to date, but assays are not routinely available and are not standardized among laboratories. No drug has been shown to eliminate Cryptosporidium spp. from the gastrointestinal tract. However, clinical signs usually resolve when azithromycin is administered orally at 10 mg/kg/day, tylosin is administered orally at 10 to 15 mg/kg three times a day, or paromomycin is administered orally at 150 mg/kg daily. Paromomycin has been associated with renal insufficiency and so should never be administered to animals with blood in the feces, which appears to allow for the absorption of this aminoglycoside. Optimal duration of therapy is

unknown; some cases have required administration of azithromycin for several weeks before clinical signs resolve. Avoiding exposure is the most effective prevention. Routine disinfectants require extremely long contact with the organism to be effective. Drying, freeze thawing, and steam cleaning can inactivate the organism. Surface water collected in the field for drinking should be boiled or filtered.

Toxoplasma gondii is an ubiquitous coccidian with worldwide distribution. Most seroprevalence studies performed in the United States suggest that at least 30% of cats and humans have previously been exposed. Cats are the only known definitive host of the organism, and they complete the enteroepithelial cycle (sexual phase) that results in the passage of environmentally resistant unsporulated oocysts in feces. Oocyst sporulation occurs in 1 to 5 days in the presence of oxygen; sporulated oocysts are infectious to most warmblooded vertebrates (see Fig. 100-1). After infection by T. gondii, an extraintestinal phase that ultimately leads to the formation of tissue cysts containing the organism develops. Infection by T. gondii occurs after ingestion of sporulated oocysts, after ingestion of tissue cysts, or transplacentally. Transplacental infection of humans and cats usually occurs only if the mother is infected for the first time during gestation.

In dogs and cats, clinical disease from T. gondii infection occurs occasionally and is manifested most commonly by fever, uveitis, pulmonary disease, hepatic disease, and CNS disease (see Chapter 99). Infected immunocompetent humans are generally asymptomatic; self-limiting fever, lymphadenopathy, and malaise occur occasionally. Transplacental infection of humans results in clinical manifestations, including stillbirth, hydrocephalus, hepatosplenomegaly, and retinochoroiditis. Presence of T. gondii antibodies has been associated with presence of behavioral abnormalities in people, but a direct cause and effect has not be established. Chronic tissue infection in humans can be reactivated by immunosuppression, leading to dissemination and severe clinical illness; this has been commonly associated with drug-induced immunosuppression and AIDS. Approximately 10% of humans with AIDS develop toxoplasmic encephalitis. Oocysts are most effectively demonstrated in cat feces after sugar solution centrifugation. Clinical toxoplasmosis is difficult to diagnose in humans, dogs, and cats but usually involves the combination of clinical signs, serologic test results, organism demonstration techniques, and response to anti-Toxoplasma drugs (see Chapter 99).

Although *T. gondii* is recognized as one of the most common zoonoses, humans are usually not infected by direct contact with cats. The oocyst shedding period usually lasts several days to several weeks (approximately 7 to 10 days if the cat was infected by tissue cyst ingestion). Because oocysts have to sporulate to be infectious, contact with fresh feces cannot cause infection. Cats are quite fastidious and usually do not allow feces to remain on their skin for periods long enough to lead to oocyst sporulation. Oocysts were not isolated from the fur of cats 7 days after completion of the oocyst shedding period. No association between cat owner-

ship and *T. gondii* seroprevalence was demonstrated in a group of HIV-infected humans (Wallace et al., 1999). In most studies veterinary health care providers do not have an increased incidence of toxoplasmosis compared with the general population. Cats do not need to be removed from households with immunodeficient people or pregnant women because of the risk for acquiring toxoplasmosis (http://www.cdc.gov/ncidod/dpd/parasites/toxoplasmosis/ToxoWomen.pdf). Prevention of *T. gondii* infection is summarized in Box 99-1.

# FLAGELLATES, AMOEBA, AND CILIATES

Giardia spp. (flagellate), Entamoeba histolytica (amoeba), and Balantidium coli (ciliate) are enteric protozoans that can be transmitted to humans by contact with feces; the cysts do not require an incubation period to become infectious. E. histolytica infection is extremely rare in dogs and cats; B. coli infection is rare in dogs and has never been reported in cats.

Giardia spp. infection of dogs and cats is common and can be detected in feces of normal dogs and cats and in those with small-bowel diarrhea (and occasionally mixed-bowel diarrhea in cats). Clinical signs of disease are generally more severe in immunodeficient individuals. Because the organism is immediately infectious when passed as cysts in stool, direct zoonotic transfer is possible. Genetic studies have detected multiple Giardia spp., and most dogs and cats are infected with the host-adapted assemblages C, D, and F. However, as is the case with Cryptosporidium, because determining zoonotic strains of Giardia spp. by microscopic examination is not possible, assume that feces from all dogs and cats infected with Giardia spp. are a potential human health risk.

Fecal examination should be performed on all dogs and cats at least yearly, and treatment with drugs with anti-Giardia activity, such as fenbendazole, metronidazole, or febantel/ praziquantel/pyrantel, should be administered if indicated (see Chapter 30). Centrifugation techniques (zinc sulfate or sugar) are considered by most parasitologists to be optimal for demonstration of cysts (see Fig. 92-3). If fresh stool is available from dogs or cats with diarrhea, examination of a wet mount to detect the motile trophozoites may improve sensitivity. Monoclonal antibody-based immunofluorescent antibody tests, fecal antigen tests, and PCR assays are available but should be used in addition to, not in lieu of, fecal flotation, which can also reveal other parasites.

Giardia vaccines for subcutaneous administration are now available for both dogs and cats (see Chapter 94). The Giardia vaccines are not currently recommended for routine prophylactic use in cats or dogs, but vaccination against Giardia could be considered in cats or dogs with recurrent infection as immunotherapy. Prevention of zoonotic giardiasis includes boiling or filtering surface water for drinking and washing hands that have handled fecally contaminated material, even if gloves were worn. In dogs and cats treated for giardiasis, infection can be documented again several weeks later in approximately 25% of animals. Thus the primary goal for the treatment of giardiasis is elimination of

diarrhea. Whether these cases are a treatment failure or a reinfection is unknown.

#### **BACTERIA**

Salmonella spp., Campylobacter spp., Escherichia coli, Yersinia enterocolitica, and Helicobacter spp. each infect dogs and cats and can cause disease in humans. Transmission from animals to humans is by fecal-oral contact. Dogs can be subclinical carriers of Shigella spp., but humans are the natural hosts. Although Helicobacter pylori was isolated from a colony of cats, whether dogs and cats are a common source of Helicobacter infection in humans is unclear. However, on the basis of epidemiologic studies, it is unlikely. In three recent prevalence studies of enteric zoonoses, Salmonella spp. and Campylobacter spp. infections were uncommon in pet dogs and cats (see Table 100-1). The prevalence of Salmonella and Campylobacter infections is greater in young animals housed in unsanitary or crowded environments.

Gastroenteritis can occur in dogs or cats after infection by Salmonella spp., Campylobacter spp., or F. coli; Y. enterocolitica is probably a commensal agent in animals but causes fever, abdominal pain, polyarthritis, and bacteremia in humans. Helicobacter infections cause gastritis, which is commonly manifested as vomiting, belching, and pica. Salmonella spp. infection in dogs and cats is often subclinical. Approximately 50% of clinically affected cats have gastroenteritis; many are presented with signs of bacteremia. Salmonellosis of cats and humans has been associated with songbirds (songbird fever). Abortion, stillbirth, and neonatal death can result from in utero infection. Diagnosis of Salmonella spp., Campylobacter jejuni, E. coli, and Y. enterocolitica is based on culture of feces (see Chapter 92). A single negative culture may not rule out infection. Rectal cytology (see Chapter 92) should be performed on all animals with diarrhea. If neutrophils are noted, culture for enteric bacteria is indicated, particularly if the animal is owned by an immunodeficient individual.

Antibiotic therapy can control clinical signs of disease from infection by Salmonella spp. or Campylobacter spp. (see Chapter 30) but should not be administered orally to animals that are subclinical carriers of Salmonella because of the risk for antibiotic resistance. Strains of Salmonella resistant to most antibiotics have been detected in several cats. Prevention of enteric bacterial zoonoses is based on sanitation and control of exposure to feces. Immunodeficient people should avoid young animals and animals from crowded or unsanitary housing, particularly if clinical signs of gastrointestinal tract disease are occurring.

# BITE, SCRATCH, OR EXUDATE EXPOSURE ZOONOSES

## **BACTERIA**

Approximately 300,000 emergency room visits per year in the United States are made by people bitten by animals. Most of the aerobic and anaerobic bacteria associated with bite or scratch wounds cause only local infection in immunocompetent individuals. However, 28% to 80% of cat bites become infected, and severe sequelae, including meningitis, endocarditis, septic arthritis, osteoarthritis, and septic shock, can occur. The majority of the aerobic and anaerobic bacteria associated with dog or cat bite or scratch wounds lead only to local infection in immunocompetent individuals. Immunodeficient humans or those exposed to *Pasteurella* spp., *Capnocytophaga canimorsus* (DF-2), or *Capnocytophaga cynodegmi* more consistently develop systemic clinical illness. Splenectomized humans are at increased risk for developing bacteremia. *Pasteurella multocida* from a cat was cultured from the lungs of a man with AIDS who had only passive contact with the cat.

Dogs and cats are subclinical carriers of multiple bacteria in the oral cavity. After a person is bitten or scratched, local cellulitis is noted initially, followed by evidence of deeper tissue infection. Bacteremia and the associated clinical signs of fever, malaise, and weakness are common, and death can occur within hours after infection with *Capnocytophaga* spp. in immunodeficient or splenectomized humans. Diagnosis is confirmed by culture. Treatment of carrier animals is not needed. Treatment of clinically affected humans includes local wound management and parenteral antibiotic therapy. Penicillin derivatives are highly effective against most *Pasteurella* infections; penicillins and cephalosporins are effective against *Capnocytophaga* spp. in vitro.

Mycoplasma spp. infections of humans resulting from cat bites, one with cellulitis and one with septic arthritis, have been reported. L-form bacteria are cell wall-deficient organisms associated with chronic draining skin wounds in cats that are commonly resistant to cell wall-inhibiting antibiotics, such as penicillins and cephalosporins. Infection of a human being after a cat bite has been documented. Diagnosis can be confirmed only by histologic examination of tissue. Doxycycline has been used to treat cats and people successfully. Gloves should be worn when attending cats with draining tracts, and hands should be cleansed thoroughly.

Bartonella henselae can infect both dogs and cats and is the most common cause of cat scratch disease as well as bacillary angiomatosis and bacillary peliosis-common disorders in humans with AIDS (Table 100-3). Dogs and cats can also be infected with several other Bartonella spp., including B. clarridgeiae, B. koehlerae, B. vinsonii (dogs), and B. quintana (see Chapter 95). B. henselae has been isolated from the blood of subclinically ill, seropositive cats and also from some cats with a variety of clinical manifestations such as fever, lethargy, lymphadenopathy, uveitis, gingivitis, and neurologic diseases. Infection of dogs has also been associated with clinical illness. Seroprevalence in cats varies by region, but as many as 93% of cats in some geographic areas of the United States are Bartonella spp. seropositive. Both B. henselae and B. clarridgeiae are transmitted between cats by fleas, so the prevalence is greatest in cats from states where fleas are common (Lappin et al., 2006). Transmission to humans commonly occurs after cat bites or scratches; the disease appears to be transmitted most commonly from

TABLE 100-3

Selected Canine or Feline Zoonoses Associated with Bites, Scratches, or Contact with Exudates

ORGANISM	SPECIES	CLINICAL DISEASE
Bacterial		
Bartonella spp.	С	Cat: subclinical, fever, uveitis, gingivitis, lymphadenopathy, neurological disease
		Human being: fever, malaise, lymphadenopathy, bacillary angiomatosis, bacillary peliosis
Capnocytophaga canimorsus	В	Dog and cat: subclinical oral carriage Human being: bacteremia
Francisella tularensis	С	Cat: septicemia, pneumonia
		Human being: ulceroglandular, oculoglandular, glandular, pneumonic, or typhoidal (depending on route of infection)
Yersinia pestis	С	Cat: bubonic, bacteremic, or pneumonic
		Human: bubonic, bacteremic, or pneumonic
fungal		
Dermatophytes	В	Dog, cat, and human: superficial dermatologic disease
Sporothrix schenkii	C	Cat: chronic draining cutaneous tracts
		Human being: chronic draining cutaneous tracts
Viral		
Rabies	В	Dog and cat: progressive CNS disease
		Human: progressive CNS disease

kittens. *B. henselae* survives in flea feces for days, so the cat's claws and teeth are likely contaminated with *B. henselae* during grooming, which emphasizes the maintenance of flea control on dogs and cats.

Humans with cat scratch disease develop a variety of clinical signs, such as lymphadenopathy, fever, malaise, weight loss, myalgia, headache, conjunctivitis, skin eruptions, and arthralgia. Bacillary angiomatosis is a diffuse disease resulting in vascular cutaneous eruptions. Bacillary peliosis is a diffuse systemic vasculitis of parenchymal organs, particularly the liver. The incubation period for cat scratch disease is approximately 3 weeks. Most cases of cat scratch disease are self-limiting but may take several months to completely resolve.

Blood culture, blood PCR, and serologic testing can be used to determine the risk of individual cats (see Chapter 95). However, although serologic testing can be used to determine whether an individual cat has been exposed, both seropositive and seronegative cats can be bacteremic, limiting the diagnostic utility of serologic testing. Thus testing healthy cats for *Bartonella* spp. infection is not currently recommended by the Centers for Disease Control and Prevention or the American Association of Feline Practitioners (Brunt et al., 2006). Testing should be reserved for cats with suspected clinical bartonellosis.

In experimental studies, administration of doxycycline, tetracycline, erythromycin, amoxicillin-clavulanate, or enrofloxacin can limit bacteremia but does not cure infection in all cats and has not been shown to lessen the risk of cat scratch disease. Azithromycin is commonly administered to cats with suspected clinical bartonellosis, but no published data document clearance of infection in cats. Thus antibiotic treatment of healthy bacteremic cats is controversial and not currently recommended by the Centers for Disease Control and Prevention or the American Association of Feline Practitioners (Brunt et al., 2006). Treatment should be reserved for cats with suspected clinical bartonellosis. Strict flea control should be maintained. Kittens should be avoided by immunodeficient people. Cat claws should be kept clipped, and cats should never be teased. Cat-induced wounds should immediately be cleansed, and medical advice sought.

Feline plague is caused by Yersinia pestis, a gram-negative coccobacillus found most commonly in Midwestern and far Western states, particularly New Mexico and Colorado. Rodents are the natural hosts for this bacterium; cats are most commonly infected by ingestion of bacteremic rodents or lagomorphs or by being bitten by Yersinia-infected rodent fleas. Dogs are more resistant to infection and have not been associated with zoonotic transfer. Humans are most commonly infected by rodent flea bites, but many cases of transmission by exposure to wild animals and infected domestic cats have been documented. From 1977 to 1998, 23 cases of human plague (7.7% of the total cases) resulted from contact with infected cats. Infection can be induced by inhalation of respiratory secretions of cats with pneumonic plague, through bite wounds, or by contamination of mucous membranes or abraded skin with secretions or exudates.

Bubonic, septicemic, and pneumonic plague can develop in cats and humans; each form has accompanying fever, headache, weakness, and malaise. Because cats are most commonly infected by ingestion of bacteremic rodents, suppurative lymphadenitis (buboes) of the cervical and submandibular lymph nodes is the most common clinical manifestation. Exudates from cats with lymphadenopathy should be examined cytologically for the presence of large numbers of the characteristic bipolar rods (see Fig. 95-2). The diagnosis is confirmed by fluorescent antibody staining of exudates; culture of exudates, the tonsillar area, and saliva; and documentation of increasing antibody titers. People who are exposed to infected cats should be urgently referred to physicians for antimicrobial therapy, and public health officials should be alerted. Doxycycline, enrofloxacin, chloramphenicol, or aminoglycosides can be used successfully for the treatment of plague. Parenteral antibiotics should be used during the bacteremic phase. Drainage of lymph nodes may be required. Cats with suppurative lymphadenitis should be considered plague suspects, and extreme caution should be exercised when handling exudates or treating draining wounds. Suspect animals should be treated for fleas and housed in isolation. Cats are generally not considered infectious to humans after 4 days of antibiotic treatment.

Francisella tularensis is the gram-negative bacillus found throughout the continental United States that causes tularemia. Dermacentor variabilis (American dog tick), Dermacentor andersoni (American wood tick), and Amblyomma americanum (Lone Star tick) are known vectors. Human tularemia occurs most commonly after exposure to ticks and less commonly from contact with infected animals. There have been at least 51 cases of human tularemia resulting from contact with infected cats. Dogs are not considered a source of human tularemia but may facilitate human exposure by bringing infected ticks into the environment. Cats are infected most frequently by tick bites or ingestion of infected rabbits or rodents. Most cases of feline tularemia have been documented in the Midwest, particularly Oklahoma. However, a recent study reported a seroprevalence of 12% in cats in a same sample set (n = 91) in the Northeast (Magnarelli et al., 2007)

Infected cats exhibit generalized lymphadenopathy and abscess formation in organs such as the liver and spleen, which leads to fever, anorexia, icterus, and death. Ulceroglandular, oculoglandular, glandular, oropharyngeal, pneumonic, and typhoidal forms have been described in humans and develop depending on the route of exposure. Unlike the situation with plague, the organism is not often recognized in exudates or lymph node aspirates from infected cats. Cultures and documentation of increasing antibody titers can be used to confirm the diagnosis in cats and humans. Most cases of tularemia in cats have been diagnosed at necropsy, so optimal treatment is unknown. Streptomycin and gentamicin are the drugs used most commonly to treat humans. Tetracycline or chloramphenicol can be used in cases not requiring hospitalization but may be associated with relapses.

The disease is prevented by avoiding exposure to lagomorphs, ticks, and infected cats. All cats dying with bacteremia should be handled carefully.

#### **FUNGI**

Of the many fungal agents that infect both humans and animals, only *Sporothrix schenckii* and the dermatophytes have been shown to infect humans on direct exposure. *Histoplasma, Blastomyces, Coccidioides, Aspergillus,* and *Cryptococcus* infections of humans and animals can occur in the same household but generally result from a common environmental exposure (see Chapter 98).

Sporothrix is cosmopolitan in distribution, and the soil is believed to be the natural reservoir. Infection of cats and humans usually occurs after the organism contaminates broken skin. Cats are believed to be infected by scratches from contaminated claws of other cats; infection is most common in outdoor males. Humans can be infected by contamination of cutaneous wounds with exudates from infected cats. Sporothrix infection in cats can be cutaneolymphatic, cutaneous, or disseminated. Chronic draining cutaneous tracts are common. Cats commonly produce large numbers of the organism in feces, tissues, and exudates; thus veterinary care personnel are at high risk when treating infected cats (Fig. 100-2). The clinical disease in humans is similar to that in cats. Dogs generally do not produce large numbers of Sporothrix in exudates, so they are less of a zoonotic risk. The organism can be demonstrated by cytologic examination of exudates or culture. Fluconazole, itraconazole, or ketoconazole are effective treatments. Gloves should be worn when attending cats with draining tracts, and hands should be cleansed thoroughly.

#### **VIRUSES**

Rabies is still the only significant small animal viral zoonosis in the United States. See Chapter 69 for a discussion of this agent.

Pseudorabies is a herpesvirus that infects pigs; dogs and humans can develop self-limiting pruritic skin disease after

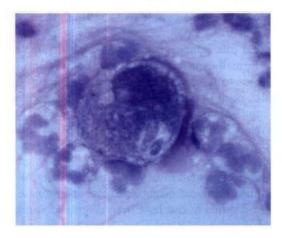

FIG 100-2 Sporothrix schenckii in a macrophage from an infected cat. Two rod-shaped organisms are visible in the cytoplasm.

exposure. Dogs occasionally develop CNS disease characterized by depression and seizures. Diagnosis is suspected on the basis of the exposure history, and prevention is by avoiding exposure.

Some authorities have been concerned whether the retroviruses of cats—feline leukemia virus (FeLV), feline immunodeficiency virus (FIV), and feline foamy virus (FeFV)—can infect humans because FeLV subtypes B and C can replicate in human cell lines. However, to date humans have not been shown to be infected with any of the feline retroviruses. In the most recent study 204 veterinarians and others potentially exposed to feline retroviruses were assessed for antibodies against FIV and FeFV, FeLV p27 antigen, and FeLV provirus; test results on all were negative (Butera et al., 2000). Because both FeLV and FIV can induce immune deficiency, infected cats should be considered more likely than retrovirus-naïve cats to be carrying other potential zoonotic agents, particularly if gastrointestinal tract signs are present.

# RESPIRATORY TRACT AND OCULAR ZOONOSES

#### **BACTERIA**

Bordetella bronchiseptica is a bacterium that induces respiratory tract infections in dogs and cats (see Chapter 21). The classic clinical manifestation is tracheobronchitis, but the organism can also cause pneumonia, sneezing, and nasal discharge. Humans rarely develop clinical disease caused by B. bronchiseptica unless they are immunologically compromised (Table 100-4). Only 39 cases of B. bronchiseptica infection in humans had been reported by 1998; most of these patients were immunodeficient. Association with a cat has only been reported once, in a person coinfected with HIV and B. bronchiseptica. Amoxicillin-clavulanate, chloramphenicol, enrofloxacin, and tetracycline derivatives are all effective treatments. Animals with upper or lower respiratory tract inflammatory disease should be kept away from immunodeficient people until the animals are clinically normal. However, treated animals can still shed the organism.

Chlamydophila felis (formerly Chlamydia psittaci) causes mild conjunctival disease and rhinitis in cats (Table 100-4). In Japan the prevalence rates of antibodies against an isolate of C. felis were 51.1% in stray cats, 15.0% in pet cats, 3.1% in the general human population, and 5.0% in small animal clinic veterinarians, suggesting that transfer between cats and humans may occur (Yan et al., 2000). Conjunctivitis in humans after direct contact with ocular discharges from cats has been described. A human isolate of Chlamydia spp. was inoculated into cats, resulting in conjunctivitis and persistent infection, suggesting that the isolate was a feline strain. Occasionally the organism is associated with systemic disease; atypical pneumonia was diagnosed in an apparently immunocompetent 48-year-old man, malaise and cough were diagnosed in an immunosuppressed woman, and endocarditis and glomerulonephritis were diagnosed in a 40-year-

# **TABLE 100-4**

Selected Canine or Feline Zoonoses Associated with Respiratory or Ocular Secretions of Dogs or Cats

ORGANISM	SPECIES	CLINICAL SIGNS
Bordetella bronchiseptica*	В	Dog and cat: upper respiratory, rarely pneumonia Immunosuppressed humans: pneumonia
Chlamydophyla felis*	С	Cat: conjunctivitis, mild upper respiratory Human being: conjunctivitis
Francisella tularensis	С	Cat: septicemia, pneumonia  Human being: ulceroglandular, oculoglandular, glandular, pneumonic, or typhoidal (depending on route of infection)
Streptococcus group A†	В	Dog and cat: subclinical, transient carrier Human being: "strep throat," septicemia
Yersinia pestis	С	Cat: bubonic, bacteremic, or pneumonic Human being: bubonic, bacteremic, or pneumonic

D, Dog; C, cat; B, dog and cat.

old woman. Diagnosis is based on organism demonstration by culture, cytologic documentation of characteristic inclusion bodies, or fluorescent antibody staining of conjunctival scrapings. Tetracycline or chloramphenicol-containing eye ointments generally are effective in the treatment of infection. Oral administration of doxycycline is still considered the optimal way to clear the carrier state. Care should be taken to avoid direct conjunctival contact with discharges from the respiratory or ocular secretions of cats, especially by immunosuppressed persons (see Box 100-2). Employees should be directed to wear gloves or wash hands carefully when attending cats with conjunctivitis.

Nosocomial spread of methicillin-resistant Staphylococcus aureus (MRSA) among veterinary or human patients and doctors was recently recognized as a significant problem in hospitals; MRSA should now also be considered a zoonotic agent (Weese et al., 2006).

Humans are the principal natural hosts for Streptococcus group A bacteria, Streptococcus pyogenes, and Streptococcus pneumoniae, which cause "strep throat" in humans. Dogs and cats in close contact with infected humans can develop transient, subclinical colonization of pharyngeal tissues and can transmit the infection to other humans. However, this is poorly documented and believed to be unusual. The organism can be cultured from the tonsillar crypts. Culture-positive animals should be treated with penicillin derivatives. If animals are to be treated in a household with chronic, recurrent strep throat, all humans should also be treated because they also could be chronic subclinical carriers.

Yersinia pestis and Francisella tularensis can be transmitted from cats to humans in respiratory secretions. In endemic areas, cats with clinical signs or radiographic abnormalities consistent with pneumonia should be handled as plague or tularemia suspects. Gloves, mask, gown, and eye protection should be worn while performing transoral airway washings in suspect cats.

#### VIRUSES

Avian influenza A (H5N1) virus has infected some cats after close exposure to infected birds. In studies of naturally exposed and experimentally infected cats, some cats developed respiratory disease (Thiry ct al., 2007) and others have become asymptomatic carriers (Leschnik et al., 2007). Results of studies assessing transmission between infected cats have been variable. To date, transmission of the infection from cats to humans has not been documented.

# GENITAL AND URINARY TRACT ZOONOSES

Coxiella burnetii is a rickettsial agent found throughout the world, including North America (Table 100-5). Many ticks, including Rhipicephalus sanguineus, are naturally infected with C. burnetii. Cattle, sheep, and goats are commonly subclinically infected and pass the organism into the environment in urine, feces, milk, and parturient discharges. Seropositive dogs have been detected, but zoonotic transfer to humans from dogs has not been documented. Infection of cats most commonly occurs after tick exposure, ingestion of contaminated carcasses, or aerosolization from a contaminated environment. Fever, anorexia, and lethargy developed in some experimentally infected cats. Infection has been associated with abortion in cats, but the organism can also be isolated from normal parturient cats. Infection of cats appears to be common; 20% of cats from a shelter in southern California and 20% of cats in Maritime Canada were seropositive, the organism was grown from the vagina of healthy cats in Japan (Nagaoka et al., 1998), and DNA of the organism was amplified from uterine tissues of cats in Colorado (Cairns et al., 2006).

Human illness associated with direct contact with infected cats occurs after aerosol exposure to the organism passed by

<sup>\*</sup> Zoonotic potential largely unknown.

<sup>†</sup>Minimal zoonotic potential.

TABLE 100-5

Selected Canine and Feline Zoonoses Associated with Contact with Urine or Genital Secretions

ORGANISM	SPECIES	CLINICAL DISEASE
Bacterial		
Brucella canis	D	Dog: orchitis, epididymitis, abortion, stillbirth, vaginal discharge, uveitis, diskospondylitis, fever, malaise Human: fever, malaise
Leptospira spp.	В*	Dog: fever, malaise, inflammatory urinary tract or hepatic disease, uveitis, CNS disease Human being: fever, malaise, inflammatory urinary tract or hepatic disease, uveitis, CNS disease
Rickettsial		
Coxiella burnetii	С	Cat: subclinical, abortion, or stillbirth Human being: fever, pneumonitis, lymphadenopathy, myalgia, arthritis

D, Dog; C, cat; B, dog and cat, CNS, central nervous system.

parturient or aborting cats; clinical signs develop 4 to 30 days after contact. Humans commonly develop acute clinical signs similar to those associated with other rickettsial discases, including fever, malaise, headache, pneumonitis, myalgia, and arthralgia. After primary infection, chronic Q fever develops in approximately 1% and can manifest as hepatic inflammation or valvular endocarditis. Tetracyclines, chloramphenicol, and quinolones are usually effective therapeutic agents in humans. Gloves and masks should be worn when attending to parturient or aborting cats. People who develop fever or respiratory tract disease after exposure to parturient or aborting cats should seek medical attention.

Leptospira spp. can be transmitted in urine from infected dogs and cats to humans, resulting in clinical disease. Host-adapted species cause subclinical infection; infection by non-host-adapted species commonly results in clinical illness. The organisms enter the body through abraded skin or intact mucous membranes. (See Chapter 95 for a detailed discussion of the clinical manifestations of this disease and its treatment in dogs and cats.) Human clinical syndromes vary with the serovar but are similar to those that occur in the dog. Animals with suspected leptospirosis should be handled while wearing gloves. Contaminated surfaces should be cleaned with detergents and disinfected with iodine-containing products.

Brucella canis is a bacterium that preferentially infects the testicles, prostate, uterus, and vagina of dogs (see Chapter 57 and 62). The infection is maintained in dogs primarily by venereal transmission. Humans can be infected by direct contact with vaginal and preputial discharges from dogs. Clinical syndromes in dogs are diverse but commonly include abortion, stillbirth, failure to conceive, orchitis, epididymitis, vaginal discharge, uveitis, discospondylitis, and bacteremia. Intermittent fever, depression, and malaise are common in infected people. Diagnosis is based on serologic testing or demonstration of the organism by culture. Dogs with clinical signs of brucellosis should be evaluated serologically for Bru-

cella infection with the 2-mercaptoethanol rapid slide agglutination card test. Seronegative dogs are unlikely to harbor *Brucella* unless the clinical syndrome is peracute. Seropositive dogs should have results confirmed by tube agglutination or agar gel immunodiffusion. Long-term antibiotic treatment (tetracyclines, aminoglycosides, quinolones) usually does not clear the infection. Ovariohysterectomy or castration will lessen contamination of the environment. Genital tract secretions should be avoided.

### SHARED VECTOR ZOONOSES

Some zoonotic agents are transmitted between animals and humans by shared vectors such as fleas, ticks, or mosquitoes. Rickettsia rickettsii (ticks), Ehrlichia spp. (ticks), Anaplasma phagocytophilum (ticks), Borrelia burgdorferi (ticks), Rickettsia felis (fleas), Bartonella spp. (fleas and ticks), Dipylidium caninum (fleas), Dirofilaria immitis (mosquitoes), and West Nile virus (mosquitoes) are examples of vector-borne zoonoses common in the United States. For the flea- and tickborne zoonoses, the pet brings the vector of the organism into the environment, resulting in exposure of the human being. Veterinary health care providers could have a slightly increased risk of exposure because they handle many animals infested with fleas and ticks. However, the vector, not direct contact with the infested animal, results in infection of the person. Flea and tick control should always be maintained animals, and infested animals that are seen in the clinic should be treated immediately. See other sections of this text for detailed discussions of these agents.

#### SHARED ENVIRONMENT ZOONOSES

Some agents that infect both animals and man are not commonly transmitted between the pet and the owner by direct

<sup>\*</sup> Cats of minimal significance.

contact but are acquired from the same environmental source. Notable examples include *Histoplasma capsulatum*, *Coccidioides immitis*, *Blastomyces dermatitidis*, *Cryptococcus neoformans*, and *Aspergillus* spp. See other sections of this text for detailed discussions of these agents.

\*The dose ranges and intervals in this table are general. Please see appropriate sections to determine the optimal dose and duration of therapy for specific syndromes or infections.

<sup>†</sup>For simple infections, azithromycin can be given daily for 3 days and then every third day.

‡The maximum daily dose should be 50 mg/kg.

§The drug can be given once daily to cats for the treatment of simple infections and to dogs and cats with ehrlichiosis.

||Clindamycin, pyrimethamine, and trimethoprim-sulfadiazine are generally used together for acute disease, and decoquinate is used for longterm maintenance therapy.

<sup>¶</sup>This drug is generally used in combination with other antifungal drugs.

# Pathogenesis of Immune-Mediated Disorders

# CHAPTER OUTLINE

GENERAL CONSIDERATIONS AND DEFINITION IMMUNOPATHOLOGIC MECHANISMS PATHOGENESIS OF AUTOIMMUNE DISORDERS PRIMARY VERSUS SECONDARY IMMUNE-MEDIATED DISORDERS

Organ systems involved in autoimmune disorders

# GENERAL CONSIDERATIONS AND DEFINITION

Immune-mediated disorders occur when the protective immune response is activated inappropriately, resulting in organ injury. Pathologic immune responses may occur in response to infectious pathogens and contribute to the clinical disease presentation for that pathogen (e.g., the hemolytic anemia associated with Mycoplasma hemofelis infection) or be stimulated by otherwise innocuous foreign substances (e.g., the allergic reactions that occur to house dust) or by self-antigens (primary autoimmunity). Autoimmunity is defined as a condition characterized by a specific humoral or cell-mediated immune response against constituents of the body's own tissues (self-antigens or autoantigens). The term primary autoimmune disease is reserved for disorders in which no underlying cause can be identified and the cause of the autoimmunity is believed to be an underlying immune system dysfunction or imbalance. The term secondary autoimmunity (also termed secondary immune-mediated disease) is used to describe immune-mediated disorders in which an underlying reason for the autoimmune response can be identified. Examples of secondary causes of autoimmunity include infection, exposure to certain drugs or toxins, neoplasia, and vaccine administration.

### **IMMUNOPATHOLOGIC MECHANISMS**

Immunopathologic injury occurs by four major mechanisms (Table 101-1). Each mechanism may either be part of an appropriate response to a foreign antigen or an inappropriate response that can lead to allergic or immune-mediated disease. More than one mechanism may be involved in a particular immune-mediated disorder.

Type I hypersensitivity involves the humoral immune system, immunoglobulin E (IgE), and mast cells. Exposure of the immune system to antigens by way of the skin, respiratory tract, or gastrointestinal tract leads to activation of antigen-specific subsets of T-helper lymphocytes and initiation of B-cell differentiation to plasma cells. Plasma cells secrete IgE, which attaches to receptors on mast cells. On future exposure to the same antigen, cross-linking of the IgE molecules on the mast cells occurs, which leads to mast cell degranulation. The potent inflammatory mediators that are released lead to vasodilation, edema, eosinophil chemotaxis, pruritus, and bronchoconstriction. Examples of diseases that are mediated primarily by a type I response include allergic bronchitis (feline asthma) and acute anaphylactic reactions.

Type II (cytotoxic) hypersensitivity involves the binding of antibody (IgG or IgM) to specific molecules on the surface of a cell. This binding typically results in destruction of the cell or receptors on the cell. In unusual situations antibodies may induce a biologic effect, such as stimulation of the thyroid-stimulating hormone receptor and induction of hyperthyroidism in humans with Graves disease. The target of antibody binding may be normal self-antigens, infectious agents bound to the cell surface, or nonbiologic antigens such as drugs bound to the cell surface. Antibodies to selfantigens may come from cell damage, resulting in exposure of previously hidden antigens, similarity between self-antigens and foreign antigens such as infectious agents and drugs, and primary immune system dysfunction or imbalance. Classic examples of diseases mediated by type II mechanisms include autoimmune hemolytic anemia, immune-mediated

TABLE 101-1

Mechanisms of Immunopathologic Injury

TYPE OF MECHANISM	IMMUNE SYSTEM EFFECTORS	ORGAN SYSTEMS COMMONLY AFFECTED	EXAMPLES
Type I (immediate)	Humoral immune system (T-helper cells and B cells), IgE, mast cells, inflammatory mediators	Skin, respiratory tract, gastrointestinal tract	Acute anaphylactic reactions, atopy, allergic bronchitis (feline asthma)
Type II (cytotoxic)	Humoral immune system, IgG and IgM	Hematologic, neuromuscular junction, skin	Immune-mediated hemolytic anemia, immune-mediated thrombocytopenia, myasthenia gravis, pemphigus foliaceous
Type III (immune complex)	Soluble immune complexes	Kidney, joints, skin	Glomerulonephritis, systemic lupus erythematosus, rheumatoid arthritis
Type IV (delayed type)	Sensitized T lymphocytes, cytokines, neutrophils, and macrophages	Endocrine glands, muscle	Lymphocytic thyroiditis, myositis

thrombocytopenia, pemphigus foliaceous, and myasthenia gravis. Antibodies involved in type II responses are usually tissue specific, and the consequence of antibody binding varies from tissue to tissue. For example, in autoimmune hemolytic anemia antibody binding results in either intravascular or extravascular red blood cell hemolysis, whereas in pemphigus foliaceous antibody binding results in disruption of keratinocyte adhesion and vesicle formation. In myasthenia gravis, antibodies directed against acetylcholine receptors cross-link and internalize the receptors, which results in failure of neuromuscular transmission.

Type III (immune complex) hypersensitivity involves the formation and deposition of soluble immune complexes (predominantly IgG) within tissues. Deposition of immune complexes in tissues results in complement fixation and a localized inflammatory response characterized by mast cell degranulation, platelet activation, and neutrophil chemotaxis. Phagocytosis of immune complexes by macrophages causes release of more inflammatory cytokines. In the presence of antibody excess the inflammatory reaction typically remains localized at the site of the initiating antibody; in the presence of antigen excess, however, soluble immune complexes enter the circulation and become deposited in vascular beds in the kidney, joints, eye, and skin. The location and extent of antibody deposition depend on a number of variables, including complex size, charge, degree of glycosylation, and Ig subclass. Classic examples of diseases mediated by type III mechanisms include infections (e.g., feline infectious peritonitis), glomerulonephritis, systemic lupus erythematosus, and rheumatoid arthritis.

Type IV (delayed-type) hypersensitivity involves the cell-mediated immune system. Exposure to either soluble or cell-associated antigen results in sensitization of specific subsets of T cells. Reexposure to the same antigen results in activation of sensitized lymphocytes, subsequent release of cyto-kines, and recruitment of neutrophils and macrophages.

Cytotoxic destruction of target cells may also occur by this mechanism. Activation of sensitized lymphocytes requires 24 to 72 hours to occur, which is why this type of response is termed "delayed." Persistence of the antigen can result in formation of multinucleate giant cells and tissue granulomas. Examples of diseases mediated by type IV immune responses include the protective immune response to intracellular microbes (e.g., leishmaniasis), contact hypersensitivity, polymyositis, and immune-mediated thyroiditis.

# PATHOGENESIS OF AUTOIMMUNE DISORDERS

In normal animals the adaptive immune system should be tolerant of self. This is achieved by a number of mechanisms that prevent B and T lymphocytes from becoming self-reactive. Most autoreactive B and T cells are deleted during maturation in the thymus, and those that escape to the periphery may undergo peripheral deletion by apoptosis, remain hidden intracellularly, or be rendered anergic in the peripheral circulation. When autoimmunity occurs, these mechanisms responsible for tolerance break down. Factors that may play a role in loss of tolerance include genetics, environmental factors, age, hormonal influences, and other diseases that lead to perturbations of the immune system.

Genetics clearly has an important role in the development of autoimmune disease. In some autoimmune diseases certain breeds of dog are at increased risk (Table 101-2). Autoimmunity is also reported more commonly in some families than others. The inbreeding that occurs in many dog breeds exacerbates the effects of such familial traits. Familial autoimmunity is not as well documented in the cat, although the Abyssinian and Somali breeds are at increased risk of myasthenia gravis. The underlying genetic changes that result in such predispositions are not yet characterized in the dog and cat.

TABLE 101-2

### Suspected Autoimmune Disorders of Various Organ Systems in Dogs and Cats

		POSTULATED IMMUNOPATHOLOGIC	
ORGAN SYSTEM	DISEASE	MECHANISM	BREED PREDISPOSITION
Hematologic	Immune-mediated hemolytic anemia	Туре II	American Cocker Spaniel, Bichon Frise, Miniature Pinscher, Miniature Schnauzer, Rough- Coated Collie, English Springer Spaniel, Finnish Spitz
	Pure red cell aplasia	Type II	None identified
	Immune-mediated thrombocytopenia	Type II	Cocker Spaniel, Poodle (all varieties), German Shepherd dog, and Old English Sheepdog
	ldiopathic neutropenia	Type II	None identified
Joints	See Table 104-8	Type III	
Skin	Various	Type II, III, and IV	
Eye	Uveitis, retinitis	Type III	
Kidney	Glomerulonephritis	Type III	
Respiratory tract	Allergic rhinitis	Type !	
	Allergic bronchitis (asthma)	Type I	
	Pulmonary infiltrates with eosinophils	Type I	Husky, Malamute
Gastrointestinal tract	Feline stomatitis/gingivitis, lymphocytic plasmacytic enteritis, anal furunculosis (perineal fistula)	Type IV	German Shepherd dog
Neurologic system	Myasthenia gravis	Type II	Abyssinian, Somali
ζ ,	Myositis	Type IV	Boxer, Newfoundland
	Polyradiculoneuritis	Únknown	·
	Granulomatous meningoencephalomyelitis	Unknown	
	Polyarteritis	Unknown	Beagle
Endocrine glands	Thyroiditis (hypothyroidism)	Type IV	Beagle, Golden Retriever
	Adrenalitis (hypoadrenocorticism)		Standard Poodle, Leonberger, Duck Tolling Retriever
	Insulitis (diabetes mellitus)		Keeshond
Multisystemic immune disease	Systemic lupus erythematosus	Type III	German Shepherd dog

Environmental factors are believed to be important in the development of autoimmunity, with exposure to infectious agents either during natural infection or as a result of vaccination being the most common factor identified. Other possible environmental factors include environmental toxins and drug exposure. Some drugs have been clearly linked to induction of autoimmunity, and many other drugs can likely cause idiosyncratic autoimmune reactions. Examples include the risk of systemic immune disease (polyarthritis, glomerulonephritis, cutaneous lesions, retinitis, polymyositis, anemia, thrombocytopenia) in Doberman Pinschers treated with trimethoprim-sulfadiazine and development of immunemediated hemolytic anemia in some cats treated with thioureylene drugs such as propylthiouracil and methimazole. Myasthenia gravis has also been reported in cats treated with methimazole.

Mechanisms by which infectious agents may induce autoimmunity include molecular mimicry, exposure of cryptic antigens after cellular damage, nonspecific polyclonal activation by superantigens, production of interferon-γ that induces major histocompatibility complex class II expression on cells that do not usually express them (e.g., thyroid follicular cells), and the innocent bystander effect in which the immune response is directed against a microbial antigen or other antigens on the surface of the cell. A complicating factor is that some infections (e.g., ehrlichiosis, borreliosis, and many other vector-borne diseases) may either mimic an autoimmune disease or cause true autoimmunity, and clinically differentiating which of the two is happening can be difficult. This is clinically relevant because the clinician is faced with a decision whether to include immunosuppressive drugs in the treatment protocol.

The role of vaccination in the precipitation of autoimmunity is unclear. Currently most of the evidence is based on anecdotal observation of a temporal association of immune-mediated disease with vaccination. A cause-and-

effect relation has been difficult to establish definitively because of the high prevalence of vaccination and the low incidence of reported adverse effects. Specific evidence for association of individual disease syndromes with vaccination is discussed in the sections on individual diseases. Altered immunoregulation and evidence of immune-mediated disease may also occur in other underlying diseases such as lymphoid neoplasia, IgA deficiency, and after chemotherapy administration.

# PRIMARY VERSUS SECONDARY IMMUNE-MEDIATED DISORDERS

Infection, drug therapy, neoplasia, and possibly vaccination may cause secondary autoimmunity. Investigation for the presence of these factors in dogs and cats with immunemediated disease is important because the presence of underlying disease may influence the treatment and the prognosis. Clearly the presence of a serious underlying disorder such as neoplasia influences the prognosis negatively. Theoretically the presence of a treatable underlying disorder should make controlling the autoimmune process easier. Unfortunately, documentation of a better prognosis with immune-mediated disorders that have an identifiable and treatable underlying disease is lacking in the dog and cat. The presence of concurrent disease may also influence choice of treatment. In particular more potent immunosuppressive drugs may be initially withheld in the presence of an underlying infectious ctiology.

# ORGAN SYSTEMS INVOLVED IN AUTOIMMUNE DISORDERS

Any organ system in the body may be damaged by immune-mediated disease processes (see Table 101-2). The

most common systems involved in the dog and cat are the joints, skin, kidney, and hematologic system, although in general immune-mediated diseases are less common in the cat than the dog. Other organs commonly involved in immune-mediated diseases are the eye, neurologic system, gastrointestinal tract, respiratory tract, and endocrine glands (see Table 101-2). Some immune-mediated diseases such as systemic lupus erythematosus involve multiple organ systems, although not all organ systems may be involved in every animal. Dogs with systemic immune-mediated disorders not uncommonly present with one manifestation of the disorder (e.g., immune-mediated hemolytic anemia) and later relapse with another (e.g., idiopathic thrombocytopenia purpura, polyarthritis). In some of these cases the underlying disorder may be systemic lupus erythematosus, but this is not always the case. A large number of autoimmune diseases affect the dog and cat. The autoimmune disorders discussed in detail in the sections that follow focus on the more-common autoimmune diseases, especially those in which the treatment of choice is immunosuppression. Other disorders in which the pathogenesis is immune mediated, but in which immunosuppression is not part of the treatment (e.g., hypothyroidism from thyroiditis), are discussed in the sections on diseases of the appropriate organ system.

Autoimmune Panels

### CLINICAL DIAGNOSTIC APPROACH

The diagnostic approach to a dog or cat with suspected immune-mediated disease depends on the clinical presentation and organ(s) involved. A complete history including questions regarding environmental or drug exposures, previous medical history, exposure to infectious agents, and vaccination history should be obtained. A thorough physical examination should also be performed. The next step is to define the extent of the problem and rule out other more common causes of the clinical signs. A typical minimal database includes a complete blood count, serum biochemical profile, and urinalysis. Because many immune-mediated diseases are characterized by fever and leukocytosis, ruling out infectious agents as the primary cause of the clinical signs is important before pursuing other less common causes. The diagnostic evaluation for immune-mediated disease is similar to that for fever of unknown origin. Bacterial culture of the urine, blood, or both—testing for common viral pathogens such as feline leukemia virus, feline immunodeficiency virus, and feline infectious peritonitis-and diagnostic imaging (thoracic and abdominal radiographs, abdominal ultrasound) are important. Investigation for vector-borne diseases such as ehrlichiosis, anaplasmosis, borreliosis, and

leishmaniasis as well as more fastidious organisms such as mycoplasma and L-forms, is usually only considered once more common bacterial and viral infections have been excluded because these tests are more expensive and the results are often not immediately available. The specific infectious agents tested for depend on whether the patient is a dog or cat as well as the disease presentation and geographic location because many infectious diseases have regional distributions.

If infection is ruled out or considered unlikely, further diagnostic evaluation should focus on organs identified as potentially involved according to the physical examination and results of the minimal database and diagnostic imaging. Organ-specific diagnostic tests may include evaluation of joint or cerebrospinal fluid, quantification of urine protein excretion, and biopsy of affected organs. (These tests are discussed in more detail in the sections on specific diseases.)

Specific tests of immune dysfunction are indicated once infectious and neoplastic diseases have been excluded and when the organ system(s) of interest has been identified. For example, in a dog with a regenerative anemia the clinician should consider doing a direct antiglobulin (Coombs) test, whereas in a dog with polyarthritis a test for rheumatoid factor would be indicated. Immune panels that include a selection of tests with different indications are rarely necessary and may result in excessive testing and results that are difficult to interpret. For example, a positive Coombs test has little relevance in a dog that is not anemic.

#### SPECIFIC DIAGNOSTIC TESTS

# COOMBS TEST (DIRECT ANTIGLOBULIN TEST)

The direct Coombs test, or direct antiglobulin test (DAT), detects the presence of antibody and/or complement bound to patient red blood cell (RBC) membranes. The test is used for diagnosis of immune-mediated hemolytic anemia (IMHA) and for diagnosis of hemolytic transfusion reactions. The DAT uses antidog or anticat antiglobulin antibody produced in a different species (usually goats or rabbits); the

reagents are species specific. The DAT is best performed on ethylenediamine tetraacetic acid (EDTA) anticoagulated blood at body temperature (37° C). Most frequently a combined Coombs reagent containing goat anticanine immunoglobulin (Ig) G, IgM, and complement component C3 is used. Addition of the Coombs reagent to washed patient RBCs results in agglutination if more than approximately 100 IgG antibody or C3 molecules are bound to the RBCs. Because the end point of the test is agglutination, the test cannot be interpreted if spontaneous agglutination persists after washing the RBCs. Results of the DAT may be reported in various forms depending on the laboratory: positive or negative, 1+ to 4+ agglutination, or as the lowest dilution of the reagent that results in agglutination. Modifications of the DAT that may improve diagnostic performance include use of monospecific antisera (usually IgG, IgM, and C3), and using more dilutions of the reagents than typically performed. The pattern of the antibody binding (IgG vs. IgM, vs. C3) can be used to increase specificity of the DAT because some patterns of binding tend to be more specific for IMHA than others. For example, in dogs with IMHA the most common pattern of binding is IgG and C3, whereas C3 alone is most commonly seen in dogs with nonhemolytic disorders and underlying inflammatory or neoplastic diseases. Using more dilutions of reagent can potentially improve the sensitivity of the DAT because it allows detection of the prozone effect in which a lack of reactivity is observed with high concentrations of antibody. Another modification of the DAT involves performing the test at 4° C to identify coldacting agglutinins. This test should only be used in animals with clinical signs of cold agglutinin disease (e.g., ear or tail tip necrosis) because nonspecific RBC agglutination occurs commonly at 4° C in many normal dogs. In some dogs with IMHA that have spontaneous agglutination, agglutination will resolve after washing of the RBCs. In this scenario a DAT may still be indicated because resolution of a previously positive DAT may be useful for disease monitoring. Both false-positive and false-negative results may occur with the DAT (Box 102-1). For this reason the DAT should be interpreted in the light of other clinical and clinicopathologic information. Recognizing that a positive Coombs test does not distinguish primary from secondary IMHA is also

important (see Chapter 104). Other more sensitive techniques such as enzyme-linked antiglobulin tests, flow cytometric techniques, and column agglutination assays have also be used to detect the presence of antibody on RBCs; however, these tests are not yet widely available in commercial laboratories.

The indirect antiglobulin test is used to detect antibody in patient serum that is capable of binding to RBCs collected from a different animal. This test is both less sensitive and less specific than the direct test and is rarely used clinically except when screening blood donor serum for anti–dog erythrocyte antigen antibodies or as part of some crossmatching procedures.

#### **SLIDE AGGLUTINATION TEST**

The slide agglutination test is used to detect the presence of spontaneous agglutination of RBCs. Spontaneous agglutination (autoagglutination) is a three-dimensional clustering of RBCs that occurs from cross-linking of RBC surface-associated antibodies. Autoagglutination occurs as a result of the presence of either high titer IgG or IgM on the RBC membrane. Agglutination must be distinguished from rouleaux formation (stacking of RBCs that occurs most often in the presence of high globulin concentrations). To evaluate for the presence of agglutination, 1 drop of saline should be added to 5 to 10 drops of blood and mixed. The RBC suspension is then evaluated both by macroscopic and microscopic examination at a temperature as close to 37° C as possible. The temperature is important because clinically insignificant cold-acting agglutinins are common in normal dogs. In most laboratories spontaneous autoagglutination that persists after saline dilution is considered diagnostic for IMHA. In other laboratories only RBC agglutination that persists after three washings of the RBCs is considered diagnostic for IMHA.

# ANTIPLATELET ANTIBODIES

Detection of platelet surface—associated antibody (direct antibody) or serum platelet bindable antibody (indirect antibody) may be useful in evaluation of dogs and cats with

BOX 102-1

Causes of False-Positive and False-Negative Results for the Direct Antiglobulin (Coombs Test)

### **FALSE-POSITIVE RESULT**

Chronic inflammatory disease

Technical problems (contamination, overcentrifugation)

Poor sample quality (clotted samples, use of serum separator tubes, collection from dextrose containing infusion lines)
Septic patient

Clinically insignificant, naturally occurring cold autoantibody Hypergammaglobulinemia

Interference by drugs (e.g., amiodarone)

### **FALSE-NEGATIVE RESULT**

Technical problems (washing, dilution, centrifugation errors)
Delay in running test (e.g., mail-in samples)
Contamination or repeated freezing of reagents
Low quantities of antibody present on cell

suspected immune-mediated thrombocytopenia. Tests for antiplatelet antibody are most commonly performed by using flow cytometric techniques. Detection of platelet surface-associated IgG is more sensitive than detection of serum platelet-bindable antibodies, presumably because the majority of antiplatelet antibody is bound to platelets rather than free in the circulation. The direct assay has a sensitivity of greater than 90% in dogs with confirmed idiopathic thrombocytopenic purpura (ITP). Because of the high sensitivity of the direct assay, a negative result for platelet surface-associated antibody makes a diagnosis of ITP unlikely. Detection of antiplatelet antibodies by either the direct or indirect technique implies an immune-mediated pathogenesis for thrombocytopenia but is not specific for primary immune-mediated thrombocytopenia. Many infectious and neoplastic diseases as well as drug exposure may cause thrombocytopenia by immune-mediated mechanisms; therefore blood samples from such patients may be positive for platelet-associated antibody. A flow cytometric assay for platelet surface-associated antibody for both dogs and cats is currently available at Kansas State University. The test requires 2 mL of EDTA blood and currently costs \$60 plus shipping. Blood samples should be shipped overnight on ice.

### **MEGAKARYOCYTE DIRECT IMMUNOFLUORESCENCE**

Antibodies directed against megakaryocytic cells in the bone marrow may be detected by direct immunofluorescence (see below for more details on immunofluorescent testing). Variable sensitivity (30% to 80%) for diagnosis of ITP has been reported. This test is also offered at Kansas State University and costs \$40. A bone marrow aspirate is required, and slides should be air dried before being sent to the testing laboratory.

### **ANTINUCLEAR ANTIBODY TEST**

Measurement of antinuclear antibody (ANA) is useful in the evaluation of dogs and cats with suspected systemic lupus erythematosus (SLE). SLE should be suspected in patients with evidence of an immune-mediated process affecting a minimum of two organ systems (see Chapter 104). Antinuclear antibodies are heterogenous antibodies directed against nuclear antigens. They are typically detected by immunofluorescent staining of frozen sections of rat liver or tissue culture monolayers of human epithelial cell lines. Results are reported as a titer that is the highest dilution of patient serum that causes definitive immunofluorescent nuclear staining. Various patterns of nuclear staining (diffuse, speckled, peripheral, and nucleolar) can be identified, but the clinical significance of the various staining patterns is still under investigation in dogs and cats. Measurement of ANA antibodies is sensitive for diagnosis of SLE in dogs and cats, although ANA-negative cases of SLE do occur. In one study of 75 dogs with SLE, 100% had a positive ANA titer (Fournel et al., 1992). In most cases the ANA titer was greater than 1:256 and the magnitude of the titer correlated with disease severity. Other studies have demonstrated lower sensitivity

of the ANA for diagnosing SLE. The variability in diagnostic sensitivity probably arises from differences in stringency in the diagnostic criteria for confirming a diagnosis of SLE and variability among laboratories in assay sensitivity and specificity. Many normal animals have low positive titers for ANA, so a cut-off for a significant positive titer should be established for each individual laboratory. The cut-off titer varies depending on the substrate and techniques used by the laboratory. Low positive ANA titers may also occur after exposure to certain drugs and in animals with chronic inflammatory or neoplastic diseases. ANAs are detected in 10% to 20% of dogs with seroreactivity to Bartonella vinsonii, Ehrlichia canis, and Leishmaniasis infantum. Dogs with seroreactivity to multiple pathogens are more likely to be ANA positive. Chronic or high-dose corticosteroid treatment may decrease the ANA titer.

#### LUPUS ERYTHEMATOSUS TEST

The lupus erythematosus (LE) test is a highly specific test for SLE but is rarely used clinically because it lacks sensitivity and the ANA test is more sensitive and less time consuming. LE cells are neutrophils that contain phagocytosed nuclear material. The test is performed in vitro. Blood collected from the patient is allowed to clot and is damaged to release free nuclei. If ANA is present it binds to nuclear material and the resulting complex is phagocytosed by neutrophils and can be identified as an LE cell by visual inspection. LE cells may also rarely be identified in vivo in blood, bone marrow, or joint fluid and, when present, are highly suggestive of SLE. The LE cell test is more sensitive to the effects of steroids than is the ANA titer. The test has been reported to be positive in the blood of 30% to 90% of dogs with SLE but may also be positive in other immune or neoplastic disorders.

#### RHEUMATOID FACTOR

Rheumatoid factor (RF) is antibody directed against an individual's own IgG. The antibody is directed against sites on the Fc portion of immunoglobulin molecules that become exposed only after antibody binds to antigen. The test is used as one of the diagnostic criteria for rheumatoid arthritis; however, the utility of the test is limited by a lack of sensitivity and specificity. The most common technique for detection of RF is the Rose-Waaler, test which uses sheep RBCs sensitized to rabbit IgG. If RF is present in patient serum, agglutination occurs. The test is performed on refrigerated serum. Samples should not be frozen because RF activity may be destroyed. Only 40% to 75% of dogs with rheumatoid arthritis are positive for RF, so a negative titer does not rule out the disease. In addition, any disease with longstanding immune complex formation may eventually cause RF, so a positive titer should not be the sole criterion for a diagnosis of rheumatoid arthritis.

### **IMMUNOFLUORESCENCE AND IMMUNOHISTOCHEMISTRY**

In many type II and type III immune-mediated diseases the presence of antibody in fixed tissues (e.g., kidney, skin) can TABLE 102-1

Clinical Indications for Use of Diagnostic Tests in Suspected Autoimmune Disease

CLINICAL SYNDROME	POTENTIAL IMMUNE- MEDIATED CONDITIONS TO CONSIDER	TESTS INDICATED TO CONFIRM	LIMITATIONS
Anemia (regenerative or nonregenerative)	Immune-mediated hemolytic anemia, pure red cell aplasia	Coombs test, slide agglutination test, review of CBC smear for spherocytes or ghost cells Bone marrow aspirate and core (if anemia is nonregenerative)	A negative Coombs test result does not rule out immune- mediated hemolytic anemia; false-positive Coombs test results may also occur
Thrombocytopenia	Immune-mediated thrombocytopenia, infectious causes of thrombocytopenia, megakaryocytic aplasia	Platelet-associated antibody, platelet-bindable antibody, bone marrow aspirate and core	Positive platelet-associated antibody test does not distinguish primary from secondary immune-mediated hemolytic anemia
Anemia and thrombocytopenia	IMHA, Evans syndrome	Coombs test Slide agglutination test Review of slide for spherocytes or ghost cells Platelet-associated antibody, platelet-bindable antibody, bone marrow aspirate and core	May be hard to distinguish blood loss anemia from hemolytic anemia in dogs with severe thrombocytopenia; Coombs test may be positive after transfusion
Shifting leg lameness, joint pain, or effusion	Nonerosive polyarthritis SLE, rheumatoid arthritis	Synovial fluid collection, radiographs of joints, RF, ANA (if other organ systems involved)	Negative RF does not rule out rheumatoid arthritis; in early rheumatoid arthritis erosive changes may not be present
Proteinuria	Glomerulonephritis	Urinalysis; protein/creatinine ratio; renal biopsy for histopathology, immunofluorescence, electron microscopy	Need to rule out inflammation arising from the lower urinary tract prior to interpreting protein/creatinine ratio
Two of the above clinical syndromes together or in combination with dysfunction of other organ system	SLE	ANA, LE preparation	LE has very low sensitivity for diagnosis of SLE; ANA titer is more sensitive, but some dogs with SLE may have a negative ANA

ANA, antinuclear antibody; IMHA, immune-mediated hemolytic anemia; LE, lupus erythematosus; SLE, Systemic lupus erythematosis.

be detected by immunofluorescent or immunoperoxidase techniques. Numerous variations on these methods exist, but in general, sections of tissue are labeled with a primary antibody (e.g., rabbit antidog IgG) and then a secondary antibody is added (e.g., antirabbit IgG), which has been conjugated to either fluorescein or the enzyme peroxidase. If antibodies are present in the tissue sample, apple green fluorescence is seen under ultraviolet light with immunofluorescent staining. In the case of immunoperoxidase peroxide, when a substrate is added in the presence of hydrogen peroxide, deposition of a brown color can be visualized with the light microscope. Tissue samples for immunofluorescent testing should be collected in Michel's medium. Routinely fixed tissue can be used for immunohistochemistry.

Common uses for immunofluorescent staining include evaluation of renal biopsies in dogs with suspected glomer-ulonephritis, detection of antibodies directed against mega-karyocytic cells in the bone marrow, and evaluation of skin biopsies from patients with suspected autoimmune skin disease.

# **AUTOIMMUNE PANELS**

Many laboratories offer an immune panel that typically includes a complete blood count and platelet count, Coombs test, ANA, and RF. It would be unusual for all these tests to be appropriate in an individual patient (Table 102-1). In addition to the cost of running such a panel, the significance of a positive test may be difficult to determine in patients in

which the test was initially not indicated. For these reasons the clinician is encourage to pick individual tests rather than automatically choosing an autoimmune panel in a dog or cat with suspected autoimmune or immune-mediated disease.

# PRINCIPLES OF TREATMENT OF IMMUNE-MEDIATED DISEASES

When treating an animal with immune-mediated disease, any underlying disease must also be treated. Although concurrent immunosuppressive therapy is typically necessary, effective treatment of underlying disease (if possible) may minimize the length of immunosuppressive therapy. The aim of treatment is to control the immune-mediated process while minimizing the adverse effects of the drugs used. In many situations short-term adverse effects must be tolerated to put the immune-mediated disease into remission. In the long term, however, medications must be tapered to minimize adverse effects. If this is not possible or if the initial drug chosen elicits a poor response, alternate or additional therapy should be considered. Monitoring the disease process before each dose reduction is critical and should be individualized depending on the underlying disease process. For example, in immune-mediated hemolytic anemia (IMHA), monitoring the complete blood count (CBC) and reticulocyte count (plus the Coombs test if it was initially positive) is adequate, whereas in dogs with immune-mediated polyarthritis repeated joint taps for synovial fluid analysis are recommended.

Supportive care and aggressive monitoring for complications caused by the immunosuppressive drugs is also critical. Detection and treatment of complications of therapy can improve long-term outcome and minimize adverse sequelae. For example, patients receiving glucocorticoids should be carefully monitored for evidence of gastrointestinal ulceration, and animals receiving azathioprine should be monitored for hepatotoxicity and bone marrow suppression. In addition, supportive care is also needed while waiting for the full effects of immunosuppressive therapy. For example, dogs with IMHA and immune-mediated thrombocytopenia (ITP) may require several transfusions before immunosuppressive treatment adequately controls the immunemediated destruction of red blood cells (RBCs) or platelets. Other forms of supportive care that may be necessary include care of the skin in animals that are recumbent, nutritional support, monitoring for and treatment of infection, and prevention of gastrointestinal ulceration.

# OVERVIEW OF IMMUNOSUPPRESSIVE THERAPY

The first line of treatment for the majority of immunemediated diseases is treatment with glucocorticoids (Table 103-1). The reasons for using glucocorticoids as the first line of therapy include rapid onset of action, low risk of toxicity, and low cost. Even in patients with concurrent conditions such as diabetes mellitis, in which long-term glucocorticoid treatment is relatively contraindicated, glucocorticoids should still be used initially with a plan to transition to other drugs (such as azathioprine) that are less likely to complicate management of the concurrent disease. In some immunemediated diseases additional immunosuppressive drugs should be added at the start of treatment. These are diseases in which a positive response to glucocorticoids alone is unlikely. Examples include canine Evans syndrome, canine IMHA with multiple poor prognostic indicators (intravascular hemolysis, agglutination that persists after washing the

RBCs, high bilirubin concentration), systemic lupus erythematosus, rheumatoid arthritis, and the polyarthritis syndrome of Akitas. In most other immune-mediated diseases, the response to glucocorticoids should be assessed before adding other immunosuppressive drugs. If response to glucocorticoids is inadequate or the adverse effects of glucocorticoids are unacceptable, azathioprine is the next drug that is most commonly added to the treatment protocol in the dog, and chlorambucil should be considered in the cat. Cyclophosphamide and cyclosporine are typically considered third-line drugs, although some exceptions are discussed in the sections on the individual immune-mediated diseases (see Chapter 104). For example, cyclosporine is used as a first-line drug in treatment of perianal fistulas in dogs, and cyclophosphamide is used as a second-line drug in cats with red cell aplasia. If immune-mediated disease has an underlying infectious cause, more caution should be used before adding an additional immunosuppressive drug. When adding a third-line drug, in most circumstances it should replace the second-line drug. Treatment with more than one additional immunosuppressive drug at the same time (e.g., azathioprine and cyclosporine together) is usually unneces-

sary and is likely to cause much more severe immunosuppression and predisposition to infection.

# **GLUCOCORTICOIDS**

Glucocorticoids (corticosteroids with primarily glucocorticoid activity) are the mainstay of treatment of most immunemediated diseases because they are effective, rapid acting, and cheap. Several different glucocorticoid drugs vary according to duration, potency, and route of administration. Glucocorticoids are characterized by their biologic half-life as measured by duration of suppression of the hypothalamic pituitary adrenocortical axis (Table 103-2). Short-acting glucocorticoids such as hydrocortisone and cortisone have a biologic half-life of less than 12 hours. Intermediate-acting steroids such as prednisone, prednisolone, methylprednisolone, and triamcinolone have a biologic half-life of 12 to 36 hours, and betamethasone, dexamethasone, flumethasone, and paramethasone have a biologic half-life of 48 hours or longer. The duration of effect of a glucocorticoid preparation is also influenced by the chemical form of the steroid. Parenteral glucocorticoid preparations are either esters or free steroid alcohols. Highly soluble esters (e.g., dexamethasone sodium phosphate, prednisolone sodium succinate) and solutions of free steroid alcohols in polyethylene glycol (dexamethasone, flumethasone) have a duration of action similar to the biologic half-life, but long-acting suspensions of insoluble steroid esters (e.g., methylprednisolone acetate suspension, triamcinolone acetamide suspension) are absorbed slowly from the injection site and do not achieve high plasma concentrations. The slow absorption also dramatically prolongs the duration of effect. Oral preparations are usually composed of the free steroid alcohol; because absorption from the gastrointestinal tract is quite rapid, the duration of effect is similar to the biologic half-life. The

Comparison of the Properties of Synthetic Glucocorticoids

COMPOUND	DURATION OF ACTION*	ANTIINFLAMMATORY POTENCY	EQUIVALENT DOSE (mg)	MINERALOCORTICOID POTENCY	APPROPRIATE FOR ALTERNATE DAY USE
Cortisone	Short	0.8	5.0	0.8	No
Hydrocortisone	Short	1.0	4.0	1.0	No
Prednisone/ prednisolone	Intermediate	4.0	1.0	0.3	Yes

\*Short = <12 hours; intermediate = 12 to 36 hours; long = >48 hours.

antiinflammatory effects of corticosteroids correlate with their glucocorticoid activity, and undesirable adverse effects such as sodium retention and edema formation are associated with mineralocorticoid activity. Synthetic steroids that possess higher glucocorticoid and lower mineralocorticoid activity than cortisol include prednisone, which has four times the potency of cortisone but 0.3 times the mineralocorticoid activity; dexamethasone, which has eight times the potency with no mineralocorticoid activity; and triamcinolone, which also has no mineralocorticoid activity.

In most patients with immune-mediated disease the ideal route of glucocorticoid administration is oral; however, in animals that are vomiting or have diseases that interfere with swallowing or gastrointestinal absorption, intravenous administration of either prednisolone or dexamethasone may be necessary. The use of long-acting parenteral drugs for treatment of immune-mediated disease is not recommended because of the failure to achieve high plasma concentrations and the long duration of effect.

The actions of corticosteroids that make them useful drugs in the treatment of various immune-mediated diseases are shown in Box 103-1. The early effects of corticosteroids are believed to result from a rapid decrease in the phagocytic activity of splenic and hepatic macrophages, whereas the long-term effects result from suppression of cell-mediated immunity. How much suppression of antibody production occurs in steroid-resistant species such as the dog and cat is controversial, but effects on B lymphocytes likely occur from suppression of T-helper cells that are required for full antibody response to an antigen.

For treatment of most immune-mediated diseases, an intermediate-acting corticosteroid such as prednisone is the treatment of choice. Prednisone is converted in the liver to prednisolone. The two drugs have historically been considered clinically identical except in the presence of hepatic failure; however, some evidence now suggests that cats do

#### BOX 103-1

# Actions of Corticosteroids that Play a Role in Treatment of Immune-Mediated Disease

- Inhibition of macrophage and neutrophil phagocytosis and chemotaxis
- Decreased neutrophil margination and migration
- Decreased lymphocyte proliferation
- Decreased numbers of circulating lymphocytes
- Altered cytokine production (decreased production of T-cell cytokines)
- Decreased cellular response to inflammatory mediators
- Inhibition of complement pathways
- Inhibition of immune complex passage through basement membranes
- Decreased prostaglandin and leukotriene synthesis
- Altered expression of phenotypic markers on canine lymphocytes
- Induction lymphocyte apoptosis (in vitro)

not convert prednisone to prednisolone as well as other species, and thus prednisolone may be a better choice than prednisone in cats. The starting dose for prednisone in dogs is 2 to 4 mg/kg/day usually given in two divided doses. Cats are more resistant to the effects of glucocorticoids than are dogs. In cats doses of 2 to 8 mg/kg/day of prednisolone or 4 mg/week per cat of dexamethasone are recommended. For immunosuppressive therapy with other glucocorticoids, the dose is based on the drug's comparative potency to prednisone. For example, the dose of dexamethasone should be approximately eight times less than the dose of prednisone for an equivalent effect. Other than this difference in potency, no evidence currently suggests that dexamethasone is more effective than prednisone or prednisolone in the treatment of immune-mediated disease. The most common reason for choosing dexamethasone rather than prednisone is for parenteral administration in patients that are vomiting or cannot tolerate oral medication.

Although glucocorticoids are extremely useful in the management of immune-mediated disease, long-term adverse effects may be debilitating to the animal and intolerable to the owner. Common adverse effects include polyuria, polydipsia, panting, weakness, dermatologic changes, predisposition to infection, gastrointestinal ulceration (at higher doses) and muscle atrophy (Fig. 103-1). Insulin resistance and hyperglycemia as well as a steroid-induced hepatopathy may also occur. Individual patients vary in their tolerance of the side effects of glucocorticoid therapy, with larger dogs often being particularly sensitive. Cats seem to be much more resistant to the side effects of glucocorticoids than are dogs.

Strategies to minimize the adverse effects of glucocorticoid therapy include using the lowest dose that will control the disease of interest, using shorter acting rather than longer acting steroids, and switching to alternate-day therapy as soon as possible. To maximize the likelihood of a good response to treatment, start with high doses initially and then slowly taper the dose rather than start with a more

FIG 103-1

Severe temporal muscle atrophy in a 7-year-old castrated male Weimaraner treated with immunosuppressive doses of prednisone for immune-mediated disease.

conservative dose and increase the dose if required. Tapering of the dose should be based on an objective measure of response to treatment (e.g., hematocrit or joint fluid analysis), and tapering of the dose should be done slowly to minimize the chance of disease relapse. As a general rule the dose should not be tapered faster than 50% per month. Remission may be harder to achieve a second time if the disease is allowed to relapse because of premature tapering of the dose. If clinical signs of glucocorticoid treatment are intolerable, other immunosuppressive drugs should be added to the treatment protocol so that the dose of glucocorticoids can be tapered more rapidly and ultimately discontinued.

#### AZATHIOPRINE

Azathioprine (Imuran) is a thiopurine antimetabolite that is a sulfur analog of adenine. After absorption, azathioprine is converted into 6-mercaptopurine and then into a number of thiopurine antimetabolites within the liver. The active cytotoxic metabolites of azathioprine are the 6-thioguanine nucleotides, which compete with purines in the synthesis of nucleic acids. This results in formation of nonfunctional nucleic acid strands. DNA and RNA synthesis is inhibited, leading to decreased proliferation of rapidly dividing cells. In hepatic insufficiency the immunosuppressive effects of azathioprine are diminished, and concurrent administration of allopurinol results in increased concentration of active metabolites. Azathioprine has a preferential effect on Tlymphocyte function with inhibition of cell-mediated immunity and T-lymphocyte-dependent antibody synthesis. Numbers of circulating monocytes are also decreased. Some confusion exists in the veterinary literature about the length of time required for azathioprine to have a clinical effect. The experimental data are sparse, but in one study azathioprine inhibited blastogenic response of canine lymphocytes to mitogens after 7 days of treatment, although serum immunoglobulin concentrations were unchanged. Clinical experience, however, suggests that the full effects of azathioprine treatment may not occur until 4 to 8 weeks after initiation of treatment.

Azathioprine is commonly used as a second-line drug in a variety of immune-mediated diseases, including immunemediated hemolytic anemia, immune-mediated thrombocytopenia, immune-mediated polyarthritis, inflammatory bowel disease, and systemic lupus erythematosus (SLE) (see Chapter 104 for the specific indications for each of these diseases). Azathioprine at the typical starting dose of 2 mg/kg PO q24h is well tolerated in dogs. Adverse effects are uncommon but bone marrow suppression, gastrointestinal upset, pancreatitis, and hepatotoxicity have been reported. A small percentage of canine patients experience life-threatening myelosuppression, characterized by neutropenia, thrombocytopenia, and sometimes anemia, when treated with azathioprine. Lower doses of azathioprine (50 mg/m<sup>2</sup> q24h or 1 mg/kg PO q24h) should be considered in dogs that show evidence of myelosuppression at the usual

2 mg/kg dose. Attempts to predict which patients are likely to have these reactions by measuring thiopurine methyltransferase activity have not been rewarding. Bone marrow suppression usually occurs within 1 to 4 months after initiation of therapy and is typically reversible within 7 to 14 days after discontinuation of therapy. Because of the potential for myelosuppression and hepatotoxicity, dogs receiving azathioprine should have a CBC and hepatic enzymes measured every 1 to 2 weeks for the first month of treatment and then every 1 to 3 months. In dogs azathioprine is typically initially used in conjunction with immunosuppressive doses of prednisone. If a positive response is observed to combined therapy, the prednisone dose should be tapered over a period of 2 to 4 months. During this time daily azathioprine should be continued at the same dose (if adverse effects are not seen). If complete discontinuation of prednisone is possible without disease relapse, then the dose of azathioprine can be gradually decreased. This is usually accomplished by initially changing the dose schedule to every other day and then to every third day before complete cessation of treatment. In patients for whom prior relapse of immune-mediated disease has already occurred, the clinician may choose to continue life-long low-dose azathioprine treatment (2 mg/kg every other day). Of note, bone marrow suppression has been reported as long as 12 months after starting azathioprine treatment, so monitoring of CBC and hepatic enzymes should be continued for the duration of treatment. Azathioprine is not recommended for use in cats because severe neutropenia and thrombocytopenia have been reported to occur even at reduced doses. Chlorambucil is a better choice for adjunctive immunosuppression in cats with immune mediated disease.

#### CYCLOPHOSPHAMIDE

Cyclophosphamide (Cytoxan) is an alkylating agent that decreases cell division of both B and T lymphocytes. Alkylating agents form covalent bonds with organic compounds, specifically nucleic acids, with resultant cross-linking of DNA, inhibition of DNA synthesis, and death in rapidly dividing cells. Cyclophosphamide affects both the cell-mediated and the humoral immune responses, but the effects on the humoral system are more pronounced. Cyclophosphamide requires hepatic transformation to its active metabolites (nornitrogen mustard, phosphoramide mustard, and acrolein). Cyclophosphamide is used to treat a range of immune-mediated diseases, but it is less commonly used than azathioprine because of the higher risk of adverse effects. In the past cyclophosphamide was a commonly used drug for adjunctive treatment of dogs with IMHA; however, recent studies suggest that other drugs such as azathioprine and cyclosporine are better choices in this disease. Adverse effects of cyclophosphamide include bone marrow suppression, gastrointestinal upset, poor hair growth, alopecia, and sterile hemorrhagic cystitis from the toxic effects on the bladder of the metabolite acrolein. Sterile hemorrhagic cystitis is most commonly reported in dogs treated with cyclophosphamide for 2 months or longer and is rare in cats. Cyclophosphamide is typically dosed in dogs either at 50 mg/m² daily for 4 days each week or as a single intravenous dose of 200 mg/m² once a week. The latter dose schedule tends to cause more profound bone marrow suppression. Lower doses are recommended in cats (Table 103-3).

# **CHLORAMBUCIL**

Chlorambucil (Leukeran) is an alkylating agent that is most commonly used as an alternative to azathioprine in cats with immune-mediated disease. Chlorambucil is a prodrug metabolized to the active metabolite phenylacetic acid mustard. It can also be used as an alternate immunosuppressive drug in dogs that do not tolerate the more commonly used cytotoxic drugs. The usual starting dose for treatment of immune-mediated diseases in both dogs and cats is 0.1 to 0.2 mg/kg PO q24h or 20 to 40 mg/m² PO q2wk (see Table 103-3). Adverse effects include bone marrow suppression, gastrointestinal upset, and predisposition to infection.

#### **CYCLOSPORINE**

Cyclosporine, a potent immunomodulating agent, is a cyclic polypeptide extracted from fungi. The major mode of action is by inhibition of the initial activation phase of CD4 T lymphocytes. Cyclosporine blocks the transcription of genes encoding several cytokines, in particular interleukin-2 (IL-2). This prevents the activation and proliferation of T lymphocytes and the secondary synthesis of other cytokines. Cyclosporine does not affect the humoral immune system; therefore treatment with cyclosporine should not influence response to vaccination. Cyclosporine is the treatment of choice for perianal fistulas in dogs and is as effective as glucocorticoids in the management of atopic dermatitis. Cyclosporine has also been used to treat other refractory immune-mediated diseases in dogs and cats, such as immune-mediated hemolytic anemia, inflammatory bowel disease, myasthenia gravis, granulomatous meningoencephalomyelitis, pure red cell aplasia, and a variety of immunemediated dermatologic diseases.

Cyclosporine is available as a vegetable oil formulation (Sandimmune, Sandoz, Holzkirchen, Germany) or as a microemulsion in gelatin capsules (Atopica, Novartis Animal Health, Basel, Switzerland; Neoral, Sandoz). Bioavailability of the microemulsion is higher than that of the oil-based product, and drug absorption is less variable. Because food intake delays drug absorption and increases variability of absorption, the microemulsion form of cyclosporine should be given 2 hours before or after feeding. Doses of cyclosporine depend on the product used and the disease being treated but range from 5 mg/kg q24h to 10 mg/kg PO q12h (Tables 103-3 and 103-4). Lower doses are typically necessary when the microemulsion product is used. Measurement

of blood cyclosporine concentration for dose individualization is recommended; however, clear-cut guidelines for appropriate therapeutic concentrations are lacking. In addition, considerable variability exists between commercial assays for cyclosporine, so following the guidelines of individual laboratories regarding the therapeutic range is important. Blood cyclosporine levels measured with high-performance liquid chromatography techniques are typically lower than those measured with other commercial techniques (fluorescent polarization immunoassay, radioimmunoassay) because these techniques also detect some cyclosporine metabolites. Trough concentrations of 400 to 600 ng/mL (depending on the assay used) are considered to be in the therapeutic range, but positive clinical responses for some disorders may be observed at lower concentrations.

Numerous interactions between cyclosporine and other drugs occur because of shared metabolic pathways involving the cytochrome P450 enzyme system. Therapeutic monitoring is especially important in animals receiving concurrent therapy with such drugs (Table 103-5). In dogs treated with cyclosporine (2 to 5 mg/kg PO q24h), concurrent ketoconazole administration (5 to 15 mg/kg q24h) can be used to decrease the required dose of cyclosporine, with considerable resultant cost savings. This strategy has primarily been used in dogs with perianal fistulas and dogs undergoing organ transplantation; however, it could also be considered in other diseases for which cyclosporine is indicated, although the effectiveness is unproven. Therapeutic monitoring of the cyclosporine concentration is important when using this strategy.

Adverse effects of cyclosporine include gastrointestinal disturbance, predisposition to infection, gingival hyperplasia, papillomatosis, and increased shedding of the haircoat. A dermatosis from atypical staphylococcal infection (psoriasiform lichenoid–like dermatosis) has also been reported in dogs treated with cyclosporine. Affected dogs improved after antibiotic therapy and a decreased dose of cyclosporine. At the doses used to treat atopic dermatitis (5 mg/kg PO q24h), no difference in prevalence of bacterial infection was demonstrated between dogs treated with prednisone and those treated with cyclosporine. The risk of infection is increased in dogs treated with higher doses of cyclosporine, such as those used to prevent transplant rejection (20 mg/kg PO q24h) and when cyclosporine is combined with other immunosuppressive drugs such as prednisone and azathioprine.

#### **VINCRISTINE**

Vincristine is an alkaloid derived from the periwinkle plant used as an antineoplastic and immunosuppressive agent. Vincristine binds to the microtubular structural protein tubulin, which is abundant within platelets. At low doses the drug causes a transient increase in circulating platelet numbers; at higher doses it can cause myelosuppression and thrombocytopenia. Proposed mechanisms for increased platelet numbers in normal dogs include stimulation of

### Immunosuppressive Drugs Used in Treatment of Immune-Mediated Diseases in Dogs and Cats

DRUG	DOSE (DOG)	DOSE (CAT)	ADVERSE EFFECTS	RECOMMENDED MONITORING
Prednisone	2-4 mg/kg/day	2-8 mg/kg/day	Signs of hyperadrenocorticism, gastrointestinal ulceration, predisposition to infection	History and physical examination, CBC, biochemical panel; monitor parameters of disease progression
Azathioprine	2 mg/kg/day	Not recommended	Bone marrow suppression, gastrointestinal upset, hepatotoxicity, pancreatitis	CBC, platelet count, liver enzymes biweekly for 2 months, then monthly
Chlorambucil	0.1-0.2 mg/kg PO q24h initially, then taper to every other day once a response is seen	0.1-0.2 mg/kg PO q24h initially then q48-72h	Myelosuppression	CBC and platelet count weekly initially; may decrease to biweekly or monthly once stable
Cyclophosphamide	50 mg/kg/day PO for 4 out of 7 days or 200 mg/kg IV once a week	2.5 mg/kg/day PO for 4 out of 7 days or 7 mg/kg IV once a week	Bone marrow suppression, gastrointestinal upset, sterile hemorrhagic cystitis (rare in cats)	CBC, liver enzymes weekly for 2 months, then monthly; urinalysis biweekly
Cyclosporine	5 mg/kg q24h to 10 mg/kg q12h. Start at lower end of dose for microemulsified products (Neoral); lower doses of 1-2.5 mg/kg q12h if in conjunction with ketoconazole (see Table 103-4)	0.5-3 mg/kg q12h (microemulsified products); lower trough concentrations recommended in cats (250-500 ng/mL)	Gastrointestinal upset, infection, gingival hyperplasia, papillomatosis, increased shedding	CBC and biochemical panel monthly
Vincristine	0.02 mg/kg IV as a single dose for treatment of IMT	NA	Myelosuppression, thrombophlebitis if allowed to extravasate outside vein	Daily CBC and platelet count to monitor response of platelets
Danazol	5 mg/kg PO q12h	5 mg/kg PO q12h	Hepatotoxicity, virilization, weight gain, lethargy	CBC and biochemical panel monthly
hIVIG	0.25-1.5 g/kg as an IV infusion over 6-12 hours (one dose only)		Vomiting, mild thrombocytopenia in normal dogs	Monitor animal during administration by frequent TPR measurements, CBC and platelet count for disease monitoring

CBC, Complete blood count; NA, not applicable; TPR, total parenteral nutrition; IMT, immune-mediated thrombocytopenia; hIVIG, human intravenous immunoglobin.

thrombopoiesis by circulating thrombopoietic factors (perhaps by concealing platelets from the thrombopoietic regulatory system) or by inducing acute fragmentation of mature megakaryocytes. In immune-mediated thrombocytopenia, in which stimulation of thrombopoiesis is already

maximal, the mechanisms for increased platelet numbers are most likely increased platelet release from the bone marrow and impaired platelet destruction from inhibition of phagocytosis, or interference with antibody binding to platelets. Decreased antibody synthesis seems less likely considering

the short time course for the increase in platelet count. Disruption of structure and function of platelets has been reported after exposure to vincristine in vitro and in vivo in dogs with lymphoma; however, the clinical significance of this finding is unclear.

The major indication for vincristine in treatment of immune-mediated disease is as an adjunctive therapy for ITP. Vincristine is administered at 0.02 mg/kg IV as a single dose in addition to treatment with glucocorticoids. Vincristine-treated dogs with ITP have a more rapid increase in platelet number and shorter duration of hospitalization than dogs treated with prednisone alone. The advantages of vincristine are that it is readily available and inexpensive. Although bone marrow suppression may occur at higher doses, this has not been reported at the low single dose used for treatment of immune-mediated thrombocytopenia. Care should be taken during intravenous administration because the drug is highly caustic if allowed to extravasate outside the vein.

#### DANAZOL

Danazol (Danocrine) is an attenuated synthetic androgen that has been used as an immunomodulating drug in dogs. In theory androgens suppress the immune response, and in people with immune-mediated hemolytic anemia and immune-mediated thrombocytopenia danazol has been found to decrease the amount of immunoglobulin and complement on the surface of RBCs and platelets. Isolated case reports have also suggested a beneficial effect in dogs with IMHA and thrombocytopenia, but confounding effects of other drugs occurred in both reports. In a double-blind study of danazol treatment in dogs with IMHA also treated with prednisone and azathioprine, no beneficial effect of danazol could be demonstrated. Side effects of danazol in dogs are uncommon but include hepatotoxicity, virilization (of females), weight gain, and lethargy. The recommended dose for danazol is 5 mg/kg q12h; however, no good evidence currently exists to support the use of this drug for treatment of immune-mediated diseases in dogs and cats.

### HUMAN INTRAVENOUS **IMMUNOGLOBULIN**

Human intravenous immunoglobulin (hIVIG) is a preparation of polyspecific immunoglobulin G (IgG) obtained from the plasma of a large number (more than 1000) of healthy human blood donors. hIVIG is available either as a solution or a lyophilized product, and a wide range of concentrations and vial sizes are available (5% to 10%, 1- to 12-g vials). Numerous commercial products are available and vary in price and availability (e.g., Gammagard S/D, Baxter Healthcare Corporation, Deerfield, Ill.; Gamimune N, Bayer Pharmaceuticals, Leverkusen, Germany). Human hIVIG is the treatment of choice for immune-mediated thrombocytopenic purpura and is also used for the treatment of a wide variety of other immune-mediated diseases in human beings. The mechanism(s) by which hIVIG modulates the immune system is unknown. In dogs the primary mechanism of hIVIG is hypothesized to be blockade of Fc receptors on mononuclear phagocytes, thereby inhibiting phagocytosis. Other potential mechanisms include decreased production of autoantibodies, possibly from effects of anti-idiotypic antibodies in hIVIG, functional modulation of T cells, decreased natural killer cell activity, blockade of complement-mediated cell damage, and modulation of the release and function of proinflammatory cytokines.

hIVIG has been used in veterinary medicine to treat immune-mediated hemolytic anemia, pure red cell aplasia, myelofibrosis, ITP, erythema multiforme, pemphigus foliaceus, and toxic epidermal necrolysis, although prospective studies evaluating the efficacy of hIVIG have yet to be performed in any of these diseases. Doses recommended for use in dogs range from 0.25 to 1.5 g/kg administered as an intravenous infusion over 6 to 12 hours. The potential limitation of treatment of dogs and cats with hIVIG is that administration of an infusion containing human protein could lead to sensitization and potential anaphylaxis if the treatment is repeated. However, no reports of anaphylactic reactions have yet been reported despite administration of the products at least twice (and in one case multiple times) in some dogs and cats. To date no clinically significant side effects have been reported in dogs or cats treated with hIVIG, although a high rate of thromboembolism was reported in one study of dogs with IMHA treated with hIVIG (Scott-Moncrieff et al., 1997). Whether this was related to the underlying disease or the treatment was not clear. Risk of thromboembolism is also a concern in people treated with hIVIG, especially in those with other risk factors for thromboembolism. Mild thrombocytopenia and occasional vomiting have been reported in normal dogs treated with hIVIG. The major limitation of hIVIG treatment is the expense, which has limited prospective studies of this mode of therapy in veterinary medicine, hIVIG is currently most commonly used as a rescue agent in dogs with immune-mediated diseases that are not responding to conventional immunosuppressive agents. Because of the rapid but short-acting effect of hIVIG on phagocytosis, the most logical use is as a bridge to suppress phagocytosis in diseases such as IMHA and ITP while waiting for other immunosuppressive drugs to become effective; however, clinical studies are currently lacking.

#### PENTOXIFYLLINE

Pentoxifylline belongs to the methylxanthine drug class and is a derivative of theobromine. Despite this derivation the drug does not have cardiac or bronchodilatory effects. The major properties of the drug relate to its effects on the immune system and blood viscosity. By mechanisms that are unclear, pentoxifylline improves the deformability of RBCs.

Pentoxifylline also has a number of immunomodulating effects, including inhibition of IL-1, IL-6, and tumor necrosis factor-α as well as inhibition of B- and T-cell activation. The pharmacokinetics of pentoxifylline have been described in the dog, and the current dose recommendation is 15 mg/kg PO q8h. In veterinary medicine pentoxifylline has primarily been used for the management of cutaneous immunemediated diseases, including dermatomyositis, SLE, and various forms of vasculitis. Whether the drug might be beneficial in other immune-mediated diseases is still to be determined. Adverse side effects in dogs are uncommon but may include vomiting, diarrhea, bone marrow suppression, and flushing.

#### **SPLENECTOMY**

Splenectomy is an adjunctive therapy that has been recommended in the management of hematologic immune-mediated diseases such as IMHA and ITP. Splenectomy is theorized to decrease the number of phagocytic mononuclear cells available for phagocytosis of antibody-coated RBCs and platelets. It is typically recommended in dogs with IMHA and ITP resistant to medical therapy. In dogs with relapsing ITP good evidence supports the merits of splenectomy in the subset of dogs with ITP that relapses after tapering of prednisone and azathioprine therapy. The merits of splenectomy in dogs with IMHA are less clear. Some case reports suggest that some dogs have better control of disease after splenectomy, but in other cases no benefit occurred. One concern regarding splenectomy in dogs with IMHA is that the spleen is an important site of extramedullary hematopoiesis, so splenectomy decreases the regenerative response. In addition, most dogs with IMHA are not good candidates for a major surgical procedure such as splenectomy.

# IMMUNE-MEDIATED HEMOLYTIC ANEMIA

#### Etiology

Immune-mediated hemolytic anemia (IMHA) is a clinical syndrome in which anemia results from the accelerated destruction of red blood cells (RBCs) by immune-mediated mechanisms (see Chapter 83). IMHA is the most common cause of hemolytic anemia in dogs but is much less common in cats. In primary IMHA (true autoimmune hemolytic anemia) antibodies are directed against RBC membrane antigens. These antigens have not been well characterized in the dog or cat, but antibodies directed against spectrin, band 3, and the family of erythrocyte membrane glycoproteins, known as glycophorins, have been identified. True autoimmune hemolytic anemia may also be a manifestation of systemic lupus erythematosus (SLE). In secondary IMHA an underlying disease is identified as a precipitating factor for the immune-mediated hemolytic process. Examples of causes of secondary IMHA include infection and neoplastic diseases (Box 104-1). Secondary IMHA may also occur after exposure to certain drugs, venoms, and possibly vaccines. Most studies in dogs suggest that primary autoimmune

hemolytic anemia is more common than the secondary form, although the frequency of identification of a secondary cause likely depends in part on how thoroughly the clinician searches for it. Secondary IMHA is more common than primary IMHA in cats.

The most common antibody classes identified on the RBC in both dogs and cats with IMHA are immunoglobulin (Ig) G and IgM, with IgA being least common. Complement is usually also present on the RBC. In secondary IMHA antibodies may be directed against antigens that adsorb to the RBC membrane or against a microbial antigen combined with a self-determinant, with the RBCs destroyed as an "innocent bystanders." Alternatively, previously hidden membrane antigens may be exposed by membrane damage from microbes or toxins, or microbial and drug antigens may be cross-reactive with self-determinants. Lastly, nonspecific activation of lymphocytes can result in formation of self-reacting lymphocytes in any chronic inflammatory process.

Recent vaccination has been implicated in the pathogenesis of IMHA. The occurrence of IMHA within 2 to 4 weeks of vaccination has been a clinical observation of concern to many owners and veterinarians. In one study of 58 dogs with IMHA, 26% of dogs had been vaccinated within 4 weeks of developing IMHA compared with a control group presenting for other disorders in which no increase in frequency of vaccination in the previous 4 weeks was observed (Duval et al., 1996). Mortality rates between the dogs that had been recently vaccinated and those that had not were not significantly different. In a later study that compared 72 dogs with IMHA to a control group, a temporal association between vaccination and development of IMHA was not identified (Carr et al., 2002). The importance of vaccination in the etiology of IMHA remains unclear.

IMHA clearly has a genetic predisposition, with the disease recognized more frequently in certain breeds (Box 104-2). The Cocker Spaniel appears to be the breed at greatest risk, accounting for as many as one third of cases. The presence of dog erythrocyte antigen 7 is associated with a protective effect in Cocker Spaniels (Miller et al., 2004). Female dogs and neutered dogs are overrepresented, suggesting a possible hormonal influence.

IMHA, Immune-mediated hemolytic anemia.

In IMHA the presence of antibody and/or complement on the RBC ultimately results in intravascular or extravascular hemolysis (see Chapter 83). Extravascular hemolysis is more common than intravascular hemolysis, is typically a less-acute process, and is commonly accompanied by spherocytes and hyperbilirubinemia (Figs. 104-1 and 104-2). Although hyperbilirubinemia is a common feature of IMHA, it does not occur in all cases and lack of hyperbilirubinemia does not rule out IMHA. Little clinical significance can be attributed to the relative proportions of conjugated and unconjugated bilirubin on the biochemical panel. Factors that determine the presence and severity of hyperbilirubinemia include the rate of hemolysis as well as hepatic function. In dogs with IMHA, hepatic function may be compromised by hypoxia and hepatic necrosis. In one study of 34 dogs that died of IMHA, 53% had moderate to severe centrilobular hepatic necrosis at necropsy (McManus et al., 2001).

#### **Clinical Features**

Dogs with primary IMHA are typically young to middleaged adults, with a reported age range of 1 to 13 years and a

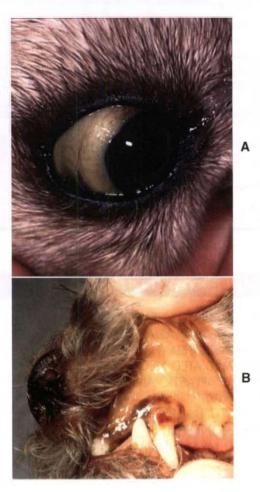

FIG 104-1 Mixed-breed dog with moderate icterus of the sclera (A) and the oral mucous membranes (B).

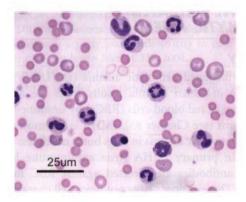

FIG 104-2 Photomicrograph of a blood smear demonstrating presence of spherocytes.

median age of 6 years. Females and neutered dogs of both sexes appear predisposed compared with sexually intact male dogs, and several breeds are overrepresented (see Box 104-2). Cats with primary IMHA tend to be younger than dogs, with a median age of 2 years. Males are slightly overrepresented, with no influence of neuter status (Kohn et al., 2006).

IMHA, Immune-mediated hemolytic anemia.

Common clinical signs of IMHA are listed in Box 104-3. The duration of clinical signs before presentation to the veterinary hospital is typically short in both dogs and cats, with a median of 4 days. Seasonal increases in diagnosis of IMHA have been reported, although the findings are not consistent among studies. The majority of reports suggest an increased frequency of IMHA during the warmer months of the year.

#### Diagnosis

Diagnosis of IMHA relies on identifying abnormalities consistent with hemolytic anemia on a complete blood count (CBC), serum biochemistry panel, and urinalysis (Box 104-4) followed by identification of antibodies directed against the RBC membrane. Further diagnostic testing is then directed at establishing whether a secondary underlying cause for IMHA can be identified.

The first requirement for making a diagnosis of IMHA is the presence of anemia. The anemia is typically moderate to marked (median hematocrit of 13%) and is usually regenerative, although in approximately 30% of dogs and more than 50% of cats the anemia is nonregenerative. Reasons for nonregenerative anemia in IMHA include an acute onset and presentation before the bone marrow has had time to respond (typically takes 3 to 5 days for maximal regenerative response) and the presence of antibodies directed against bone marrow precursors. In the latter situation, reticulocytes are destroyed before they enter the peripheral circulation. In the absence of a regenerative response, a rapid fall in the hematocrit with little change in the serum total protein or

- Increased alkaline phosphatase

CBC, Complete blood cell count; IMHA, immune-mediated hemolytic anemia.

albumin concentration should be considered suspicious for hemolysis. In anemia caused by decreased RBC production from the bone marrow, the hematocrit should not decrease by more than approximately 1% per day, whereas in blood loss anemia the drop in the hematocrit is usually accompanied by a concurrent decrease in the total protein or albumin (Table 104-1).

Most dogs with IMHA also have an inflammatory leukogram, often with a shift toward immature cells; thrombocytopenia; and abnormalities of the coagulation system, including prolongation of both the activated partial thromboplastin time (aPTT) and prothrombin time, elevations in D-dimer and fibrinogen degradation products, decreased antithrombin, and increased fibrinogen. Reasons for thrombocytopenia include the presence of antibodies directed against platelets as well as RBCs (Evans syndrome), disseminated intravascular coagulation, or sequestration in the spleen.

Identification of autoagglutination or spherocytosis (2+ or more) on a blood smear is considered definitive evidence of antibody-mediated RBC hemolysis (Fig. 104-3). Autoagglutination is detected by macroscopic or microscopic examination of the blood smear and is generally considered diagnostic for IMHA. Agglutination must be distinguished from rouleaux formation (see Chapter 83).

Spherocytes are formed by partial removal of antibody-coated RBC membranes by macrophages (see Fig. 104-2). This results in a loss of the normal discoid shape, decreased size, and loss of central pallor. Spherocytes are more rigid and less deformable than normal RBCs and are removed when they pass through the spleen. Spherocytes are readily identified in the dog but difficult to recognize in cats because of the lack of significant central pallor in their normal RBCs.

### TABLE 104-1

### Expected Changes on the CBC in Different Causes of Anemia

TYPES	RATE OF DECREASE OF HEMATOCRIT	RETICULOCYTE COUNT	SERUM PROTEINS	EVIDENCE OF INFLAMMATION ON CBC	THROMBOCYTOPENIA
Hemolytic anemia	Fast Slow	High	No change	Yes	Yes (mild to severe)
Nonregenerative anemia Blood loss anemia	Fast	Low High	No change Decreased	No No	Depends on cause Yes (mild only)

CBC, Complete blood cell count.

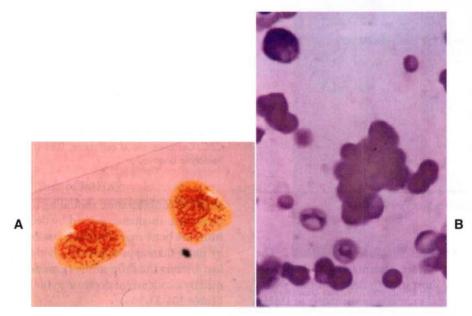

FIG 104-3
Blood smear showing gross (A) and microscopic (B) agglutination. Note the three-dimensional clustering of red blood cells on the microscopic view.

Spherocytes are considered a hallmark morphologic change in IMHA, and when present in sufficient numbers (2+ or greater) may be regarded as diagnostic for IMHA in dogs. Of note, low numbers of spherocytes (1+) may be observed on a blood smear when damage to the RBC is nonimmune (e.g., zinc toxicosis, hypophosphatemia, oxidative damage, rickettsial diseases, neoplasia, microangiopathic anemia). Techniques for quantitation of spherocyte numbers are typically semiquantitative (Table 104-2). In retrospective studies approximately 90% of dogs with IMHA have spherocytes present on the blood smear; however, low numbers may be present in dogs with per-acute hemolysis. Ghost cells are remnant membranes of RBCs that have undergone intravascular lysis. Lysis can be induced by immune- or nonimmune-mediated mechanisms, so ghost cells are not diagnostic for IMHA.

The direct Coombs test with polyvalent antisera is the most commonly used diagnostic test for IMHA when autoagglutination or spherocytosis is not present; however, this test is neither particularly sensitive nor specific for confirm-

ing a diagnosis of IMHA. A positive Coombs test indicates that antibody, complement, or both are on the surface of the RBC but does not mean that the antibody is directed specifically against the RBC membrane or that the antibody is causing hemolysis. Approximately 60% to 80% of canine patients with IMHA have a positive Coombs test. Conversely, a positive Coombs test can occur in a variety of other inflammatory diseases causing false-positive results (see Chapter 102).

A search for secondary causes of IMHA should always be undertaken in a dog or cat with IMHA because the underlying disease may influence management strategy and prognosis. Potential secondary causes of IMHA are listed in Table 104-3. The diagnostic approach to ruling out secondary IMHA includes a thorough history of drug, vaccine, and toxin exposure; detailed physical examination, including rectal, ophthalmologic, and neurologic examinations; tests for specific infectious diseases; investigation into causes of chronic antigenic stimulation; and a search for evidence of neoplasia. Diagnostic tests to consider in addition to a CBC, biochemical panel, and urinalysis include urine culture,

abdominal and thoracic radiographs, abdominal ultrasound, bone marrow cytology or histopathology (or both if the anemia is nonregenerative), and appropriate titers for infectious diseases.

Results of bone marrow evaluation in dogs with nonregenerative primary IMHA typically reveal erythroid hyperplasia with a low mycloid/erythroid (M/E) ratio, although maturation arrest at the rubricyte or metarubricyte stage may also be observed. Some dogs initially suspected to have IMHA based on the presence of spherocytosis or a positive Coombs test have pure red cell aplasia. Myelofibrosis can be detected on bone marrow core biopsy in many dogs with nonregenerative IMHA. In dogs with myelofibrosis, collection of adequate bone marrow elements by aspiration cytology is difficult. Myelofibrosis is likely a secondary response to bone marrow injury and may resolve in dogs that respond to treatment.

In dogs without the classic morphologic changes of immune-mediated hemolysis (regenerative anemia, autoagglutination, spherocytes), confirming a diagnosis of IMHA may be challenging. A positive direct Coombs test should be

TABLE 104-2

Semiquantitative Scoring System for Numbers of Spherocytes on a Slide

APPROXIMATE NUMBER OF					
ASSIGNED SCORE					
1+					
2+					
3+					

interpreted cautiously in such cases because false-positive results may occur. The logical approach is to rule out other causes of anemia (see Chapter 83) and use the Coombs test and other indications of hemolysis as supporting evidence of IMHA if no other cause of anemia is identified.

#### **Treatment**

Choosing an appropriate treatment regimen for dogs with IMHA is a frustrating task for the clinician (Fig. 104-4). Lack of prospective studies of treatment efficacy, the poor prognosis associated with the disease, and the high cost of treatment and supportive care are some reasons for this frustration. In addition, serious complications such as pulmonary thromboembolism and disseminated intravascular coagulation are relatively common occurrences but hard to predict in individual patients. Because of the lack of prospective studies of treatment efficacy, recommendations for approach to treatment in dogs with IMHA are based primarily on clinical experience rather than objective data.

When planning the management of a dog with IMHA, the goals of treatment should include prevention of RBC hemolysis, alleviation of tissue hypoxia by blood transfusion, prevention of thromboembolism, and provision of supportive care.

**Prevention of hemolysis.** Immunosuppressive drugs are the key for prevention of RBC hemolysis in dogs with IMHA. The mechanism of action and adverse effects associated with the use of various immunosuppressive drugs recommended for use in dogs and cats with autoimmune disorders are discussed in Chapter 103.

High doses of glucocorticoids are the first line of treatment for controlling RBC hemolysis in dogs with IMHA. In dogs that can tolerate oral medication, prednisone at a dose of 1 to 2 mg/kg PO q12h is the corticosteroid of choice. The

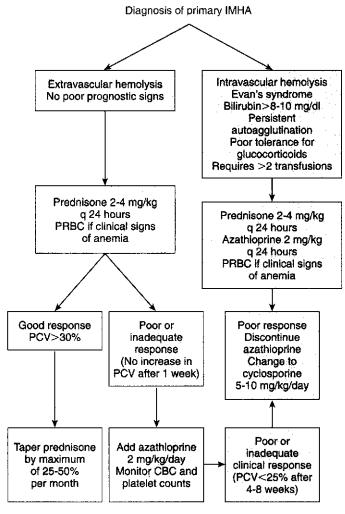

FIG 104-4 Flow diagram showing approach to treatment in dogs with immune-mediated hemolytic anemia.

higher end of the dose range is recommended as a starting dose except in large breed dogs (more than 30 kg). Most dogs that will respond to prednisone show some improvement within the first 7 days of treatment, but the full therapeutic effect may not be evident until 2 to 4 weeks after initiation of treatment. Once the hematocrit increases above 30%, the dose may be decreased to 1 mg/kg q12h. Subsequently the dose is tapered by a maximal rate of 25% to 50% per month over a 3- to 6-month period depending on the hematocrit and severity of side-effects. If after 6 months the prednisone dose is tapered to a low every-other-day dose and the disease is in remission, discontinuation of medication should be attempted. A CBC and reticulocyte count should be performed before and 2 weeks after any change in immunosuppressive therapy. Indications of resolution of the hemolytic process in addition to improvement in the anemia include a negative Coombs test (if it was initially positive), resolution of autoagglutination, resolution of spherocytosis, normalization of the reticulocyte count, and improvement in the leukogram with resolution of inflammation.

Most cats with IMHA respond to prednisone alone and rarely have problems with the adverse effects of glucocorticoids. In the occasional cat that needs an additional immunosuppressive drug to treat IMHA, treatment with chlorambucil, cyclophosphamide, or cyclosporine should be considered. Not enough published information exists on which to base a recommendation of one drug over another. Azathioprine is not recommended in cats because of the risk of unacceptable side effects (see Chapter 103).

Some dogs with IMHA do not respond to glucocorticoid treatment alone, or the dose of prednisone cannot be tapered enough for adequate resolution of adverse effects of glucocorticoids. In those cases an additional cytotoxic drug should be added to the treatment regimen. One common clinical dilemma is whether all dogs with IMHA should be treated with an additional immunosuppressive drug early in the course of treatment, or whether waiting and identifying which dogs are likely to benefit is more appropriate. The advantage of starting another immunosuppressive drug early is that no time is lost waiting to identify which patients will respond to glucocorticoid treatment alone. The disadvantages include the risk of adverse effects and the lack of evidence of benefit in all cases. In studies at Purdue University approximately 20% of dogs with IMHA are ultimately treated with another immunosuppressive drug in addition to prednisone. Use of more than one additional immunosuppressive drug at any one time is not recommended because of the potential for severe immunosuppression and resultant susceptibility to infection.

The choice for additional immunosuppression varies among clinicians. Viable options include azathioprine, cyclophosphamide, and cyclosporine. In our hospital azathioprine is added early in the course of treatment in dogs that do not respond within 5 to 7 days of initiating glucocorticoid treatment and in dogs that require more than two transfusions of blood or a hemoglobin-based oxygen carrier. Azathioprine is also used in dogs known to have a poor tolerance of the side-effects of glucocorticoids (e.g., large-breed dogs) and in those with other poor prognostic indicators (e.g., intravascular hemolysis, serum bilirubin level greater than 8 to 10 mg/dL, persistent autoagglutination, Evans syndrome). The recommended starting dose for azathioprine in dogs is 2 mg/kg q24h. Once control of IMHA is attained, azathioprine should be continued at the same dosage while the dose of prednisone is tapered. Azathioprine is then tapered slowly once the prednisone has been discontinued. If a relapse occurs, life-long prednisone, azathioprine, or both are recommended at the lowest dose that controls RBC hemolysis. CBC and hepatic enzymes should be monitored biweekly initially, then every 1 to 2 months in dogs treated with azathioprine.

Historically, cyclophosphamide has been recommended for treatment of dogs with severe acute IMHA. However, evidence is mounting that addition of cyclophosphamide does not improve outcome and that its use may be associated with a poorer prognosis in dogs with IMHA. Cyclophosphamide is usually reserved for dogs that do not tolerate oral drugs because of persistent vomiting or gastrointestinal

disease (cyclophosphamide can be administered intravenously; see Table 103-3) or because of expense (cyclosporine).

Cyclosporine is currently the preferred immunosuppressive drug for dogs that do not respond to prednisone and azathioprine. The cost of cyclosporine is a major deterrent to its use, and its potent immunosuppressive effects mandate frequent monitoring of the patient for infections. Interestingly, in a prospective study of 38 dogs with IMHA, no difference in survival was found between dogs treated with prednisone alone and those treated with prednisone and cyclosporine; however, most of the deaths occurred early before the effects of cyclosporine had likely reached maximal effect (Husbands et al., 2004). Cyclosporine appears to be relatively safe in dogs with IMHA, and clinical experience suggests that it is useful and effective in the treatment of dogs with IMHA that do not respond to prednisone or azathioprine. (For dosing and monitoring recommendations for cyclosporine, see Tables 103-3 and 103-4.)

Human intravenous immunoglobulin (hIVIG) has had beneficial effects in dogs with IMHA that are refractory to other therapy. Administration of hIVIG may be most useful early in the treatment of acute severe IMHA to control acute hemolysis while waiting for other immunosuppressive drugs to become effective. Cost is a deterrent to using hIVIG, and multiple treatments are not currently recommended because of the potential for sensitization to this human product, although dogs have been treated twice with no obvious deleterious effects.

**Blood transfusion.** Most dogs and cats with acute, severe IMHA need oxygen-carrying support while waiting for the anemia to improve. Oxygen supplementation alone is of limited benefit. The need for blood transfusion depends on the severity of anemia, the rapidity of onset and chronicity of the anemia, and the presence and severity of concur-

rent disease such as pulmonary thromboembolism and gastrointestinal blood loss. No specific hematocrit level is necessary as a transfusion trigger; rather, each patient should be considered individually. In general, transfusion should be considered when the dog has problems with tachycardia, tachypnea, anorexia, lethargy, or weakness while at rest. Most dogs with acute IMHA and a hematocrit level less than 15% have some degree of tissue hypoxia and will benefit from a blood transfusion regardless of how the dog appears to be doing clinically. Severe tissue hypoxia likely exacerbates the complications of IMHA, such as hepatic necrosis, disseminated intravascular coagulation, and thromboembolism.

Options for providing oxygen-carrying support include transfusion of packed RBCs (pRBCs) or a hemoglobin-based oxygen carrier (HBOC) such as Oxyglobin (Biopurc, Cambridge, Mass.). Transfusion of whole blood is acceptable but less ideal because the plasma component is not necessary and may increase the risk of transfusion reactions. Disadvantages of HBOC include the short duration of effect (74 to 82 hours at the 30-mL/kg dose) and the discoloration of serum caused by the transfused hemoglobin, which interferes with many analytes on the biochemical profile (see Table 104-4 for a list of valid analytes). In dogs with hematocrit levels less than 8%, HBOC alone will not provide adequate oxygencarrying support, and additional support with pRBCs or whole blood is recommended. (See Chapter 83 for more information about blood transfusions and HBOCs.)

**Prevention of thromboembolism.** Thromboembolic events (TEs) are a common complication and important cause of death in dogs with IMHA. TEs have been documented at necropsy in 29% to 80% of dogs with IMHA. Intravenous catheter placement and identification of certain laboratory abnormalities, such as thrombocytopenia, hyper-

bilirubinemia, leukocytosis, and hypoalbuminemia, are associated with an increased risk of TE in dogs with IMHA. The pathogenesis of thrombus formation is unknown, and effective regimens for prophylaxis have not been established. Treatment options currently used for prevention of thromboembolic complications include heparin, lowmolecular-weight heparin, aspirin, or a combination of these modalities. The recommended starting dose for heparin in patients with IMHA is 200 to 300 U/kg q6h, and the dose is adjusted by measuring anti-Xa activity (0.35 to 0.7 U/mL) or, less ideally, monitoring the aPTT with the aim to prolong aPTT by 25% to 50% of baseline. (For a discussion of the use of low-molecular-weight heparin, see Chapter 12.) Low-dose aspirin (0.5 mg/kg q24h) has also been used to prevent thromboembolic complications in dogs with IMHA. Weinkle et al (2005) reported that dogs treated with a protocol that included prednisone, azathioprine, and lowdose aspirin had the longest survival times. (See Chapter 12 for more information on treatment and prevention of thromboembolism.)

**Supportive care.** Aggressive supportive care is critical to a good outcome in dogs with IMHA. Identification and treatment of underlying disease, detection of complications associated with immunosuppressive drug therapy, and good nursing care positively influence outcome. In addition to transfusion, fluid therapy should be administered in dogs with evidence of dehydration to improve tissue perfusion. In dehydrated dogs fluid therapy will decrease the measured hematocrit, but this does not change the total RBC mass. Fluid therapy should not be withheld because of fear of exacerbating anemia. In reality, fluid therapy reveals the true severity of the anemia.

Careful investigation and treatment of underlying disease in dogs with IMHA are important. Immunosuppressive therapy is usually still necessary in dogs with secondary IMHA. However, the duration of immunosuppression may be shorter if an underlying cause can be identified and treated. If an infectious disease is identified, addition of cytotoxic drugs (e.g., azathioprine, cyclophosphamide, chlorambucil) should be avoided.

Complications of immunosuppressive drug therapy include bone marrow suppression, infection, gastrointestinal ulceration, and iatrogenic hyperadrenocorticism. Gastrointestinal hemorrhage can contribute to anemia in dogs with IMHA, either from the gastrointestinal effects of high doses of glucocorticoids or concurrent thrombocytopenia, vasculitis, ischemia, or other concurrent disease. Recognition of occult gastrointestinal hemorrhage is important because the resulting anemia may be confused with a failure to respond to treatment for IMHA (see Chapter 83). Drugs used for treatment of gastrointestinal hemorrhage include gastrointestinal protectants such as sucralfate and H<sub>2</sub> blockers (e.g., famotidine).

### **Prognosis**

Reported mortality rates of dogs with primary IMHA range from 26% to 70%, with thromboembolism being the cause of death in at least 30% to 60% of cases. Other common causes of death include infection, disseminated intravascular coagulation, and failure to control anemia. Factors that clinically appear to confer a good prognosis in dogs with IMHA include a rapid response to treatment with glucocorticoids, ability to maintain the packed cell volume at greater than 25% to 30% with glucocorticoids alone, and identification of a treatable secondary cause. The prognosis is more guarded in dogs that require multiple drugs to control the disease and those with persistent autoagglutination, an elevated bilirubin concentration, marked thrombocytopenia, and severe leukocytosis. If a major TE does occur in a dog with IMHA, particularly if blood supply to a major organ is disrupted, the long-term prognosis is typically very poor. Contrary to popular opinion the prognosis in Cocker Spaniels with IMHA does not differ from that of other breeds. In approximately 60% of dogs with IMHA, medications can ultimately be discontinued after a slow tapering of the dose. The remaining dogs require long-term immunosuppressive therapy.

# **PURE RED CELL APLASIA**

Pure red cell aplasia (PRCA) is a rare disorder characterized by severe, nonregenerative anemia with marked depletion or absence of erythroid precursors in the bone marrow. In some cases evidence of concurrent peripheral RBC hemolysis is present, based on the presence of spherocytes and a positive antiglobulin test. Other cell lines are usually normal. The erythroid aplasia in PRCA is in contrast to the nonregenerative form of IMHA, in which there is erythroid hyperplasia or sometimes maturation arrest of the erythroid maturation sequence. PRCA is likely one end of the spectrum of IMHA, with acute peripheral hemolysis at the other end of this spectrum (Table 104-5). The affinity of circulating antibody for different erythroid precursors likely influences the level at which damage occurs in the bone marrow. As with IMHA, both primary and secondary forms of PRCA are recognized. Secondary causes of PRCA include treatment with recombinant human erythropoietin and parvovirus infection in dogs. Infection with feline leukemia virus subtype C is a cause of PRCA in cats.

Dogs with PRCA have a similar signalment and present with similar clinical signs as dogs with IMHA. Cats with primary PRCA are typically younger than dogs, with an age range of 8 months to 3 years. Dogs and cats with PRCA have severe, nonregenerative anemia; the platelet count and leukogram are typically normal. In contrast to IMHA the biochemical panel and urinalysis are also usually unremarkable, with no evidence of peripheral hemolysis. Low numbers of spherocytes are sometimes present in dogs with PRCA. The Coombs test is usually negative.

Diagnosis of PRCA is made by evaluation of a bone marrow aspirate and bone marrow core biopsy. In dogs with PRCA, erythroid precursors are rare or absent and the M/E ratio is quite high (more than 99:1). In contrast to dogs with nonregenerative IMHA, severe myelofibrosis is rare.

# Comparison of Regenerative IMHA, Nonregenerative IMHA, and PRCA in Dogs

	RATE OF DECREASE OF HEMATOCRIT	RETICULOCYTE COUNT	(% POSITIVE)	EVIDENCE OF INFLAMMATION ON CBC	THROMBOCYTOPENIA	BONE MARROW EVALUATION
Regenerative hemolytic anemia	Fast	High	60%-80%	Severe inflammatory leukogram in most dogs	Yes (60%)	Erythroid hyperplasia, myelofibrosis some cases
Nonregenerative anemia	Variable	Low	57%	Mild inflammation in 50% of dogs only	Rare	Erythroid hyperplasia, myelofibrosis common
PRCA	Slow	Low	Rarely positive	No .	No	Erythroid hypoplasia, myelofibrosis uncommon

IMHA, Immune-mediated hemolytic anemia; PRCA, pure red cell aplasia; CBC, complete blood cell count.

Treatment of PRCA is similar to IMHA. Most dogs with PRCA respond to prednisone alone. Azathioprine or cyclophosphamide may be necessary for a complete response in some dogs or may be added to allow tapering of the prednisone dose in dogs with unacceptable side effects of corticosteroid therapy. The time taken to achieve complete remission (2 to 6 months) is longer in dogs with PRCA compared with IMHA, and it is sometimes difficult to judge whether a particular protocol is failing or whether inadequate time has been allowed for the bone marrow to respond to treatment and begin to produce and release RBCs into the circulation. Sequential bone marrow evaluations should ideally be used to determine when to change the treatment protocol. A repeat bone marrow aspirate should be considered after 2 months of treatment if no improvement in the anemia is observed. Repeated transfusion of pRBCs or whole blood is necessary while waiting for a response to treatment. Dogs with PRCA do not typically have evidence of systemic inflammation and are not at increased risk of TEs, so anticoagulant treatment is not indicated. The prognosis for PRCA in dogs is better than for IMHA, with mortality rates being less than 20%. The major cause of death is euthanasia because of the high cost of supportive care. Response to treatment and mortality rates in cats with PRCA appears to be similar to dogs, although cats respond to treatment more quickly (1.5 to 5 weeks). See Chapter 83 for additional information on PRCA.

# IMMUNE-MEDIATED THROMBOCYTOPENIA

# Classification/Etiology

Immune-mediated thrombocytopenia (idiopathic thrombocytopenic purpura [ITP]) is a clinical syndrome in which thrombocytopenia results from antibody-mediated accelerated destruction of platelets. Immune-mediated thrombocytopenia is diagnosed in approximately 3% to 18% of cases of thrombocytopenia and is the most common cause of severe thrombocytopenia in dogs (Table 104-6). Immunemediated thrombocytopenia is classified as primary or secondary. In primary thrombocytopenia (true autoimmune thrombocytopenia) antibodies are directed against platelet antigens, presumably because of an underlying defect in immune regulation. Antibodies directed against platelet membrane glycoproteins IIb and IIIa have been identified as target antigens in dogs, although others may be important as well. Primary ITP is a common cause of thrombocytopenia in dogs but is rare in cats. Environmental factors suspected to precipitate ITP in some cases include stress, changes

in environmental temperature, hormonal changes, vaccination, and surgery.

In secondary ITP antibody-mediated platelet destruction occurs as a result of an underlying inflammatory or neoplastic disease. Causes of secondary immune-mediated thrombocytopenia in dogs and cats are listed in Table 104-6. Immune-mediated thrombocytopenia may also be a component of SLE and may occur in conjunction with IMHA (Evans syndrome).

#### **Clinical Features**

Dogs with primary ITP range in age from 8 months to 15 years, with a median age of 6 years. Females are affected twice as often as males, and although any breed can be affected the Cocker Spaniel, Poodle (all varieties), German Shepherd dog, and Old English Sheepdog are overrepresented. Common findings include sudden onset of petechial and ecchymotic hemorrhages in the skin and mucous membranes, epistaxis, hematochezia, hematemesis, easy bruising, lethargy, weakness, and anorexia. Additional findings on physical examination may include melena, hematuria, hyphema, retinal

the oral mucous membranes.

hemorrhage, and pale mucous membranes (Fig. 104-5). Neurologic signs and blindness may occur from bleeding into the CNS and eye, respectively. Because rapid-onset, lifethreatening hemorrhage is rare in dogs with ITP, anemia is usually initially mild and slowly progressive unless IMHA is concurrent. As affected dogs become moderately to severely anemic, lethargy, exercise intolerance, tachypnea, tachycardia, and a heart murmur may be evident. In some dogs with ITP clinical signs of hemorrhage are not present and thrombocytopenia is an incidental finding on bloodwork performed for another reason. The platelets present in dogs with ITP are often larger and may be hemostatically more competent, which may explain why not all dogs with severe ITP bleed spontaneously. However, platelet dysfunction (impaired aggregation) has been documented in normal canine platelets after incubation with serum from dogs with ITP, suggesting that antibodies or other factors in the serum impair platelet function in some dogs with ITP. Certain breeds, such as the Cavalier King Charles Spaniel and the Greyhound, are known to have lower platelet counts than other dogs and do not appear to have increased risk of bleeding.

Photographs of three dogs with immune-modulated thrombocytopenia and ecchymotic hemorrhage. **A,** Note the ecchymotic hemorrhages in the skin of the abdomen. **B,** Note the hemorrhage into the anterior chamber of the eye. **C,** Note petechial hemorrhage in

#### Diagnosis

Because immune-mediated thrombocytopenia can occur in association with many other disorders (see Table 104-6 and Chapter 87), a diagnosis of primary ITP can only be made by ruling out other causes of thrombocytopenia. Dogs with ITP usually have severe thrombocytopenia (less than 50,000 platelets per  $\mu L$ ), and platelet fragments (microthrombocytosis) may be present on the blood smear. Platelet fragments are reported to be a specific but insensitive indication of ITP. Platelet fragments may be present as a result of immune injury or because larger platelets are preferentially removed from circulation. The presence of enlarged platelets on the blood smear supports the presence of increased bone marrow production of platelets, but this is not specific for a regenerative response because bone marrow injury may also cause enlarged platelets.

Diagnosis of ITP is confirmed by ruling out other cause of severe thrombocytopenia (see Table 104-6 and Chapter 87). Spurious thrombocytopenia from platelet clumping, other technical problems, and breed-related thrombocytopenia should be considered in dogs that do not have clinical signs of bleeding. In dogs with thrombocytopenia, examination of a bone marrow aspirate should be performed early in the diagnostic workup to rule out disorders such as myelophthisis, neoplasia, megakaryocytic aplasia, and aplastic anemia (see Chapter 87). Bone marrow aspiration and biopsy can be safely performed even in severely thrombocytopenic dogs because hemorrhage can be controlled with local pressure. In most dogs with ITP normal to increased numbers of megakaryocytes are present on a bone marrow aspirate. Decreased numbers of megakaryocytes in the bone marrow have been associated with a poorer prognosis in dogs with ITP. Megakaryocytic aplasia is a rare disorder in which aplasia of the megakaryocytic cell line results in severe thrombocytopenia. This disease may be a primary immunemediated disease or occur secondary to infections such as Ehrlichia canis and Borrelia burgdorferi. Immune-mediated megakaryocytic aplasia has a poor prognosis unless it is caused by underlying infection.

The presence of a positive assay for platelet-bound antibody (see Chapter 102) is highly sensitive but not specific for a diagnosis of ITP. A diagnosis of ITP is unlikely if the test result is negative. A positive test result is not specific for ITP because immune-mediated mechanisms are responsible for many causes of thrombocytopenia in dogs, including Babesia canis, Dirofilaria immitis, E. canis, myelodysplasia, SLE, drug reactions to trimethoprim sulfadiazine, and various forms of neoplasia.

#### **Treatment**

**Immunosuppression.** Immunosuppressive drugs are the key to treating ITP. High doses of corticosteroids block macrophage-mediated destruction of platelets and are the first line of treatment in dogs with ITP. Prednisone at a dose of 1 to 2 mg/kg q12h is the corticosteroid of choice. Treatment with one dose of vincristine (0.02 mg/kg IV) should also be considered early in the course of treatment for dogs

with severe ITP (platelet count less than 15,000/ $\mu$ L). Dogs treated with vincristine have a more rapid increase in platelet count and shortened duration of hospitalization compared with untreated dogs. Most dogs with ITP have a rapid response to prednisone or prednisone combined with vincristine, and in most cases the platelet count increases to more than 50,000 per  $\mu$ L within 7 days of treatment. Once the platelet count is in the reference range, the dose of prednisone can be slowly tapered. Because of the risk of relapse the dose should not be tapered more rapidly than 25% to 50% per month over a 3- to 6-month period. If after 6 months the prednisone dose has been tapered to a low everyother-day dose and the disease is in remission, discontinuation of medication should be attempted.

Azathioprine therapy should be considered in dogs that do not have an adequate response to prednisone alone (platelet count less than 100,00 per μL) or in whom the dose of prednisone cannot be tapered low enough to manage the adverse effects of glucocorticoids. The dose of azathioprine is 2 mg/kg q24h. If azathioprine is tolerated the dose should be continued while the dose of prednisone is tapered. Azathioprine is tapered slowly once prednisone has been discontinued. If a relapse occurs, life-long prednisone and/or azathioprine should be continued at the lowest dose that maintains the platelet count within the reference range. A platelet count should be performed before and 2 weeks after any change in immunosuppressive therapy. In some dogs with ITP maintaining the platelet count within the reference range is difficult without severe glucocorticoid side effects. In these dogs maintaining the platelet count greater than 100,000 per µL is acceptable because this level of thrombocytopenia is usually not associated with increased risk of bleeding. Other drugs that can be considered in dogs with refractory ITP include danazol, cyclophosphamide, cyclosporine, and hIVIG (see Chapter 103). None of these drugs has been extensively evaluated in dogs with ITP, but they may be useful in treatment of refractory cases. Splenectomy may also be indicated in dogs with ITP that have chronic relapses after tapering prednisone and azathioprine therapy (see Chapter 103).

**Supportive care.** Supportive care for dogs with ITP is critical to a positive outcome. Cage rest and exercise restriction to prevent trauma, eliminating all except absolutely necessary diagnostic procedures, and minimizing other invasive procedures will decrease risk of hemorrhage. A balance between appropriate monitoring and minimizing venipuncture is important. Careful monitoring for clinically significant changes that could be from new hemorrhage, especially involving the nervous system or eye, should be performed frequently. Blood transfusions should be administered to actively bleeding patients and those with clinically significant anemia. The only blood products that provide clinically significant platelet activity are fresh whole blood, platelet-rich plasma, and platelet concentrate. Fresh whole blood often provides enough platelets to stop an episode of clinical bleeding, although an increase in the platelet count is not expected. The beneficial effect of a fresh whole blood transfusion typically lasts approximately 48 hours. Blood typing of the donor and cross-matching of the recipient should be performed as described in Chapter 83. Platelet-rich plasma or platelet concentrate are the ideal products for administration to actively bleeding patients before they become anemic. However, availability and cost limit their use in most hospitals. Administration of gastric protectants such as H<sub>2</sub> blockers (e.g., famotidine), or proton pump inhibitors (e.g., omeprazole) and sucralfate may help prevent adverse effects of glucocorticoid treatment on the gastrointestinal tract, especially in dogs with gastrointestinal bleeding.

Treatment of Evans syndrome (concurrent IMHA and ITP) is managed as described for IMHA. However, azathioprine should be administered in addition to glucocorticoids. One dose of vincristine should be considered if the thrombocytopenia is severe (platelet count less than 15,000/µL). Whole blood transfusion rather than pRBCs should be administered in dogs with Evans syndrome that are actively bleeding. Dogs with Evans syndrome should not be treated with heparin because of the risk of hemorrhage.

# **Prognosis**

The prognosis for dogs with ITP is good to guarded, with a mortality rate of approximately 30%. Most dogs respond to medical treatment, although relapse is common, occurring in as many as 50% of dogs. Dogs with megakaryocytic hypoplasia have a more guarded prognosis. The prognosis for dogs with concurrent IMHA and ITP is poor, with a reported mortality rate of 80% or higher. See Chapter 87 for more information on this topic.

# IMMUNE-MEDIATED NEUTROPENIA

# **Etiology**

Autoimmune causes of neutropenia are rare in dogs and cats, accounting for approximately 0.4% of cases of neutropenia (see Chapter 85). In immune-mediated neutropenia (also called *idiopathic neutropenia* or *steroid-responsive neutropenia*), serum antineutrophil IgG antibodies can be detected by flow cytometry in the serum (Weiss, 2007). Antibody and complement directed against myeloid cells within the bone marrow have also been identified. In most cases of suspected immune-mediated neutropenia, the diagnosis is one of

exclusion because commercial testing for antineutrophil antibodies is not readily available. As with other immune-mediated disorders, immune-mediated neutropenia may be a primary disorder or occur secondary to drug therapy, neoplasia, or other immune-mediated disorder (Table 104-7). The majority of canine cases reported in the literature have been primary. Only one case of suspected immune-mediated neutropenia in a cat has been reported.

### **Clinical Features**

In a retrospective report of 11 dogs with suspected immunemediated neutropenia, a variety of breeds were represented and eight of 11 cases were female (Brown et al., 2006). Affected dogs were typically young, with a median age of 4 years. Clinical signs included fever, lameness, anorexia, and lethargy and the duration of clinical signs ranged from 3 to 180 days. Common abnormalities detected on CBC, serum biochemistry panel, and urinalysis included severe neutropenia (median 110 cells/µL), mild anemia, hyperglobulinemia, and increased alkaline phosphatase level. Further evaluation of affected dogs with bacterial culture, infectious disease serology, and imaging did not reveal a cause for the neutropenia. Bone marrow cytology and histopathology revealed myeloid hyperplasia in the majority of affected dogs and myeloid hypoplasia in two dogs. All dogs had resolution of neutropenia 1 to 18 days after initiation of treatment with glucocorticoids.

## **Diagnosis and Treatment**

A clinical diagnosis of immune-mediated neutropenia is made by exclusion of other causes of neutropenia and by rapid response to treatment with glucocorticoids at an initial dose of 2 to 4 mg/kg/day of prednisone. Gradual withdrawal of corticosteroid therapy is possible without relapse in most dogs; however, some dogs require long-term immunosuppression. Routine monitoring is important to detect recurrence of neutropenia and monitor for infection. See Chapter 85 for more information on this topic.

### IDIOPATHIC APLASTIC ANEMIA

Aplastic anemia (aplastic pancytopenia) is characterized by cytopenia of all three marrow-derived cell lines and a hypo-

Causes of Severe Neutropenia in Dogs and Cats

ETIOLOGY	EXAMPLE
Infection	Parvovirus, ehrlichiosis, bacterial sepsis
Drug associated	Chemotherapeutic agents, cytotoxic drugs, vincristine, estrogens, trimethoprim/ sulfadiazine, phenobarbital
Bone marrow suppression	Aplastic anemia, Ehrlichia canis infection, myelodysplasia, myeloid hypoplasia, leukemia
Immune mediated	Primary immune-mediated neutropenia

cellular/acellular bone marrow, with the marrow elements replaced by adipose tissue. Reported causes of aplastic anemia in dogs and cats include infectious agents (Ehrlichia spp, parvovirus, sepsis, feline leukemia virus, feline immunodeficiency virus) hormonal (estrogens), drug associated, radiation associated, and idiopathic. By definition the cause of idiopathic aplastic anemia is unknown; however, evidence in humans suggests that it may be immune mediated. Although an immune-mediated cause has not been established for idiopathic aplastic anemia in dogs and cats, trial therapy with prednisone, cyclosporine, or both may be considered once other causes of aplastic anemia, most notably infectious agents, have been ruled out. An immune-mediated cause for idiopathic anemia is currently difficult to prove but should be suspected in cases that respond to immunosuppressive therapy. The prognosis for idiopathic aplastic anemia is generally guarded to poor. See Chapter 86 for more information on this topic.

### **POLYARTHRITIS**

# Etiology

Immune-mediated polyarthritis is defined as chronic synovial inflammation in two or more joints, failure to isolate an organism from the joint fluid, and a positive response to immunosuppressive therapy. Immune-mediated polyarthritis is primarily a type III immune complex hypersensitivity disorder (see Chapter 101) in which immune complexes are deposited in the synovial membrane, initiating local

inflammation and release of proteolytic enzymes and cytokines, with resultant cartilage degeneration. In rheumatoid arthritis type IV hypersensitivity may also be present with perivascular infiltration of mononuclear cells into the synovial membrane (see Chapter 101). Immune-mediated polyarthritis may be classified as primary or secondary. In secondary polyarthritis immune complex deposition in the joints is secondary to an underlying inflammatory or neoplastic disease. Infectious agents are an important cause of secondary polyarthritis. Chronic bacterial infections may cause secondary or reactive polyarthritis, and Anaplasma spp., Ehrlichia spp., and Borrelia burgdorferi also cause polyarthritis, although they cannot usually be visualized in or cultured from affected joints. Administration of live calicivirus vaccine also causes transient polyarthritis in cats.

In primary immune-mediated polyarthritis no underlying cause of polyarthritis can be identified. This form of polyarthritis is believed to be attributable to an underlying immune system dysfunction or imbalance (true autoimmunity; see Chapter 101). The most commonly recognized forms of polyarthritis in the dog and cat are idiopathic nonerosive polyarthritis, reactive nonerosive polyarthritis secondary to underlying inflammatory disease (gastrointestinal disease, chronic inflammation, neoplasia, or infection), rheumatoid arthritis, and proliferative polyarthritis (Table 104-8). A number of breed-specific syndromes are recognized in dogs. A nonerosive polyarthritis is also a prominent feature of SLE. See Chapter 74 for a more detailed discussion of the various forms of polyarthritis.

TABLE 104-8

Forms of Polyarthritis Recognized in Dogs and Cats

SYNDROME	CLINICAL MANIFESTATIONS	BREED PREDISPOSITION
Idiopathic nonerosive	Small distal joints	Large-breed dogs, rarely cats
Secondary nonerosive	Similar to idiopathic but clinical signs of underlying disease also present	Any breed
Breed-specific idiopathic nonerosive	Similar to idiopathic but more severe and often concurrent meningeal inflammation	Akita, Weimaraner, Newfoundlands
Familial Sharpei fever	Recurrent fever, soft tissue swelling around affected joints, predisposition to systemic amyloidosis	Sharpei
Lymphoplasmacytic synovitis	No sign of systemic illness, cranial cruciate rupture, lymphocytes and plasma cells in synovial fluid	Rottweiler, Labrador Retrievers, Newfoundlands, Staffordshire Terriers
SLE	Multisystemic immune disease	German Shepherd dogs, rarely cats
Rheumatoid arthritis	Initially similar to nonerosive form but progresses to joint crepitus, laxity, luxation, and deformity of affected joints (carpi, hocks, phalanges)	Small and toy breeds
Erosive polyarthritis of greyhounds	Erosive changes in phalanges, carpi, hocks, elbow, stifles; lymphoplasmacytic inflammation in synovial fluid	Young Greyhounds
Feline chronic progressive polyarthritis	Erosive or proliferative changes in multiple joints	Young male cats infected with FeFSV or feline leukemia virus

# BOX 104-5

# Clinical Signs of Polyarthritis in Dogs and Cats

#### Dogs

- Palpable joint swelling
- Distension of joint capsule
- Shifting leg lameness
- Unwillingness to rise
- · Hesitant or "walking on eggshells" gait
- Joint pain
- Fever
- Anorexia
- Lethargy
- Cervical pain

#### Cats

- Palpable joint swelling
- Distension of joint capsule
- Joint pain
- Fever
- Anorexia
- Lethargy
- Generalized hyperesthesia
- Decreased activity/hiding

#### **Clinical Features**

The clinical hallmark of immune-mediated polyarthritis is the presence of nonseptic inflammation within the synovial membrane of two or more joints. Consequently the diagnosis is made by analysis of synovial fluid collected from joints suspected to be affected. Common clinical signs are listed in Box 104-5. In some cases neurologic disease is initially suspected because the animal is unable to ambulate; however, the neurologic examination in dogs with polyarthritis is normal. Many dogs and cats with polyarthritis have clinical signs of systemic illness, including fever, anorexia, and lethargy. In some cases joint pain and swelling may be mild or not clinically detected and fever is the only clinical sign. Polyarthritis is one of the most common causes of unexplained fever in dogs. Joint pain from polyarthritis may also cause cervical pain, and concurrent meningeal inflammation has been reported in dogs with polyarthritis (Webb et al., 2002). Polyarthritis should therefore be considered in any dog or cat presenting with cervical pain without neurologic deficits. Cats with polyarthritis may appear to have generalized hyperesthesia and resist handling. Cats may also present for decreased activity, and the owners often note that the animal has become withdrawn, often hiding in inaccessible locations. In the less-common erosive forms of polyarthritis, affected joints may become distorted or collapsed as the disease progresses, resulting in a severe gait abnormality. These changes are typically irreversible.

# **Diagnosis**

Diagnosis of immune-mediated polyarthritis is made by documentation of inflammation within the synovial fluid,

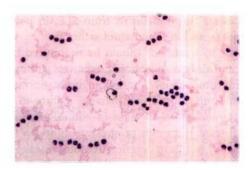

FIG 104-6
Direct smear of synovial fluid from a dog with idiopathic immune-mediated polyarthritis. Note the presence of increased numbers of nondegenerate neutrophils.

synovial membrane, or both (Fig. 104-6). Synovial fluid for cytologic evaluation and culture should be collected from at least three and preferably four joints. Synovial fluid should be collected from the more distal joints (carpus, tarsus, stifle) because these are the most commonly affected. The approach to joint fluid collection is discussed in Chapter 73. Joint fluid may be grossly turbid, with decreased viscosity and increased volume. Cytologic evaluation reveals neutrophilic inflammation with no evidence of sepsis. Fluid should always be collected for culture and sensitivity to rule out an occult infection (especially likely if the animal has been previously treated with antibiotics). Once inflammation within multiple joints has been documented, the next step is to identify the type of polyarthritis (see Table 104-8) and whether it is from a primary autoimmune disease or secondary to underlying inflammation, infection, or neoplasia. Diagnostic tests should include a CBC, biochemistry profile, urinalysis, urine culture, thoracic radiographs, abdominal ultrasound, and infectious disease titers or SNAP test (E. canis, A. phagocytophilum, B. burgdorferi) (SNAP test, IDEXX, Westbrook, Maine). In some cases blood cultures may also be indicated. In dogs with suspected rheumatoid arthritis, a rheumatoid factor test should be performed (see Chapter 102). In dogs and cats with evidence of multiple organ involvement, an antinuclear antibody (ANA) titer is indicated to investigate for SLE (see Chapter 102).

#### **Treatment**

Treatment of secondary immune-mediated polyarthritis depends on identification of an underlying cause. Polyarthritis usually resolves with appropriate treatment and use of antiinflammatory doses of glucocorticoids or nonsteroidal antiinflammatory drugs. In dogs with primary (autoimmune) polyarthritis, immunosuppressive dosages of glucocorticoids are the initial treatment of choice (2 to 4 mg/kg/day). Additional immunosuppressive treatment is necessary in dogs that do not respond to corticosteroids alone or that relapse as glucocorticoids are withdrawn. Drugs that are useful include azathioprine, cyclophosphamide, and cyclosporine. Azathioprine is typically the first drug added to the treatment regimen. More aggressive immunosuppression is

often necessary in polyarthritis from SLE, in polyarthritis seen in Akitas, and in rheumatoid arthritis.

Response to treatment should be monitored by assessment of clinical signs and cytologic changes within the joint fluid. Joint fluid should be cytologically normal before tapering immunosuppressive therapy. Failure to establish cytologic remission in addition to clinical remission may result in disease relapse or progressive injury to the joints that ultimately results in degenerative joint disease. Approximately 80% of dogs with idiopathic nonerosive polyarthritis treated with prednisone alone respond well to initial treatment, and half of these dogs can be weaned off therapy after 3 to 4 months. The prognosis for idiopathic nonerosive polyarthritis is good, with a mortality/euthanasia rate of less than 20%. Relapses are common, however, and some dogs require life-long therapy. The prognosis for other forms of immune-mediated polyarthritis varies with the different forms of the disease. See Chapters 73 and 74 for more information on this topic.

## SYSTEMIC LUPUS ERYTHEMATOSUS

# **Etiology**

SLE is a multisystemic immune disorder in which antibodies to specific tissue proteins (type II hypersensitivity) and immune complex deposition (type III hypersensitivity) result in immune-mediated damage to multiple organs. Type IV mechanisms (delayed hypersensitivity) may also contribute to tissue damage. The underlying cause of SLE is still poorly understood, but an increased CD4/CD8 ratio, increased expression of a T-cell activation marker, and marked lymphopenia have been reported in dogs with active disease. These findings suggest that T-suppressor cells may be defective in dogs with SLE. The disease is heritable although not by simple autosomal mechanisms. Breeds that are predisposed include the German Shepherd dog, Shetland Sheepdog, Collie, Beagle, and Poodle. Several colonies of dogs with a high predisposition toward SLE have been established, and an association with certain MHC (DLA) types exists. Other risk factors likely include environmental factors and exposure to certain infectious agents and drugs.

# **Clinical Features**

The disease is uncommon in dogs and rare in cats. In dogs SLE most commonly occurs in middle-aged dogs (age range, I to 11 years), and there is no sex predisposition. Because any organ system may be affected in SLE, a wide range of clinical signs is possible. The most common signs are fever (100%), lameness or joint swelling from nonerosive polyarthritis (91%), dermatologic manifestations (60%), and signs of renal failure such as weight loss, vomiting, polyuria, and polydipsia. Proteinuria from glomerulonephritis is detected in 65% of patients. The dermatologic lesions often involve areas of skin exposed to sunlight, with photosensitization being common. The dermatologic manifestations are highly variable, with alopecia, erythema, ulceration, crusting, or

hyperkeratosis common. Mucocutaneous lesions may also occur. Other clinical manifestations may include hemolytic anemia, PRCA, thrombocytopenia, leukopenia, myositis, pleuropericarditis, and central nervous system dysfunction. A similar spectrum of disease manifestations has been reported in cats with SLE. SLE typically has a relapsing and remitting course, and different organ systems may be involved with subsequent relapses. For example, a dog initially presenting with clinical signs predominantly relating to the neuromuscular system (polyarthritis or myositis) may later relapse with signs of IMHA or ITP.

# Diagnosis

A diagnosis of SLE should be suspected when evidence of involvement of more than one organ system is present in a dog or cat with immune-mediated disease. Because of the large number of organ systems that may be involved, the diagnostic testing required varies widely from patient to patient. Diagnostic tests that should be performed in all dogs and cats with suspected SLE include a CBC, serum biochemical profile, urinalysis, quantitation of urine protein, collection of synovial fluid for cytology and culture, and fundic examination. Additional tests that may be indicated include thoracic and abdominal radiographs (investigating fever), abdominal ultrasonography (investigating renal dysfunction), infectious disease titers (investigating fever, thrombocytopenia, hemolytic or nonregenerative anemia, proteinuria, or polyarthritis), Coombs test (in presence of hemolytic anemia), bone marrow aspirate and core (in cases of cytopenia), and skin or kidney biopsy if dermatologic or renal lesions are present. The extent of diagnostic testing for infectious disease will depend on the species and geographic location. For example, testing for feline leukemia virus, feline immunodeficiency virus, and feline infectious peritonitis should be considered in any cat with suspected SLE. In dogs in Europe, testing for leishmaniasis should be strongly considered because this disease can mimic SLE.

Numerous criteria for the diagnosis of SLE in dogs have been extrapolated from the literature in humans. The most commonly accepted and clinically applicable criteria are shown in Table 104-9. Measurement of serum ANA titers is a relatively sensitive test to confirm the diagnosis of SLE, although the sensitivity reported in the literature ranges from 50% to 100% (see Chapter 102). The variability in diagnostic sensitivity probably arises from variation in the diagnostic criteria for confirming the diagnosis as well as variations in the populations of dogs tested. When used in dogs that have appropriate clinical criteria for SLE, the ANA test is an excellent test; however, false-positive results can occur in dogs and cats with other inflammatory or infectious disorders or neoplasia. ANAs are detected in 10% to 20% of dogs with seroreactivity to Bartonella vinsonii, Ehrlichia canis, and Leishmania infantum. Dogs with seroreactivity to multiple pathogens are more likely to be ANA positive. A recent study of 120 dogs in which an ANA titer was measured emphasized the importance of appropriate patient selection for testing (Smee et al., 2007). In this study measurement of an ANA titer was not a

Criteria for Diagnosis of SLE

MAJOR SIGNS	MINIMUM DIAGNOSTIC TESTING NECESSARY TO SUBSTANTIATE MAJOR SIGN	MINOR SIGNS	DIAGNOSTIC TEST NEEDED TO SUBSTANTIATE
Polyarthritis	Synovial fluid analysis and culture	Fever of unknown origin	Abdominal radiographs, urine culture, no response to antibiotics
Dermatologic lesions (consistent with SLE)	Skin scraping, skin biopsy	CNS signs	CT or MRI scan, CSF tap with infectious disease serology
ĠŇ ,	Urine protein/creatinine ratio >2, renal biopsy useful but not required	Oral ulceration	Biopsy of lesions
Polymyositis	Increased creatinine kinase or muscle biopsy demonstrating inflammation	Lymphadenopathy	Lymph node aspirate
Hemolytic anemia	Regenerative anemia, positive Coombs test, bone marrow aspirate if anemia not regenerative, negative infectious disease testing	Pericarditis	Echocardiography
Immune-mediated thrombocytopenia	Bone marrow aspirate, negative infectious disease testing	Pleuritis	Thoracic radiographs, thoracocentesis
Immune-mediated leukopenia	Bone marrow aspirate, negative infectious disease testing		

A diagnosis of SLE is considered confirmed if there are two major signs compatible with SLE and the antinuclear antibody (ANA) titer or LE test is positive or if there is one major sign and two minor signs and the ANA test or LE test is positive. A diagnosis is considered probable if there is only one major sign or two minor signs and a positive ANA titer (or LE test), or if there are two major signs and a negative ANA titer. Immune-mediated hemolytic anemia in conjunction with immune-mediated thrombocytopenia (Evans syndrome) is not considered to be a diagnosis of SLE unless there is an additional major or minor sign. Not all testing listed above is necessary in all cases. Specific diagnostic test will depend on the individual case presentation and geographic location.

Modified from Marks SL, Henry CJ: CVT update: diagnosis and treatment of systemic lupus erythematosus. In Bonagura JD: Kirk's current veterinary therapy XIII: small animal practice, ed 13, Philadelphia, 2000, WB Saunders, p 514.

SLE, Systemic lupus erythematosus; GN, glomerulonephritis, CNS, central nervous system; CT, computed tomography; MRI, magnetic

useful diagnostic test in dogs without any major clinical or clinicopathologic abnormalities suggestive of SLE. Only one of 47 dogs tested that did not have any major signs of SLE had immune-mediated disease, and this dog was seronegative for ANA. Ten (21%) of 47 dogs were seropositive for ANA. Conversely, 13 of 16 dogs with two major signs compatible with SLE had immune-mediated disease, and ANA was positive in 10 of these dogs. These results emphasize that the positive predictive value of a diagnostic test is lower in a population of animals in which the disease prevalence is low.

resonance imaging; CSF, cerebrospinal fluid; LE, lupus erythematosus.

The LE test is rarely used clinically for diagnosis of SLE because of very low sensitivity. A number of other antibody tests have been investigated in groups of dogs with SLE, including antinative DNA antibodies, antiextractable nuclear antigen antibodies, and antihistone antibodies. None of these tests has been extensively evaluated in dogs, and none is currently commercially available.

#### **Treatment**

Immunosuppressive therapy for SLE begins with high doses of corticosteroids (1 to 2 mg/kg q12h). The dose is then tapered if disease remission is achieved. Addition of other cytotoxic drugs (e.g., azathioprine, cyclophosphamide,

cyclosporine) is usually necessary to induce or maintain remission. Little information is available on the efficacy of drug protocols for treating SLE. One study reported a protocol of prednisone (0.5 to 1.0 mg/kg q12h) combined with levamisole (2 to 5 mg/kg [maximum 150 mg per patient] every other day; Chabanne et al., 1999b). The prednisone is tapered over a 1- to 2-month period and the levamisole continued for 4 months. In cases that relapse, levamisole is administered for a further 4 months. This protocol was effective in inducing remission in 25 of 33 dogs with SLE. The prognosis for dogs with SLE is guarded to poor. Relapse is common regardless of the drug protocol used, and longterm and often life-long immunosuppressive therapy is necessary to control the disease. Relapses may involve different organ systems and clinical signs than at initial presentation (e.g., hemolytic anemia initially and polyarthritis at relapse).

### **GLOMERULONEPHRITIS**

### Etiology

Acquired glomerulonephritis (GN) is more common in dogs than cats and results from the presence of immune complexes within the glomerular capillary walls. Immune complexes may be circulating antigen-antibody complexes that are deposited or trapped in the glomerulus or may form in situ when circulating antibodies react with either endogenous glomerular antigens or nonglomerular antigens within the glomerular capillary wall. Soluble circulating immune complexes formed in the presence of mild antigen excess, or when both antigen and antibody are present in approximately equal quantities, may be deposited along capillary walls resulting in a granular pattern observed on immunofluorescent or immunoperoxidase staining. Infectious and inflammatory diseases are common identifiable causes for deposition of immune complexes within the glomerulus (Box 104-6). Unfortunately in the majority of cases of GN, an underlying cause is not identified. When immune complexes form in situ, a smooth linear pattern is observed with immunofluorescent or immunoperoxidase staining. Causes of in situ deposition of immune complexes may be either true autoimmune disease when antibodies are directed against the basement membrane of the glomerular capillaries (not yet documented as a spontaneous disease in dogs and cats) or when antigen becomes localized in the glomerular capillary wall. For example, in dogs with heartworm disease, soluble Dirofilaria immitis antigens have been shown to adhere to the glomerular capillary wall by a carbohydrateglycoprotein interaction.

Whatever the cause of immune complex deposition, the consequences are similar (see Chapter 43) and ultimately lead to severe proteinuria, systemic hypertension, renal failure, and predisposition to thromboembolism.

### **Clinical Features**

The hallmark of GN is proteinuria, which is readily detected on routine urinalysis. In many cases proteinuria is initially identified as an incidental finding and the animal may have no obvious clinical signs or only subtle abnormalities (e.g., weight loss, lethargy, decreased appetite). In other cases animals present with clinical signs of renal failure (e.g., anorexia, weight loss, vomiting, polyuria, polydipsia), and proteinuria is identified in the course of the evaluation. In nephrotic syndrome, which is defined as the presence of proteinuria, hypoalbuminemia, hypercholesterolemia, and

BOX 104-6

- Leptospirosis
- Borreliosis
- Brucellosis
- Endocarditis
- Pyelonephritis
- Prostatitis

GN, Glomerulonephritis.

either edema or ascites, the clinical signs are more severe and often rapidly progressive. Other clinical signs in dogs with glomerulonephritis may relate to the presence of hypertension or hypercoagulability. Hypertension may result in retinal changes and blindness, whereas TEs may occur as a result of the hypercoagulable state.

# **Diagnosis**

A diagnosis of protein-losing nephropathy is made by documentation of persistent proteinuria that cannot be explained by inflammation of the lower urinary tract or blood contamination of the urine. Initial dipstick estimates of urine protein should be evaluated in the light of the urine sediment and specific gravity of the urine. The severity of protein loss should then be quantitated by measurement of a protein/ creatinine ratio, preferably on a urine sample with no inflammation or hematuria. A protein/creatinine ratio greater than 0.5 is abnormal; most dogs and cats with protein-losing nephropathy have a ratio greater that 2.0. Once persistent proteinuria has been documented, further testing is necessary to determine whether evidence of tubular dysfunction also exists and to investigate for the presence of underlying infectious or inflammatory diseases implicated as causes of GN. Diagnostic tests that should be performed include a CBC, serum biochemical profile, urinalysis and urine culture, blood pressure, and radiographs of the thorax and abdomen. Ultrasonography of the kidneys is useful to investigate for evidence of pyelonephritis, nephroliths, or other underlying renal disease, but it rarely detects changes associated with glomerulonephritis. An occult heartworm test should be performed and serum titers submitted for the infectious diseases discussed in Box 104-6. Testing for hyperadrenocorticism should be considered in dogs if the appropriate signalment and clinical signs are present. Renal biopsy should be considered if an underlying cause for the proteinuria cannot be identified. Tissue samples should be submitted for routine histopathology, electron microscopy, and immunopathology. Goals of renal biopsy should be to confirm the underlying disease process (specific type of GN, hereditary nephritis, glomerulosclerosis, amyloidosis), determine severity of the disease and, if possible, determine a prognosis as well as guide specific therapy.

#### **Treatment**

Therapy for immune-mediated glomerulonephritis should be directed at treating the underlying disease (if identified), decreasing protein loss in the urine, decreasing the likelihood of thromboembolism, and initiating appropriate dietary therapy and supportive care. Angiotensin converting enzyme inhibitors (ACEI) (e.g., enalapril 0.25-0.5 mg/kg q12-24h) are currently the most effective treatment for proteinuria. Anticoagulation is recommended to decrease the likelihood of thromboembolism in dogs with GN, especially in those with documented antithrombin deficiency (less than 70%). Low-dose aspirin (0.5 mg/kg q24h) may be beneficial for its anticoagulant effects and for decreasing the glomerular response to immune complexes. Other supportive measures include control of hypertension (if not controlled by ACEI

alone); dietary sodium restriction; a low-protein, highquality protein diet with n-3 fatty acid supplementation; and control of ascites and edema if present. Therapy for overt renal failure may also be necessary. See Chapter 44 for further details on general management of renal failure.

In theory, immunosuppression should be useful in idiopathic immune-mediated GN; however, no studies have documented beneficial responses to immunosuppressive therapy in dogs with GN, and the use of corticosteroids may exacerbate rather than ameliorate proteinuria. Immunosuppressive therapy is indicated when glomerulonephritis occurs as part of an immune-mediated disease known to respond to corticosteroids, such as SLE. Other indications for immunosuppressive treatment are currently poorly defined.

Careful monitoring of response to therapy with monthly measurement of protein/creatine ratios, blood urea nitrogen, creatine, and blood pressure is important to assess adequacy of therapy. Prognosis for GN varies depending on the severity of disease, underlying histopathology, and response to treatment. In general, the prognosis is guarded in animals that initially present with concurrent azotemia. The outcome is best in dogs with reversible causes of immune complex deposition and those that respond to diet and ACEI to control proteinuria. See Chapter 43 for more information on this topic.

# **ACQUIRED MYASTHENIA GRAVIS**

Myasthenia gravis (MG) is a disorder of neuromuscular transmission resulting from deficiency or dysfunction of the nicotinic acetylcholine receptor (AChR) on the postsynaptic membrane. Acquired myasthenia gravis is an autoimmune disease in which antibodies directed against the AChR interfere with the interaction between acetylcholine and its receptor. Antibodies also cross-link AChR and cause receptor internalization. Complement-mediated damage to the postsynaptic membrane also contributes to neuromuscular blockade. As with other immune-mediated diseases, MG may be a primary autoimmune disorder or occur in association with other disorders, such as thymoma, and other neoplasms. Hypothyroidism and hypoadrenocorticism, which are also immune-mediated disorders, may also occur in association with MG. A breed predisposition exists for MG in dogs, with the Akita, various terrier breeds, and German Short-Haired Pointer being at increased risk. Abyssinian and Somali cats also have an increased risk of MG compared with other breeds.

The most common clinical presentation of MG is generalized weakness (60% of cases), either with or without concurrent megaesophagus. In focal MG, in which signs of generalized weakness are absent, the most common clinical sign is regurgitation because of megaesophagus, but dysphagia, voice change, and cranial nerve dysfunction may also occur. An acute fulminating form of MG is characterized by severe weakness, sometimes with loss of spinal reflexes and usually in conjunction with megaesophagus and aspiration pneumonia. In cats, the two most common clinical presentations are generalized weakness without megaesophagus and generalized weakness associated with a cranial mediastinal mass.

Definitive diagnosis of MG is by measurement of serum autoantibodies against AChR by immunoprecipitation radioimmunoassay. The assay is sensitive and specific and false-positive results are rare. Seronegative MG occurs in only 2% of dogs with MG. Canine and feline specific assay systems should be used. Immunosuppressive doses of corticosteroids lower the antibody concentration and can interfere with testing. Because antibodies are not the cause of congenital MG, results of antibody testing will be negative. Other useful tests in diagnosis of MG include evaluation of the response of clinical signs to a short-acting anticholinesterase drug (edrophonium chloride [Tensilon]) and electrodiagnostic testing. Once a diagnosis of MG has been confirmed, additional testing is necessary to investigate for the presence of other underlying disorders that may lead to secondary MG or occur concurrently.

The first line of treatment for MG is oral or injectable anticholinesterase inhibitors such as neostigmine or pyridostigmine (Table 104-10). These drugs act by prolonging the action of acetylcholine at the neuromuscular junction. Immunosuppression with glucocorticoids should be considered in patients that do not respond well to anticholinesterase inhibitors alone. The advantages of the immunosuppressive effects of glucocorticoids in MG are often outweighed by adverse effects such as worsening of muscle weakness and muscle atrophy. Corticosteroids may be problematic in animals with aspiration pneumonia, diabetes mellitus, and gastrointestinal ulceration, and if corticosteroids are necessary for MG care should be used to avoid excessive doses. Therapeutic approaches include starting glucocorticoids at the low end of the immunosuppressive range (prednisone 1 mg/kg q12h) or starting glucocorticoids at an even lower dose (prednisone 0.5 mg/kg PO every other day) and slowly increasing the dose after 2 weeks if a satisfactory response is not seen. Other immunosuppressive drugs that have been used for adjunctive management of MG include azathioprine and cyclosporine. Drug regimens and doses used in the routine management of MG are given in Table 104-10.

Spontaneous remission of acquired MG is common in dogs. Clinical remission is accompanied by a decrease of the AChR antibody titer into the reference range. Repeated measurement of the AChR titer is a useful guide for identifying when clinical remission is occurring and when adjustments to therapy may be indicated. The majority of dogs that do not go into remission have underlying neoplasia. See Chapter 71 for more information on this topic.

# **IMMUNE-MEDIATED MYOSITIS**

### **MASTICATORY MYOSITIS**

Masticatory myositis is a focal myositis affecting the muscles of mastication (temporalis, masseter, digastricus). Masticatory muscles contain a unique muscle fiber type (type 2M) that differs histopathologically, immunologically, and bio-

Drug Regimens and Doses Used for Routine Management of MG in Dogs and Cats

DRUG	DOGS	CATS
Pyridostigmine	0.5-3.0 mg/kg PO q8-12h	0.25-3.0 mg/kg PO q8-12h (start at low end of dose)
Neostigmine (use to bypass gastrointestinal tract in presence of severe regurgitation)	0.04 mg/kg IM qóh	0.04 mg/kg IM q6h
Prednisone	0.5 mg/kg PO q48h to 1.0 mg/kg q12h	0.5 mg/kg PO q48h to 1.0 mg/kg q12h
Azathioprine	2 mg/kg PO q24h	Do not use in cats
Cyclosporine	5 mg/kg PO q24h to 10 mg/kg PO q12h (see Chapter 103)	0.5-3 mg/kg PO q12h (microemulsified)

MG, Myasthenia gravis.

chemically from fiber types in limb musculature. Antibodies directed against this unique muscle fiber type are present in more than 80% of dogs with masticatory myositis.

Masticatory myositis is the most common form of myositis that occurs in dogs. It has not been reported in cats. Young large-breed dogs are overrepresented, and there is no breed or gender predisposition. Clinical signs include inability to open the mouth (trismus), swelling and/or pain of the masticatory muscles, and severe muscle atrophy. In some dogs an acute phase is recognized in which muscle swelling and pain predominate. If untreated this acute phase progresses to a chronic phase characterized by severe muscle atrophy and trismus. In many affected dogs the acute phase is not recognized and the first clinical signs that are recognized are severe muscle atrophy and inability to open the jaws. In severe cases the jaws can only be separated by a few centimeters, and the affected animal is unable to eat or drink. Less severely affected dogs may be able to use the tongue to lick up fluids or liquidized food. Other clinical signs include fever, depression, weight loss, dysphagia, dysphonia, and exophthalmus from swelling of the pterygoid muscles.

Diagnosis of masticatory myositis is made based on the characteristic clinical signs, and presence of antibodies against type 2M fibers. This test is positive in greater than 80% of cases and has a specificity approaching 100%. Muscle biopsy is useful to determine the degree of fibrosis and likelihood of return to normal function with treatment and to confirm the diagnosis in dogs in which the antibody test is negative. Multifocal infiltration with lymphocytes, histiocytes, and macrophages, with or without cosinophils, is found on histopathology. Moderate to severe muscle fiber atrophy, fibrosis, and sometimes complete loss of muscle fibers with replacement by connective tissue may be present. Other adjunctive tests that may be useful include measurement of creatinine kinase, which is increased in some but not all dogs with masticatory myositis, and electrodiagnostic testing, which allows identification of the most severely affected muscles. Typical electrodiagnostic findings include presence of fibrillation potentials and positive sharp waves.

Treatment of masticatory myositis relies on the use of immunosuppressive doses of corticosteroids (prednisone 2-4 mg/kg PO q24h). Under no circumstances should force be used to open the jaws because fracture or luxation of the temporomandibular joint may result. Once resolution of clinical signs is achieved with corticosteroids, the dose should then be slowly tapered over several months. Disease activity and progression should be monitored by clinical signs (especially range of motion) and measurement of creatinine kinase (if elevated at presentation). Long-term treatment with prednisone or an additional immunosuppressive drug such as azathioprine is required in dogs that relapse when prednisone is tapered. Tapering of prednisone too quickly increases the chance of relapse. The goal of therapy is a return to normal muscle function and a normal quality of life. In many cases, especially in the presence of severe fibrotic changes, muscle atrophy persists and is exacerbated by glucocorticoid therapy. Prognosis for return to function is good in most cases. See Chapter 72 for more information on this topic.

#### **POLYMYOSITIS**

Polymyositis is characterized by multifocal or diffuse infiltration of skeletal muscle by lymphocytic cells with negative serology for infectious disease. Although most cases are primary autoimmune, paraneoplastic immune-mediated myositis may be associated with malignancies such as lymphoma (particularly in Boxers), bronchogenic carcinoma, myeloid leukemia, and tonsillar carcinomas in dogs. The specific inciting antigen is not known, although the mechanism of injury is believed to be mediated by cytotoxic T cells (type IV delayed-type hypersensitivity).

Polymyositis is uncommon in dogs and rare in cats. The disease is most common in young large-breed dogs, and Boxers and Newfoundlands are overrepresented. Clinical signs include generalized weakness that worsens with exercise and a characteristic stiff gait. Cervical ventriflexion may occur, especially in cats. Most animals show pain on palpation of affected muscles, particularly the proximal muscle groups. Dysphagia, generalized muscle atrophy, dysphonia, and fever may also be present. Megaesophagus has been

#### Infectious Causes of Polymyositis in Dogs

- Toxoplasma gondii
- Neospora caninum
- Borrelia burgdorferi
- Ehrlichia canis
- Rickettsia rickettsii
- Hepatozoon americanum

reported in 15% of cases. Some dogs with polymyositis also have signs of masticatory myositis, and these dogs are positive for antibodies against type 2M fibers. Polymyositis may also occur in SLE and in canine polyarthritis/myositis syndrome.

Diagnosis of polymyositis is based on characteristic clinical signs, presence of an elevated creatinine kinase level (more commonly increased in polymyositis than in masticatory myositis), electrophysiologic testing abnormalities consistent with myositis, and muscle biopsy. Muscle biopsy is very important in dogs with polymyositis to rule out infectious causes of myositis (Box 104-7). Muscle biopsies have similar changes to those described for dogs with masticatory myositis; however, the presence of eosinophils in dogs with polymyositis increases the index of suspicion for an infectious cause. Polymyositis may be a preneoplastic syndrome, especially in Boxers, so a complete evaluation for neoplasia should be performed in Boxers with polymyositis.

Treatment of polymyositis is similar to treatment of masticatory myositis (see previous page). Prognosis for return to function is good in most cases. See Chapter 72 for more information on this topic.

### **DERMATOMYOSITIS**

Dermatomyositis is an uncommon immune-mediated disorder affecting the skin, skeletal muscle, and vasculature of Collies and Shetland Sheepdogs. The disorder has an autosomal-dominant pattern of inheritance, and the pathogenesis is suspected to be immune complex deposition, although the target antigen is not known.

In dermatomyositis cutaneous lesions develop between 2 and 4 months of age, with signs of myositis developing later. The temporalis muscle is most commonly affected and clinical signs include dysphagia and muscle atrophy. More severe signs may include megaesophagus and generalized polymyositis with diffuse muscle atrophy, especially of the distal appendicular muscles. Diagnosis of dermatomyositis is based on the classic signalment (age, breed, presence of cutaneous signs). The creatinine kinase level is usually only minimally increased. Definitive diagnosis is based on skin and muscle biopsy.

Treatment of dermatomyositis relies on symptomatic care of cutaneous lesions and immunosuppression. The protocol for corticosteroid therapy is similar to that used for polymyositis, but prolonged therapy is needed and relapses are common. Additional recommendations include avoidance

of exposure to sunlight, neutering of sexually intact dogs, and vitamin E supplementation. Pentoxifylline has also been shown to be of some benefit in affected dogs (see Chapter 103). The prognosis depends on severity, being good for mild cases and poor for severely affected dogs. See Chapter 72 for more information on dermatomyositis.

GENERIC NAME /TRADE		RECOMMENDED DOSE	
GENERIC NAME (TRADE NAME)	PURPOSE	DOG	CAT
Aspirin	Prevent thromboembolic complications of IMHA	0.5 mg/kg q24h	Not applicable
Azathioprine (Imuran) Chlorambucil (Leukeran)	Immunosuppression Immunosuppression	2 mg/kg q24h 0.1-0.2 mg/kg PO q24h initially, then taper to every other day once a response is seen	Not recommended 0.1-0.2 mg/kg PO q24h initially then q48h
Cyclophosphamide (Cytoxan)	Immunosuppression	50 mg/kg/day PO for 4 out of 7 days or 200 mg/kg IV once a week	2.5 mg/kg/day PO for 4 out of 7 days or 7 mg/ kg IV once a week
Cyclosporine (Atopica, Neoral, Sandimmune)	Immunosuppression	5 mg/kg q24h to 10 mg/kg q12h; start at lower end of dose for microemulsified products Lower doses of 1-2.5 mg/kg q12h if in conjunction with ketoconazole	0.5-3 mg/kg q12h (microemulsified products)
Danazol (Danocrine) Dexamethasone Enalapril (Enacard) Famotidine (Pepcid)	Immunosuppression Immunosuppression Treatment of proteinuria Treatment and prevention of gastric ulceration	5 mg/kg PO q12h 0.25-0.5 mg/kg PO q24h 0.25 to 0.5 mg/kg q12-24h 0.5-1.0 mg/kg PO/IM/SC q12-24h	5 mg/kg PO q12h 0.25-1.0 mg/kg PO q24h Not applicable 0.5 mg/kg PO/IM/SC q12-24h
Heparin (unfractionated) Hemoglobin-based oxygen carrier (Oxyglobin)	Anticoagulation Provision of oxygen- carrying support	200-300 U q6h 10-30 mL/kg as IV infusion	Not applicable Not recommended
hIVIG	Immunosuppression	0.25-1.5 g/kg as an IV infusion over 6-12 hours (one dose only)	Not applicable
Levamisole	Immunosuppression in SLE	2 to 5 mg/kg (maximum 150 mg per patient) every other day	Not applicable
Neostigmine (Prostigmin) Pentoxifylline Prednisone/prednisolone Pyridostigmine (Mestinon)	Anticholinesterase inhibitor Immunomodulation Immunosuppression Anticholinesterase inhibitor	0.04 mg/kg IM q6h 10-15 mg/kg PO q8h 2-4 mg/kg/day PO 0.5-3.0 mg/kg q8-12h	0.04 mg/kg IM q6h Not applicable 2-8 mg/kg/day PO 0.25-3.0 mg/kg q8-12h (start at low end of dose)
Sucralfate (Carafate)	To prevent drug-induced gastritis	0.5-1 g PO q6-12h	0.25-0.5 g PO q8-12h
Vincristine (Oncovin)	Increase platelet count in ITP	0.02 mg/kg IV as a single dose	Not applicable
